It is conceivable that in regions where spring run-off and all floods are in large part due to the melting of snow, as in the Rocky Mountains, a flood-control reservoir might safely store for power or other purposes the last installments of spring run-off, once the melting of snow has been completed or has reached a predetermined stage.

(3) *Reservoirs for Joint Power Development and Flood Control.*—There have been various proposals for the construction of such reservoirs, some of these proposals having been made under the auspices of the Federal Power Commission. However, the writer knows of no actual instance of construction.

A clause for this purpose, proposed by the Federal Power Commission to be embodied in a license for a series of water power developments on a tributary of the Ohio River, reads as follows:

"If at any time any agency shall contribute funds to provide additional reservoir capacity for the purpose of storage of water for flood control, the licensee shall co-operate with such agency by constructing or permitting to be constructed, to the extent of the funds so contributed, additional reservoirs or additions to existing reservoirs as may be agreed between the licensee and such agency; and the licensee shall so operate its project works as to hold, or permit to be held, in reserve for flood control the storage capacity provided by funds so contributed."

The prospective licensee indicated that the clause would be satisfactory.

Usually, it is contemplated that the flood-control reservoir capacity be literally superimposed upon that intended for power uses. The object is to take advantage of favorable reservoir sites, especially in regions where favorable sites are scarce. Presumably, there are situations where the combination of the two objects can be attained at less expenditure for reservoir capacity

than would result from the construction of separate reservoirs for power and for flood control.

In effect, the combined reservoirs must be considered and operated as if they were separate. The danger is that the desires, or the needs, for power will tend to hold water too long in that part of the reservoir allocated to flood control. However, the penalty of mal-operation of the flood-control component of the reservoir is so great that power development ought not to be benefited more than it would be if the storage capacity allocated to flood control were actually in a separate reservoir.

Such a combination in a single reservoir would have the incidental effect of making impossible the development of power from the head which is represented by the depth of the flood-control component of the reservoir.

This subject is too involved for detailed treatment within the limits of this paper. However, in the light of the foregoing the following conclusions are offered:

1.—As regards the flood control of a given stream, power developments involving reservoirs on that stream generally have a beneficial effect and in especially favorable cases may have important beneficial effect.

2.—On streams which are under complete regulation by storage, that is, where approximate equalization of flow is attained, the requirements of both power development and of flood control on that stream may be met adequately and without conflict. Complete regulation is a desideratum, even if it is not a necessity, from both standpoints. (However, in the case of the Mississippi River it seems certain that adequate flood control, let alone complete regulation, cannot be obtained solely by means of storage reservoirs. Even for streams with drainage areas as small as several thousand square miles, complete regulation artificially must remain a rarity.)

3.—In the cases of streams which are under only partial regulation by storage, power developments may have favorable or unfavorable effects from the standpoint of flood control; in the main, however, such effects of power development will tend to be beneficial.

4.—So far as flood control by means of reservoirs involving only partial regulation of a given stream is concerned, the benefits which power developments even on that particular stream would derive are, in general, so limited in amount and so uncertain in occurrence that power could not economically contribute any substantial financial aid toward flood control.

5.—As regards the flood control of the Mississippi River, power is likely to be a minor consideration, both as to effects of power reservoirs in reducing Mississippi River floods and as to financial aid toward flood control.

THE EFFECT OF AGRICULTURAL DRAINAGE UPON FLOOD RUN-OFF

By Sherman M. Woodward* and Floyd A. Nagler,† Members, Am. Soc. C. E.

Synopsis

A survey of completed drainage enterprises in the Upper Mississippi Valley indicated that a comparison of stream-flow conditions prior and subsequent to extensive drainage could best be made upon the Des Moines and Iowa Rivers, a large portion of the water-sheds of which have been covered with artificial drains subsequent to the establishment of stream-gauging stations.

A critical examination of the records of these two streams shows that during flood periods there has been no significant change in their behavior which may be attributed to drainage. The total run-off from storms of like precipitation, the maximum rates of discharge, and the rain-water storage conditions within the basins seem to have been unaltered by the extensive drainage operations. It is believed that if any of these factors had been changed by a measurable amount, such fact could easily have been detected by the analysis made in this paper.

The drainage operations on the water-sheds of these two rivers involved the construction of tile drains, open ditches, and some straightening of stream channels, typical operations in drainage projects in the Upper Mississippi Valley. Since there has been no appreciable change in the run-off from these water-sheds which have experienced extensive drainage, it appears, therefore, that agricultural drainage has had a negligible effect upon the magnitude of either the total flow or the maximum discharge of the floods of the Mississippi River, less than 5% of the water-shed of which has witnessed agricultural drainage operations.

Although many references have been made in recent years to the effect of agricultural drainage upon flood run-off in general, and numerous statements have been published regarding the relation of such drainage to the magnitude and frequency of floods in the Mississippi and other rivers, almost no actual numerical evidence has hitherto been brought forward tending definitely to prove or disprove any of the relationships alleged.

This paper is a painstaking effort to determine whether existing records indicate the presence of any relationship or no relationship between agricultural drainage and flood run-off. All the data contained herein are based upon official Government records; the data concerning drainage are abstracted from the Fourteenth Census of the United States for 1920, Volume VII, Irrigation and Drainage; the data concerning run-off are taken from the *Water Supply Papers* of the U. S. Geological Survey; and the data on rainfall from the publications of the U. S. Weather Bureau.

*Vol. VII, Irrigation and Drainage.

In the Census report a distinction is made between farm drainage on the one hand, that is, the small-scale drainage, such as tile drainage, for example, that can be carried out by an individual farmer independent of any action by his neighbors, and drainage enterprises on the other hand, those larger co-operative undertakings requiring the joint effort of more than one land owner to consummate the community enterprise. As all familiar with agricultural drainage on an extensive scale will know, this latter class of drainage work is much the more extensive of the two and is the class that may be expected to have the chief effect upon stream run-off. All the subsequent references to drainage contained herein pertain solely to this second class. Table 30 presents a summary of statistics on drainage operations within the United

States and those portions of the Mississippi River water-shed that were intensively studied in this investigation.

Fig. 29 is a diagram showing the rate of increase in the area embraced in drainage enterprises in the whole United States during the last fifty years. It will be noted that the rate of progress was relatively slow until 1900, and that its greatest rate of increase was between 1905 and 1915.

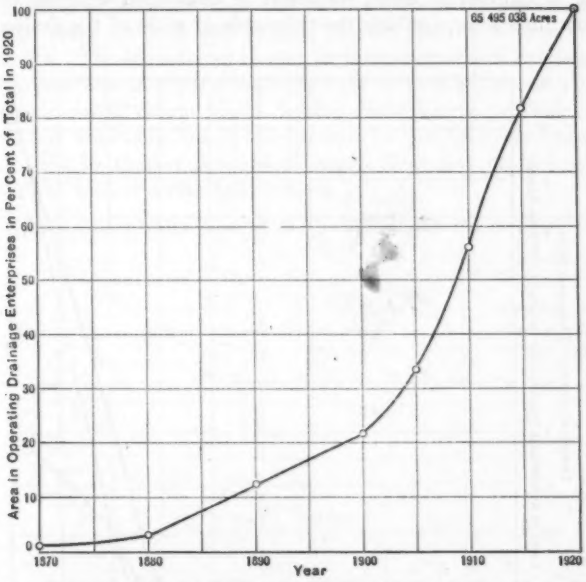

FIG. 29.—PROGRESS OF DRAINAGE IN THE UNITED STATES. FROM CENSUS OF 1920.

A map of the United States published in the 1920 Census report,* shows all the area included on January 1, 1920, in operating drainage enterprises, that is, enterprises the construction work of which had either been completed or begun. Of the total area included in these enterprises, about one-half is embraced in the Mississippi Valley. According to the Census figures between 4 and 5% of the total Mississippi River drainage area is included in operating drainage enterprises. Most of this is in the northern part of the country, that is, in the areas tributary to the Missouri, the Upper Mississippi, and the Ohio Rivers. Two large, compact, drained areas stand out conspicuously, the more eastern one in Ohio, Indiana, and Illinois, the other in North Central Iowa.

A study of the records shows that in the more easterly area much of the drainage work antedated extensive reliable stream measurements, thus precluding a satisfactory comparison of stream flow before and after drainage. A more satisfactory condition exists with reference to the Iowa area. In this region, drainage work was not extensive until after the passage of the 1904

* U. S. Census Rept., 1920, Pt. VII, p. 347.

Drainage Law, but nearly all the work was completed by 1917. The greater part of this compact area of drained Iowa land lies in the upper portions of the drainage areas of the Des Moines and the Iowa Rivers. Most fortunately for the purpose of this paper, stream measurements were begun upon these rivers by the U. S. Geological Survey in 1903. The progress of drainage in Iowa is shown in Fig. 30. For successive dates, the full line curve shows the area, in millions of acres, contained in authorized drainage enterprises; the broken lines show similarly the thousands of miles of tile drains and open ditches.

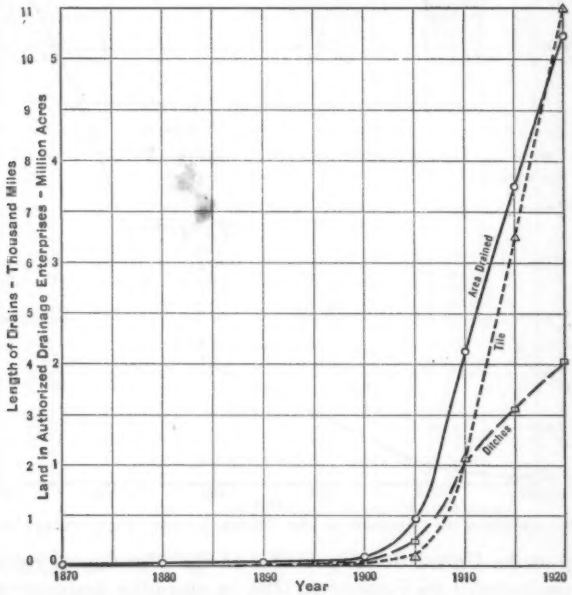

FIG. 30.—PROGRESS OF DRAINAGE IN IOWA. FROM U. S. CENSUS OF 1920.

After a careful scrutiny of the situation it was decided to be best to study the stream-flow records for a four-year period, from January 1, 1903, to December 31, 1906, to ascertain the behavior of these rivers prior to drainage, and to use the records similarly for the six-year period, January 1, 1918, to December 31, 1923, to learn their behavior subsequent to extensive drainage operations. Apparently, nowhere else in the United States are conditions so favorable for making this kind of comparison.

On the Iowa River a record of discharge has been maintained since 1903 at Iowa City, Iowa, above which point the drainage area is 3 140 sq. miles. Of this area, more than one-third is in operating drainage enterprises.

On the Des Moines River three gauging stations were started before the period of greatest drainage activity, and have been maintained to date (1927) with some fragmentary intermissions. The uppermost station was established

near Fort Dodge, Iowa, with a drainage area of 4 170 sq. miles, nearly all of which has been embraced in drainage enterprises. The second gauging station is at Des Moines, Iowa, with a tributary area of 6 180 sq. miles, about two-thirds of which has been drained. The lowest station is at Keosauqua, Iowa, embracing 13 900 sq. miles, more than one-third of which has been artificially drained.

Fig. 31 shows on an outline map of Iowa the position of the drainage areas of the Iowa and Des Moines Rivers, and the locations of the gauging stations. The drainage areas are long and narrow, that of the Des Moines extending into Minnesota. The shaded area is that portion embraced in drainage enterprises. The map also shows the isohyetal lines or rainfall contours for what is subsequently called Storm No. 1, lasting from May 8 to June 26, 1903. This storm was unusually heavy, the greatest in the four-year pre-drainage period, and will be further referred to later. The dots on the map show rainfall stations used in subsequent studies.

FIG. 31.—DRAINAGE AREAS OF DES MOINES AND IOWA RIVERS, SHOWING AREA OF OPERATING DRAINAGE ENTERPRISES IN 1920.

The northern part of these drainage areas is a flat prairie, with scanty, natural, shallow, drainage channels. Before artificial drainage a large portion of the land was in marshes or too wet in the spring for profitable cultivation.

The lower part of the drainage areas is rolling, with the highest portions of the land nearly 100 ft. above the rivers. Originally, most of this lower part was covered with hard-wood timber, but the greater portion of this forest has long been removed. The drainage improvements have included the construction of open ditches and tile drains as well as the deepening and straightening of natural channels.

Iowa streams yield in run-off less than one-quarter of the water which they receive in the form of precipitation. About three-quarters of this annual run-off is discharged during periods of high water, and it is the high-water periods only that make any significant contributions to Mississippi River floods. If the carrying out of agricultural drainage affects the flow of streams in any measurable way, such effects must be most conspicuous near the drained areas. More remote points down stream would naturally be less affected, in spite of any cumulative result from many tributaries. If no effect can be perceived in the streams traversing the drained areas, it may reasonably be concluded that no similar effects are produced at remote points on the larger rivers.

As a first preliminary study, the monthly run-off was compared with the monthly precipitation during the spring months of March, April, and May, and all other single months in which the stream flow was exceptionally large during the adopted pre-drainage and post-drainage periods. In this study, the precipitation was computed by taking the arithmetical average of that recorded at selected rainfall stations distributed over each basin so that each station represented an area of about 800 sq. miles. On the Iowa River five stations were used; on the Des Moines, five were used above Fort Dodge, seven above Des Moines, and fourteen above Keosauqua. These values of monthly precipitation and run-off are shown in Table 31 and in Fig. 32, in order that the stream behavior prior to drainage may be compared with that subsequent thereto.

The quantity of water appearing as run-off from a given amount of precipitation is no doubt larger during the early spring months than later, decreasing with the increase in temperature and the growth of vegetation. This fact was taken into consideration by plotting the monthly values for each gauging station in three separate groups. One group includes the records for March and a few for February; the second group includes those for the month of April; and the third group includes those for the month of May, and a few for the months of June, July, and September. In this, as in subsequent diagrams, the values of run-off prior to drainage, have been indicated by solid symbols, in contrast to the open symbols used for the post-drainage period.

The plotting of data such as these naturally results in a wide scattering of points, because the run-off for a given month may have been the result of precipitation which fell during the previous month, to say nothing of the various hydrologic factors which may have caused variations in the stream yield. The points showing the run-off previous to drainage seem to group themselves well within and about the system of points obtained for the post-drainage period, and no other conclusion is possible than that the average

monthly yield of the streams subsequent to drainage does not seem to be different from that previous to drainage. If any difference can be detected from this plotting, it would appear to indicate that the streams yielded a greater quantity during the flood months of 1903 to 1906 than during those of 1918 to 1923. Certainly, other factors than drainage have been more significant in producing differences in stream yield during both the pre-drainage and the post-drainage period.

In order to make a more delicate and conclusive comparison of the behavior of the streams before and after drainage than that presented in Fig. 32, every flood of significance which occurred on these streams during these periods, was next studied in considerable detail. Each flood that produced a maximum run-off greater than 2 sec-ft. per sq. mile was included in this investigation. The total run-off was computed from the beginning of the flood until the dis-

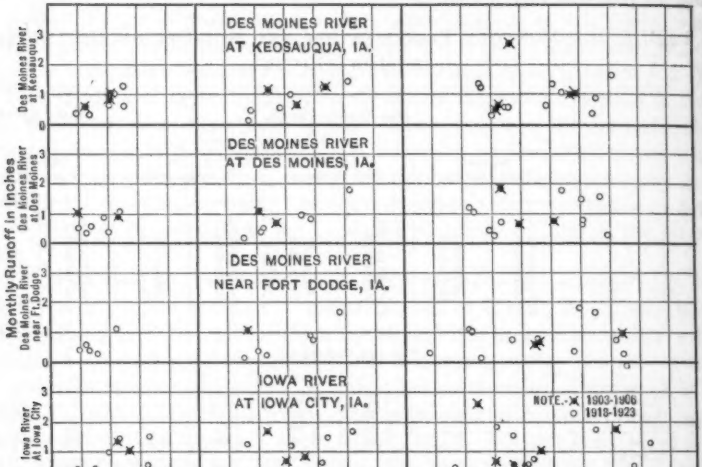

FIG. 32.—RELATION OF PRECIPITATION TO RUN-OFF IN MONTHS OF HIGH WATER ON THE DES MOINES AND IOWA RIVERS, COMPARING 1903-1906 WITH 1918-1923.

charge had diminished to a flow of ½ sec-ft. per sq. mile, or lower, and the average precipitation producing this high water was evaluated from all rainfall stations within and about the water-sheds in question. Nine such floods occurred during the pre-drainage period, 1903 to 1906, and eleven during the post-drainage years, 1918 to 1923. Individual hydrographs of these floods are shown in Figs. 33 and 34.

The average precipitation was computed by applying the method suggested by Thiessen* to obtain the true weighted average precipitation on the water-shed. All available precipitation stations were used, the number considered for each water-shed varying somewhat from year to year. The maximum and minimum numbers were as given in Table 32.

Isohyetal lines were also drawn, for each stormy period, upon maps of the drainage area in order to visualize the distribution of the storm. Other values pertinent to the study of these storms and their yield have been given in Tables 33 and 34.

In order to study the amount of run-off produced by a given amount of "effective precipitation" these quantities for each storm period were plotted

* *Journal*, New England Water Works Assoc., March, 1924, p. 26.

on Fig. 35, employing the same general scheme of symbols used previously in Fig. 32. In order to facilitate this study these storms were first classified into three groups according to the average temperature which existed during the storm period. One group, with average temperatures below 45°, includes all early spring storms coming before the growing season had started; a second group, with average temperatures between 45° and 60°, includes those storms

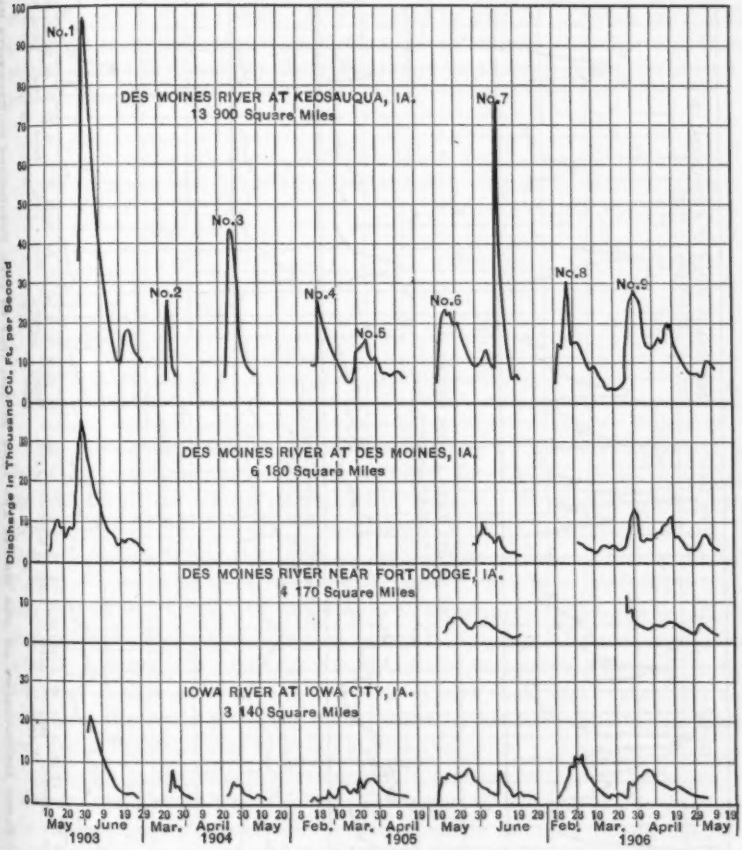

FIG. 33.—FLOOD HYDROGRAPHS ON DES MOINES AND IOWA RIVERS, 1903 TO 1906, PREVIOUS TO EXTENSIVE DRAINAGE.

which occurred during the early growing season; the third group, with average temperatures exceeding 60°, includes the early and late summer storms which occurred in June, July, and September, the storms which generally include the most intense rainfall and produce the highest floods on these streams. Some distinction was made in plotting the run-off from these storms, depending upon the location of the greatest amount of rainfall on the basin.

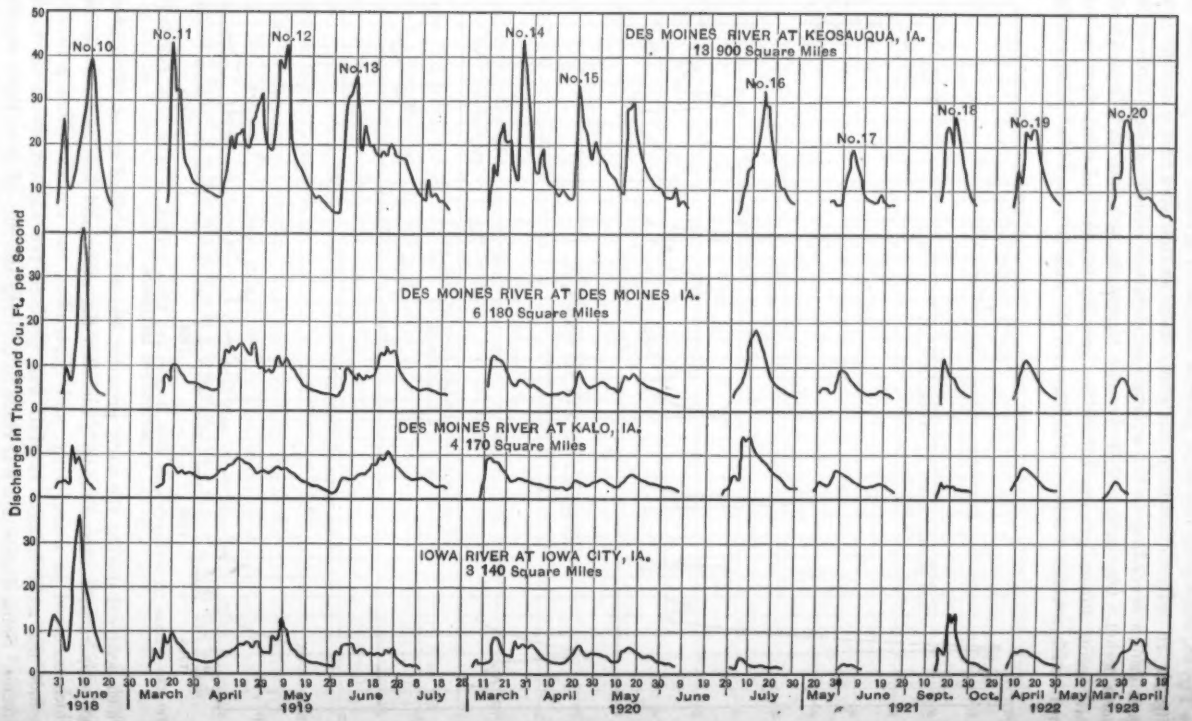

FIG. 84.—FLOOD HYDROGRAPHS ON DES MOINES AND IOWA RIVERS, 1918 TO 1923, SUBSEQUENT TO EXTENSIVE DRAINAGE.

Triangles are used to indicate the storms in which the heaviest rainfall occurred on the upper part of the drainage area; circles to indicate storms near the center, or spread uniformly over the whole drainage area; and squares to indicate storms heaviest on the lower portion of the basin. The lines showing the average relation between rainfall and run-off were drawn from the point of zero rainfall and precipitation through the area covered by the open circles, representing those storms which were of a general nature or concentrated about the center of the basin. It was noted in plotting the data on storms subsequent to drainage that those in the upper basin gave a lower run-off than general storms (indicated by the circles), and that storms in the lower basin gave a higher run-off.

The dark symbols on Fig. 35 indicate the run-off of the floods previous to drainage. In general, they fit in very well with the system of points indicating the behavior of the stream subsequent to drainage. If any difference exists there is some indication that storms concentrated on the upper portions of these water-sheds produced a larger run-off previous to drainage than at present (1927). The correlation of rainfall and run-off in Fig. 35 is much better than that secured in Fig. 32, and would seem to be adequate to detect any significant difference which may have been caused by drainage. It is apparent from Fig. 35, however, that drainage has caused no measurable difference in the total flow of these streams during periods of high water and hence could not have been effective in producing higher stages in the Lower Mississippi River, only 4% of the water-shed of which has been subjected to drainage operations.

Although no significant difference can be detected in the total flood run-off of these Iowa streams since drainage in contrast to that previous to drainage, the statement has often been made that certainly the peak run-off has been increased by these operations. It is difficult, indeed, to correlate the maximum flow of a storm with any single hydrologic factor, since it is dependent upon so many. Nevertheless, the maximum average 24-hour rate of discharge during these twenty periods of high water was plotted in Fig. 36 against the average daily precipitation during the storm which produced the run-off. Symbols similar to those in Fig. 35 were used, and lines were drawn from the point of zero rainfall and run-off through the open circles which represent

NOTE.—*L* = near Iowa City; *M* = near Marshalltown; *U* = above Iowa Falls; and *G* = general. *Incomplete record of stream flow. † Winter storage and light rains resulted in a run-off in excess of rainfall.

the peak run-off of those storms during 1918 to 1923 which were of general distribution or concentrated near the center of the water-shed. Again, it may be noted in Fig. 36 that storms the centers of which occurred in the lower part of the basin produced higher rates of run-off than the average, and those storms which occurred in the upper part of the basin (which had been drained) produced lower run-off than the average. The black symbols, representing the pre-drainage flood peaks, fit in very well with the general system of post-drainage points. If any difference at all exists, pre-drainage storms have produced higher peaks than post-drainage storms of the same intensity, although the storms are so few in number that this difference can hardly be considered to be of significance.

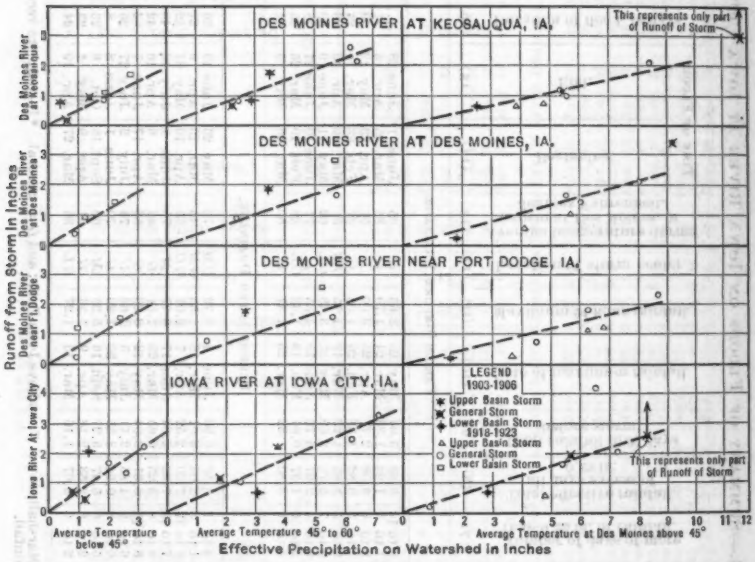

FIG. 35.—RELATION OF PRECIPITATION TO RUN-OFF ON IOWA AND DES MOINES RIVERS DURING HIGH-WATER PERIODS IN 1903-1906 AND 1918-1923.

It remains only to describe the last and most sensitive test applied to the stream-flow records in this attempt to detect some appreciable change caused by agricultural drainage. This test was applied to the curve of diminishing flow following the peak of the storm, during those days of high water when there was no additional precipitation received on the basin. If within a given basin the surface storage has been decreased by drainage in such a fashion that the water is carried away with greater rapidity, the daily rate of run-off should decrease at a more rapid rate than that existing when the ground possesses a higher retentive value. The daily decrease in discharge at given stages of the stream, when undisturbed by subsequent precipitation, was averaged for all floods previous to drainage and compared with similar values

subsequent to drainage. The results are shown in Fig. 37. It is natural that the points should scatter somewhat, due to the difference in depletion rate caused by the location, distribution, and season of the storm, but it is significant that the black symbols representing the pre-drainage conditions show no appreciable difference from the open symbols representing the behavior of the stream subsequent to drainage. Thus, no appreciable difference in the retentive value of the water-shed in so far as it affects the stream flow is revealed by this analysis.

Certain storms which were of unusual intensity, and others which were concentrated over the land which experienced most of the drainage operations, may be of particular interest, and are shown in Figs. 31 and 38. Storms

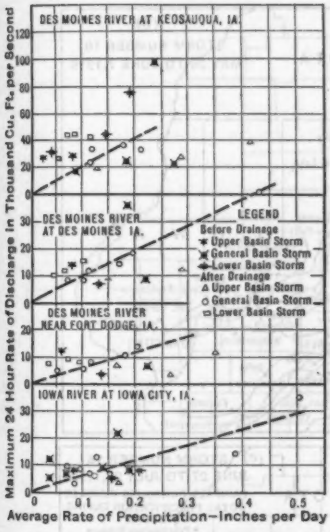

FIG. 36.—RELATION OF PRECIPITATION RATE TO MAXIMUM DISCHARGE OF DES MOINES AND IOWA RIVERS, 1903–06 AND 1918–23.

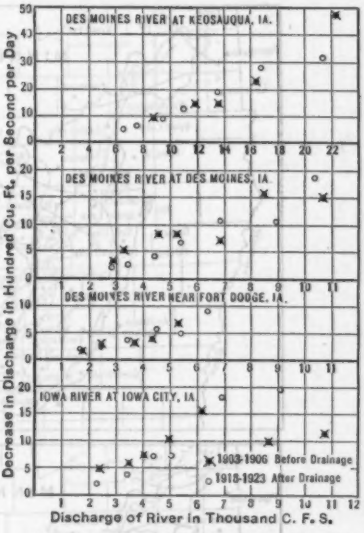

FIG. 37.—RATE OF FLOW DEPLETION, DES MOINES AND IOWA RIVERS.

differ as much as human faces—there are no two alike in amount, location, and time of occurrence, hence no direct comparison is possible between particular storms in the periods before and after drainage. The storm occurring in May and June, 1903, is remarkable in the amount and general distribution of its precipitation, while the storm of May and June, 1918, produced an unusually high rate of rainfall over a large area within a few days.

This exhausts the writers' ingenuity in trying to find a way to detect a measurable effect of drainage upon flood run-off. It may be of interest, however, to note in conclusion that the largest known flood in the Des Moines River Valley occurred in 1851. The flood which reached a peak on June 1, 1903, almost equalled this flood in stage, but since 1903 no flood has occurred which has attained the height of these pre-drainage floods.

FIG. 38.—DRAINAGE AREAS OF DES MOINES AND IOWA RIVERS, SHOWING DISTRIBUTION OF RAINFALL IN STORMS NOS. 9, 10, AND 16.

Likewise, the maximum known flood in the Iowa River Valley occurred in 1851, and again in July, 1881, a torrent only slightly smaller passed down the river. The flood that occurred in June, 1918, in the post-drainage period, attained the highest stage recorded since stream measurements were started, but it was exceeded in magnitude by both of the pre-drainage floods of 1881 and 1851.

DISCUSSION

J. P. SNOW,* M. AM. SOC. C. E. (by letter).—Since before 1850, the levees along the Mississippi River have been added to, strengthened, and perfected. This has resulted, of course, in compelling more and more of the flood waters to flow in the river channel. Before levees were built, any rise above bank level distributed itself over the surrounding territory, resulting in low gauge readings along the river. Records show that flood readings at Natchez, Miss., were:

1882	47.8	1913	52.6
1892	48.1	1916	53.6
1897	49.8	1922	55.5
1903	50.4	1927	56.6
1912	51.4		

These were maximum floods for the past fifty years. The increases in height were due, without doubt, quite largely to the continual improvement in the effectiveness of the levees. The 1927 flood, in spite of the vast volume of water lost through the various breaks, was so high at New Orleans, La., that an artificial crevasse, involving large reparation payments for damages, had to be made to save the city. Further efforts to control maximum floods by levees alone would seem to be absurd. In 1927, if there had been no breaks above Baton Rouge, thereby forcing all the great flood to follow the river channel, the levee system of its lower course would have looked puny indeed.

The normal flow must be held in the present channel of the river to serve the cities and landings along its banks. The surplus of flood flow, above what can be safely carried by the present levees, perfected to a consistent standard, should be taken off by adequate spillways at strategic points. These points are naturally at the mouths of large tributaries, where a great influx of water seeks to enter the river.

The first large tributary north of the Gulf is the Red River, with its branch, the Black River. This is the natural place for the principal spillway. A large basin should be provided there, making use of old bayous, with a substantial spillway with stop-logs along its southern border. The crest of the spillway should be above the level required for satisfactory navigation in the river during the summer season and below the gauge reading at which the present levees, after repairs, can carry the flow safely to the sea; perhaps but little above what is known as bank-full for the general run of the river. It should be long enough to prevent a flood from rising so high as to seriously endanger the levees of the lower river. Perhaps a height of 3 ft. below the tops of the levees may be assumed as a proper summit of flood from which to compute the length of the spillway. It should be designed to carry, at maximum flood, two-thirds of the water at this point seeking transportation to the Gulf, leaving one-third for the main river to handle.

The spillway must be built as a mere overflow without abrupt fall on the down-stream side. Undercutting at the toe of the masonry must be prevented

* Cons. Engr., Boston, Mass.

by sheet-piling properly protected against decay. The Atchafalaya Channel must be cleared to carry the flow from the spillway without obstruction. Width in its upper course is necessary, rather than depth. The slope from the spillway to Grand Lake will be much steeper than that of the main river, and protection against undue scour must be provided. This will be particularly needed for a distance below the spillway. No abrupt fall should be allowed. A particularly wide channel is advisable between Grand Lake and the Gulf, so that the lake will be practically an arm of the sea.

If levees are needed along the Atchafalaya it may be best to construct drainage canals to take the tributaries on each side to Grand Lake rather than to build levees along these side streams. The work of construction is simple in detail throughout, but its magnitude will call for a great expenditure. Its probable ultimate benefit, however, justifies its cost.

This by-pass should hold the flow at a level that will make the river safe as far north as Vicksburg, Miss., at least, and it should prevent overflow of the Red and Black Rivers if their levees are in order. It would seem justifiable to ascertain what the by-pass would do in a flood toward ameliorating the conditions in the upper section of the flood area before attempting further work. If necessary, another spillway could be constructed near the mouth of the Arkansas, or possibly opposite Greenville, Miss., and a channel cut *via* various bayous and creeks into Black River and thence to the Red River Basin. This spillway would probably lower the main river enough, so that the St. Francis Valley would be made safe, and danger would be prevented on the east side at Mound Landing and other points.

The objective is to run off the top of the flood, so as to render the present levee system safe for the main river below Cairo, Ill. Hydraulic data collected during the last seventy-five years should be sufficient to enable computations to be made for the safe design of the structures contemplated herein.

FRANK B. MALTBY,* M. AM. SOC. C. E.—The problem of flood control as a whole is discussed in this Symposium. Other problems treated are the effect of rainfall and run-off on the stage and discharge of the river, forestation, reservoirs, levees, and spillways and auxiliary channels as means of controlling the floods, so as to prevent a repetition of the disastrous results of the record flood of 1927.

All the papers have been prepared by men of experience, of close association with the existing conditions, and with access to an enormous amount of data that have been accumulated by the Mississippi River Commission and others. The sole object of this wide discussion was not simply to add to the available fund of engineering information, nor for the benefit of engineers only. The whole country is vitally interested in the problem, and is looking to the Engineering Profession for a solution.

Engineers are seldom unanimous in their opinion on any subject, and there has been a wide divergence in the ideas expressed on this one, but from discussions of this kind it should be possible to arrive at a consensus of opinion of value to those responsible for the enactment of necessary legislation.

* Cons. Engr., Norristown, Pa.

It is fortunate that, thus far, prominent engineers have led in the discussion of this problem as it has been presented to the public. Especial reference is made to the address of General Jadwin delivered at the Flood Control Congress at Chicago, Ill., in June, 1927. It has so often happened that such conventions have been influenced by poor advice, and have adopted unwise resolutions that have had considerable weight with the uninformed. Engineers have often been content to sit back, shrug their shoulders, and remark that the whole scheme is impracticable. How much better and more valuable it is to lead and to guide than to follow and to criticize!

When it is remembered that the Mississippi River, below the mouth of the Red River, drains from 40 to 50% of the entire area of the United States, and that the alluvial valley of the river contains about 19 000 000 acres of fertile land subject to overflow if unprotected, the assumption that the problem of flood control on the Mississippi is a National one, is well warranted. The whole matter assumes such large proportions and affects such large areas that the solution and the control can only be handled by the Federal Government.

Viewing all the vast and extensive work done by the Mississippi River Commission during the last forty years, it should be particularly remembered that not the least valuable are the accurate, detailed surveys and maps that have been made, the establishment and maintenance of numerous gauges and records, the extensive discharge measurements made at various stages, sedimentation studies, and the collecting and recording of all kinds of data concerning the river. The speaker doubts if there exists anywhere in the world any more complete and accurate information of any river than that collected by the Mississippi River Commission. The voluminous records have made possible the scientific determination of the various features of locating and building levees, bank protection, dredging, etc.

The speaker wishes to advocate the Commission plan for the work of such magnitude as is being done on the Mississippi River, and to make a plea for the continuance of such a form of control of the work to be undertaken by the Federal Government. It is believed that a mixed commission of seven members, as well chosen as the members of the Mississippi River Commission have been thus far, can handle a problem of such magnitude much better than it can be done by any other form of control. Every one appreciates the advantages of centralized control; but this is too big a project for any one man even with the assistance he might command. The membership of the Commission may change, and it does; but all the members do not change at the same time. This results in a fixed and continuing policy which is not affected by each change of administration.

The economic problem of the Mississippi River covers various features, that of providing for the needs of navigation at low stages, prevention of erosion of the banks, as well as control of the flood waters, etc. The speaker will confine his discussion to the latter feature. Floods are caused by rainfall and run-off, as has already been discussed. No man has any control whatever over the rainfall and its distribution, and, consequently, engineering efforts

can only be directed to a proper and reasonable control of the floods after they have reached the river. The only control necessary or desirable is some method of preventing the loss of life, overflow of valuable and fertile lands, railroads, highways, cities, and towns.

In speaking of the control of floods after they have reached the Mississippi River, it is proposed to include that part of the river below Cairo, Ill., or its vicinity only. This limitation will not meet the approval of engineers who feel that the flood solution lies in the construction of reservoirs near the head-waters of the streams. It may be that the construction of reservoirs on the Allegheny, Monongahela, Miami, Upper Mississippi, and other rivers, may be warranted for local control, but it is believed that it has been conclusively demonstrated that any flood control in the Mississippi River delta by reservoirs would necessitate their construction in the delta itself, or immediately adjacent to it. These reservoirs would require such enormous areas to be condemned and abandoned as to make the plan impracticable. The problem is to save from overflow the 19 000 000 acres in the delta, and the States can not give up 4 000 000 or 5 000 000 acres for reservoirs, if it can be done in some other way.

The papers on spillways, auxiliary channels, and their various features as means of flood control are most valuable and interesting. The methods outlined may assist to some extent, but the speaker is firmly convinced that the real solution lies in the construction of adequate levees properly located. Engineers are familiar with the history and growth of the levee system. Their construction has been going on for many years, and the acreage of land protected has steadily increased with the growth of the system. To the present time practically the only method used for controlling the floods, or protecting the land from overflow, has been that of building levees.

When the disastrous flood of 1927 came, a cry went up that the levee system had failed, and that some other solution of the problem must be found. The levees have not failed but, on the other hand, inadequate as some of them were in size, they did, in 1927, protect one-third of the area subject to overflow, and the protected area contains a much larger percentage of cultivated land than that flooded.

One might as well contend that, because costly roads have failed under the increasing demands of automobile traffic, the public should seek some other means of transportation. Instead of abandoning the automobile, people build better roads; so instead of abandoning the levee system, better levees must be built.

It is interesting to note that only one break occurred in Government levees built to standard height and cross-section based on the flood of 1912-13. It does not seem that the engineers made any very great error in designing the levee system as proposed. It is true that occasionally a fire-proof building burns, or a bridge or a dam fails, but that is no reason why every one should stop building fire-proof buildings, or dams, or bridges. Build them better and stronger; also, build better levees if necessary.

The greater part of the area inundated by the failure of levees was caused by breaks in those built by State or local authorities, and largely on the tributaries, where they were not built to the standard cross-section. This statement is not made in criticism of the local authorities or their engineers as they did the best they could with the money available. It only emphasizes the fact that the jurisdiction of the Mississippi River Commission should be extended to embrace the construction of levees on the tributaries as far at least as the protection of the Mississippi delta demands.

There is no desire on the part of the speaker to enter into a discussion of the size, height, or cross-section of an adequate levee. These are details, which can safely be left to those in responsible charge of their construction. It is conceded that provision for a flood, even one somewhat higher than that of 1927, should be made, and that the present standard cross-section is somewhat too small, as in some places the line of saturation falls outside the base on the land side. This results in greatly increasing the cost of maintenance, because a leaking levee must be watched continually as it is liable to fail at any time. The section should be such that in any given material the line of saturation should be always within the base, with water against the levees to within 1 ft., at most, of the top.

The speaker does not wish to be understood as advocating levees, and levees only, as the entire solution of the problem of flood control on the Mississippi River. In determining the grade line of the top of the levees, due consideration should be given to the economy of construction. It would seem hardly necessary to build levees that will provide for the extreme floods that may possibly occur once in 50 or 100 years.

For such unusual floods it may be, and probably will be, more economical in cost, and provide greater safety, to build controlled spillways that will take care of the floods above a predetermined elevation. The time of arrival and height of the crest of the flood will be known and can be provided for by the manipulation of the spillways. Instead of spillways with mechanical control, those of the automatic siphon type might be used. The latter type has proven very satisfactory in operation on a smaller scale, and is worthy of very careful consideration. In any event they should be of large and ample dimensions and of sufficient size to prevent the flood in the channel between the levees going above a predetermined height, even with a discharge as great as may be thought to be possible. A comparatively small acreage of land would be flooded by these spillways and that for a short time.

Owing to the universal use of automobiles and trucks and the scarcity of boats, it would seem desirable to construct a highway on top of the levees to permit ready access during high water for repairs and inspection. Maintenance of the roads would result in more careful inspection of the levees.

The only feature of this discussion that the speaker wishes to emphasize is that of levees. It is believed that they furnish the only adequate method of controlling the floods of the Mississippi. It may be that they can be supplemented to a certain extent by spillways as mentioned, but the main reliance must be found in the levee system.

Remember that the levees protected 6 000 000 acres of fertile land during the recent unprecedented flood. The work done and the money expended on levees to date is not wasted, but will be utilized as a part of the system to be completed to the dimensions that experience has found necessary. Control by other methods, at the best, is problematical. Engineers know the weak features of the levee system and can correct them.

MORRIS KNOWLES,* M. AM. SOC. C. E.—The Ohio River is an important tributary of the Mississippi and it frequently contributes disasters to the lower river. It also has problems of its own, some of which are of local character and have already been solved, notably at Dayton and Columbus, where one can see the works of construction resulting from thorough study.

The head-waters of the Ohio River are at Pittsburgh, Pa., where the Allegheny and Monongahela Rivers unite. At this place, there still remains unsolved (so far as construction is concerned) and lacking in determinative opinion, except from study, "the most important [flood problem] in the United States, in which a single city is the chief interest concerned and in which the chief reliance for protection so far proposed is an extensive reservoir system".†

First impressions of the papers and discussions in this Symposium indicate a note of discouragement. It has been stated that if the present levees had held, the recent flood would have been 6 to 8 ft. higher at several places between Helena, Ark., and New Orleans, La. The Mississippi River Commission reports that a discharge 25% greater may be expected as a probability and that to care for such a flood, within "levees only" would require an increase in present levee heights of from 7 to 20 ft., in the stretch of river to 900 miles below Cairo, Ill.

It is further stated by Colonel Townsend, that:

"Any project which contemplates increasing the heights of existing levees at certain localities about 15 ft., not only affects the item of cost, but raises the question of the practicability and feasibility of maintaining such a levee line after it has been constructed."

* * * * * * * * * *

"* * * no matter how much money is expended on the levee line, it will still be at the mercy of the combination of a muskrat, a dark night and a careless levee inspector. * * * To try to construct a levee line which will resist the river flow under all the imaginary conditions which now fill the public mind, is to attempt the impossible".

Again, it is said by Colonel Kutz, that:

"* * * an 1 800-mile levee line of the height necessary to contain such a flood, would carry with it a menace to the people living behind it that should be avoided if practicable".

At the same time, few, if any, words of encouragement seem to be forthcoming about any of the alternative methods of substitution or means of alleviating conditions and lessening the volume of flood waters to be restrained by such a levee line. Certainly, if these are the facts, then the people of the

* Pres. and Chf. Engr., Morris Knowles, Inc., Pittsburgh, Pa.

† "Flood Control," by the late H. M. Chittenden, M. Am. Soc. C. E., *Transactions*, Inter. Eng. Cong., San Francisco, 1915 (Waterways and Irrigation), Paper No. 30, p. 110

Lower Mississippi Valley should be informed frankly and told that nothing will avail against the greater catastrophe that may and probably will happen. Common honesty and fairness dictate that they should not be lulled into a sense of false security.

The speaker believes, however, that all is not as dark as it is colored, and that the knowledge, training, ingenuity, and research of the American engineer will not falter at the problem. Granted the first three, then research must be brought into action. Mr. Morgan has well argued, based on long and familiar experience with such problems, for the efficacy and necessity of information, resulting from long-time study of an accurate and detailed nature. As to the opportunity for this, as distinguished from the need of haste, people are assured that by 1928 the line of levees will be re-established to the full extent at which they existed prior to the flood of 1927. It has been stated* that:

"Our lines of defense will be closed before the next flood season. * * * Although not entirely completed to standard grade and cross-section, it would seem that, by all the laws of probability, we should be reasonably safe until the revised project can be started."

If this is true, then why all the haste to spend fabulous millions until sufficient data have been received on which to base such large expenditures? American engineers have a real duty to educate the public so as to prevent a stampede of Congress on this important question, to the end that no unwise conclusions be reached, under the false urge of haste, which may burden the country with an erroneous policy for generations to come.

Pittsburgh Problem.—The speaker has been asked to discuss the Upper Ohio situation. This problem and the proposed solution, the reasons for delay, the progress to date, and the possible effect on the lower river have all been subjects of misconception and misunderstanding.

At times, the flood flows from the Ohio River Basin may be an important contribution to great disasters on the Lower Mississippi. While the drainage area is only one-third that of the Missouri (the great tributary of the Mississippi), the rainfall is normally about the same over this area as upon that of the greater river. It frequently contributes one-half the flow to great floods in the lower river. It is possible, also, for its outpouring to synchronize with that of the lower river, according to Dr. Frankenfield.

Western Pennsylvania, including the Allegheny and Monongahela River Basins and the upper portion of the Ohio, together with their tributaries, have been visited by disastrous floods for half a century, culminating in three such events, in 1907 and 1908. The flood of 1907 is the greatest one of which there is any record. It is possible, however, by certain combination of circumstances, distribution of rainfall, degree of saturation of the soil, and conditions of the surface, to have a flood at Pittsburgh at least 10 ft. higher than that which was so disastrous in 1907.

In twenty years, including 1908, the damages at Pittsburgh have been estimated to amount to $17 000 000, of which $6 500 000 was for the three floods of 1907 and 1908. In 1907 the total damage in the Ohio Valley was about

* *Engineering News-Record*, October 20, 1927, p. 636.

$100 000 000. While the streams are reasonably well constricted and the downtown district of Pittsburgh, on both banks of both rivers, contains only about 3 000 acres, about 1 600 acres are affected by large floods. This area includes 100 office buildings, 17 miles of main-line steam railroad, 33 miles of streets, and 7 bridges rendered inaccessible.

Effect of Encroachments.—Statements are constantly made, even in professional circles, but sometimes without adequate basis, that Man's encroachment has been an active agent in increasing, intensifying, and even in producing recent floods. Care should be exercised in such discussions to differentiate between encroachments by embankments in wide alluvial valleys (as they have been described), and those in narrow stretches, restrained by comparatively high elevations on either side, such as exist in many of the upper tributaries. It is, of course, true that floods have been more disastrous in recent years, but to a large extent this may have been because of the greater monetary value of improvements within flood areas, due to the extension of Man's activity. In some cases, of course, encroachments do intensify, floods above such a situation. However, where such restriction is made, it is often possible—in rectifying, straightening, and narrowing the streams—to make the flood discharge of the same capacity and sometimes even greater, by reveting, smoothing, and straightening the banks. Thus, the advent of human occupancy may, in some instances, and can, in most situations, be made not to intensify but to lessen flood troubles.

Organization of Pittsburgh Flood Commission.—Realizing the adverse effect of these occasional visitations and, for the purpose of studying the problem, the business interests of Pittsburgh (acting on suggestions of local engineers through the Chamber of Commerce), created what was called the Pittsburgh Flood Commission, in 1908. This commission included representatives of Allegheny County, the City of Pittsburgh, manufacturing and industrial companies, and the transportation interests. There was a goodly representation of engineers and these were grouped and designated as the Engineering Committee.*

In addition to the question of securing accurate information (by surveys and otherwise) upon which to base an intelligent consideration, the Commission devoted considerable time to studying the effect, both physically and financially, as to the floods which had occurred from time to time. It may be said frankly that the problem was approached, in the first instance (as such problems usually are), with a desire to relieve the local situation. It was thought that the raising of the street and land levels near the rivers, with the possible building of walls, or other barriers, along the water-front, would be of immense benefit. As a result of this discussion, in the subsequent year of 1915, about $500 000 was spent on such regrading work by the City, public

* There were nine engineers, seven of whom were members of this Society, three of whom, Messrs. Swenssen, Wilkins, and Long, have since died. The members of the Engineering Committee were: E. K. Morse, M. Am. Soc. C. E., *Chairman*, the late Emil Swenssen, M. Am. Soc. C. E., *Vice-Chairman*, the late William G. Wilkins, M. Am. Soc. C. E., *Vice-Chairman*, George S. Davison, Past-President, Am. Soc. C. E., Paul Didier, M. Am. Soc. C. E., the late S. C. Long, Gen. Mgr., P. R. R., Julian Kennedy, Morris Knowles, M. Am. Soc. C. E., George M. Lehman, M. Am. Soc. C. E., Secretary and Executive Engineer, and A. B. Shepherd (resigned), Superintendent, Pittsburgh Bureau of Water. (Mr. Didier died May 19, 1928, since this discussion was written.)

utilities, and private owners. Many streets in the low areas of the city were raised and re-arranged to considerable advantage to their use for business purposes. The occasions and the extent of flooding were diminished thereby.

Local Solution not Sufficient.—However, it soon appeared that it was quite possible that such local or selfish consideration would not solve the problem as completely as it should be undertaken. Such restraining walls might have slight effect on some other places near and above the city, but would not materially lessen floods below the city. In addition, a little consideration showed that, at Pittsburgh, as at many other places, while there is too much water at certain seasons of the year, there is too little at other times. This condition sometimes renders the banks of the river and the bed unsightly, diminishes the navigable capacity at times of low stream flow, and increases the injurious effects of pollution and contaminating influences. Dilution has been found to be an important factor in the power of bodies of water to take up and render foreign substances innocuous.

As a natural result of such realization, the Pittsburgh Flood Commission early began to study the possibilities of lessening the large volume of flood waters which comes down to the city at certain times, and increasing the flow during low periods. This naturally meant a study of the drainage area, which is about 19 000 sq. miles, of which 11 580 sq. miles is on the Allegheny and 7 340, on the Monongahela; and 20% of this area is within Pennsylvania; it also comprises about 10% of the Ohio drainage area tributary at Cairo.

Reservoir Possibilities.—By careful surveys and studies of the area within the water-shed of the Allegheny and Monongahela Rivers, it was found there were forty-three possible reservoir sites, which were considered practicable and worthy of intensive investigation. More could have been found if such study had been conducted a half century ago or even a generation prior to this. It is possible that not all of these, found in 1908 and 1909, will be considered now as feasible sites. Thus, does Man by his own works and extensions, sometimes render the problem of conservation more difficult.

Careful and selective study of the availability, effectiveness, and efficiency of the various suggested reservoirs revealed that, of these forty-three, seventeen would be practically and sufficiently effective to take care of all the floods which had ever been experienced at Pittsburgh, except that of 1907. This flood would have been reduced about 8 ft., the average reduction being 10 ft. for all floods. Additional important considerations are, that the use of such reservoirs would not only have reduced flood stages, but would have increased the low-water flow to a measurable extent; the Allegheny low-water discharge would be increased three times, and that of the Monongahela six times.

Each flood since 1900 has been analyzed as to its time of occurrence, duration, and intensity, and the effect that would be produced by each of the seventeen reservoirs proposed on the two water-sheds. Of course, there is no guaranty that floods would occur in the same situations, to the same extent, or with the same periodicity as to extent of time or intensity. However, that which has occurred through several years of recorded

history is quite persuasive as to the probable climatological, meteorological, and physical conditions that are likely to occur in the future. Periods of high water in the streams of the western slope of the Alleghenies occur more frequently at certain times of the year, just as it is more often that there is low water in the autumn. Of the floods in the Pittsburgh District, 75% of which there is any record has occurred between December 1 and April 1, and there never has been a flood of any marked intensity during the months of September, October, and November.

Effect on Lower Rivers.—Some ill-considered comments have been expressed as to the probable effect or non-effect of such reservoirs, wherever they may be placed, on the flow of the Lower Mississippi River. The Pittsburgh Flood Commission and its engineers have never made any claims as to such results, because they have not investigated and studied the effect of the reservoirs on the Allegheny and Monongahela Rivers, on the Mississippi floods. They have, however, made some study extending down the Ohio River about 90 miles. The greatest flood on record at Wheeling, W. Va., would be reduced, by this proposed system of reservoirs, from 13 to 14 ft., and the low-water flow would be increased three times its minimum, on the basis of average normal assumptions as to condition of reservoirs.

Below this point on the Ohio River, there are many large tributaries, and it would be idle, with present lack of data, to say what the effect of the upper reservoirs would be on the high and low-water stages of the river below, to Cairo. It is undoubtedly true, however, that for some distance below Wheeling, perhaps even extending to Cincinnati, Ohio, there would be a marked beneficial effect by the construction of the seventeen reservoirs. The most important requirement, however, is that the solution proposed above Pittsburgh, be studied in connection with the topography, possible locations, distribution of rainfall, and stream flow on the important tributaries below Wheeling, so that idle and immature conjecture as to effect will be replaced with sound opinion founded on careful estimate. It may then appear that favorable sites are found, with possible reduction of flood heights and increase of low-water flow, as a result of the use of such reservoirs. If such be found then, in order to obviate possible injurious interference or clashing, in the use of one reservoir system on another, it points to the need of National control, as to operation and manipulation of reservoir outlets.

National Character of Problem.—It is a National question, because that which is done in one part of the country may vitally affect the lives and property of people in another part. This does not necessarily mean Federal appropriation and expenditures alone, for an important National policy is to create that feeling of responsibility as well as action, to the end that payment for benefits shall be assessed upon and paid to some degree by those particularly receiving benefits. It is well to have, however, the conception of National responsibility, as well as unified control, in order that such a system of reservoirs may be basin-wide in influence. The manipulation of the large systems of storage reservoirs on water supply projects indicates too the kind of centralized control that would make such a system effective and

helpful rather than inefficient and hurtful. Perhaps it should be pointed out that the criterion is not the storage of the entire volume of flood flow, but the retardation of that portion of the excess which, added to the flood flow of other tributaries, produces the disastrous result.

It is recognized, in speaking of possibilities on the Ohio River water-shed, that this has been a matter of controversy for several years. Both proponents and opponents have been outspoken in their assertions, beginning with the monograph by Charles Ellet, Jr., in 1853. However, since then, such discussions have related to the usefulness of reservoirs to increase low-water stages for navigation, in preference to the use of locks and dams for such purpose. Now that canalization is about completed, this question need not be considered and engineers can discuss reservoirs, if and when they have adequate data as to their usefulness in restraining floods. It remains, however, to determine the actual facts as a result of careful and conservative surveys. It is hoped that the forthcoming reports,* requested by the President and Secretary of War, as a result of the Mississippi disaster, will throw some light on such agencies and the best location, construction, and effective use of reservoirs in conjunction with that other very valuable agency of restraining the lower river within suitable and safe levees. It is suggested, however, with present meager information as to topographic maps, stream flow, and precipitation at salient points all over the country, that nine months is too short a time to conclude a study on such a project adequately and comprehensively. If stations for measuring rainfall and stream flow were distributed over the country and universal topographical maps existed, it now would be possible to solve these problems much more quickly.

No Conflict with Power Uses.—One frequently hears the axiomatic statement that empty reservoirs are needed for flood protection and full reservoirs for navigation and water power. In these days when considerable attention is being paid to the development of water resources for power, that is, "white coal", one is constrained to look into the question, is there any necessary antagonism? The Pittsburgh Flood Commission and its engineers believe there is not. It does not, however, advocate the building of great hydroelectric plants in connection with the construction of reservoirs for flood protection, unless real economy and efficiency are to be obtained thereby. The need and request for flood protection should not be used as a guise for securing public appropriations for the development of water power not yet needed; but it may be prudent, in arranging for design, that future possibilities of power requirements be not forgotten.

However, although stated head and constant supply of water are needed for power, and although empty reservoirs are the safe criterion for flood protection, it is still asserted that both uses are not incompatible. By this is meant use at a location and site and not as to volume or storage within certain elevations. The explanation is that a certain volume is needed for flood storage, and a certain head is needed for power. There is nothing antagonistic in providing necessary flood storage at that upper portion of

* The report was presented to Congress in December, 1927.

the dam and within the upper reaches of the reservoir above the elevation required for power. It will frequently be found true that the building of the dam, at a slight increased height necessary for flood storage, on top of a dam required for power, will be less expensive than the building of a separate dam, providing the same amount of storage solely for flood protection.

This point is emphasized, because of the misconception previously mentioned and in order that the position of the Pittsburgh Flood Commission may be made plain; that is, it is not opposed to the development of power, where economically wise, on the streams which unite at Pittsburgh. It has always taken the position of welcoming the investment of private capital, where it can be found to be efficiently done, in the production of electric power by the use of flowing water. It is realized that, even if there cannot be an arrangement to build a dam at increased height, there is a valuable retarding effect, due to flow over the crest of a dam as a weir, thus raising the pond level, whenever there is a heavy precipitation or run-off.

As an example of investigation into this subject, the Flood Commission made a study on three proposed sites on the Clarion River, one of the main tributaries of the Allegheny, having a drainage area of 1 260 sq. miles. The total storage proposed for power purposes was 32 000 000 000 cu. ft. It was even in excess, by more than 20 000 000 000, of storage proposed at some similar sites by the Flood Commission for the complete control of the Clarion River. However, such power dams, not built primarily for flood purposes, would not have as complete effect as if those proposed by the Flood Commission were to be erected. However, they would have had an important deterring and retarding effect on most of the flood heights at Pittsburgh during the last quarter of a century. Of almost equal importance was the fact that the constant flow of water from these power dams would increase the low-water flow of the Allegheny River about three times, and this from the development of reservoirs on one tributary only.

Why the Delay?—It is natural now to ask, if this project be so meritorious, why the country has not heard more about it and something of its construction. The answer is plain. The Allegheny River has portions of its water-shed in two States, New York and Pennsylvania. The Monongahela River has its water-shed in three States, Maryland, West Virginia, and Pennsylvania. Reservoir sites have been proposed in several States and affect the flow of the stream in each. It is not possible, therefore, for the city, county, or even the State of Pennsylvania to carry out the project in its entirety, or in the comprehensive way in which it should be undertaken. Such a contemplation should not be undertaken in a small way—it means National action and control. Heretofore, and from time immemorial, the consideration of the Federal Government has related to the use of large streams for navigation only. The question has been how much would the destruction of the forest, the building of a bridge, encroachment on a stream, or the building of a reservoir affect navigation. If seriously and injuriously, then it became a matter of interest to National agencies and, if this were not true, then Congress was not concerned.

Recently, however, there has been a change of consciousness. Perhaps now, with a realization of the 1927 calamity of the Mississippi River disaster, with an appreciation that the drainage area, population, and wealth comprehends about 40% of the Continental United States, for the first time, Congress may have an appreciation that flood control and regulation of streams is a question to be considered within the whole drainage area, from the source to the mouth, and is a problem for National study, construction, and control.

Forest Benefits.—One of the first acceptances of this view happened when the Week's Appalachian Forest Bill was passed by Congress, in 1911, as a result of which many thousands of acres of land have been secured on the Appalachian Mountain Range for the purpose of protecting slopes from erosion and growing forest cover for its many beneficial purposes. The Pittsburgh Flood Commission early joined hands with the National Forest Commission and upheld its work for this purpose. More than $15 000 000 has been spent in Eastern States, of which $1 200 000 has been on the Allegheny and Monongahela water-sheds, acquiring 367 000 acres of land. Ultimately, it is expected that there will be secured more than 860 000 acres in West Virginia, 80 000 acres in Maryland, and 425 000 acres in Northwestern Pennsylvania. Some of the proposed reservoirs are on lands contemplated for National Forest procurement.

Authoritative Review.—It is appreciated that National action cannot come without Congressional approval, based on a report from authoritative governmental agencies. Shortly after the report of the Pittsburgh Flood Commission was issued, it was reviewed by the U. S. Engineer Office, having to do with the question of the effect of the proposed reservoir system on the navigability of the Ohio River. No question was suggested of course that it would in any way supplant, or replace, or do away with the construction of the locks and dams which are now nearing completion. However, it was realized that at several times in years of low flow, there has not been sufficient water in the Monongahela to allow the boats to pass through the locks without letting out water from the upper pools of the river formed by the dams. Such was the rather general experience during the drouth of 1908.

It was found by the Government engineers that, while such a system of reservoirs would be feasible and practicable, the effect on navigation would be little and would not warrant a participation in expense in excess of 10 per cent. More recently, however, with the newer view of National responsibility as to control of streams, another survey and investigation is in progress by the Federal authorities.

This was brought about through the joint action of the State of Pennsylvania and the National Congress. The State of Pennsylvania, at the session of 1919, appropriated $25 000 to the National Government for making a study of reservoirs proposed by the Pittsburgh Flood Commission and their general effect on the flood question. The Chief of Engineers, under date of December 21, 1916, recommended that the War Department be authorized to make such study. On May 31, 1924, a similar bill was passed by Congress, appropriating $25 000 for this purpose, to be used with the $25 000 from the State of Pennsylvania.

As a result, a study has been going on since 1925, under the District Engineer Officer at Pittsburgh, to look into the question of the feasibility and advisability of reservoirs on the Allegheny and Monongahela drainage areas, to control floods, to increase the low-water flow, and the attendant effect on navigation. This examination is most thorough and extended. It is to be expected that study and criticisms of the location and method of arrangement of the reservoirs proposed by the Pittsburgh Flood Commission will now be forthcoming from an authoritative source.

Times have changed and the cost of public works has notably increased. It is well, therefore, that there be this thorough investigation to settle the question. The country may look forward to receiving the report within a reasonable time, perhaps early in 1928. Then, there may be formulated a constructive program of the National Government as to the development of such a system of reservoirs and its effect locally and extending to the lower river. Perhaps it may be relied on as an example of what may reasonably be done in other places, with similar conditions as to topography, construction possibilities, and relative effectiveness; to the end, in conjunction with other protective measures, that disastrous floods in the entire Mississippi Basin may be prevented forever.

CHARLES H. PAUL,* M. AM. SOC. C. E.—The work of the Miami Conservancy District has been referred to many times in the course of these discussions of the Mississippi River problems. It is significant, however, that it is only the retarding basins, or so-called reservoirs, of the District that have been mentioned. One fact seems to have been overlooked, that nearly one-half the construction cost of the Miami Flood Control System went into levees and river channel improvements. In other words, the Miami Conservancy project is a combination of retarding basins and of river channel improvements, the latter feature including the straightening, widening, and deepening of channels, and the construction or reinforcement of levee systems. The evolution of the plan was to accomplish as much by the channel improvement works as was economically feasible, and to rely on the retarding basins to take care of the surplus water that could not be handled within the limits of economy by further enlargement of channel capacities.

It has been stated that the retarding basins of the Miami Conservancy District have had, or will have, little effect on the flood crests of the Mississippi, and there seems to be a tendency to use this as an argument against any use of reservoirs in connection with the Mississippi River control. It might easily be shown also that the levee system of the Miami Conservancy District will have no effect on the flow in the Mississippi, but certainly no one would go to the extent of giving this as an argument against the use of levees on the Mississippi, although that position would be about as reasonable as the other. The point is that the Miami Conservancy plan was designed solely for the control of the situation in the Miami Valley, and it would only be incidental if the work there had any effect one way or the other on the big problem of the Mississippi.

* Managing Director, Dayton Industrial Assoc.; Cons. Engr., Dayton, Ohio.

The Miami Conservancy project is fully effective for the object for which it has been designed (every one agrees to that), and this is so only because the plans were made after a thorough and comprehensive study of all necessary data. If there is one outstanding fact about the work of the Miami Conservancy District it is the thoroughness with which all necessary information was secured and studied before decision was made relative to the final details of the plan. This fact has impressed not only all former employees, but also all those who have studied the details of the plan. The speaker came into that situation after the general details of the plan had been decided upon; therefore, in commenting on the thoroughness of the preparatory work, he is speaking of the work of other engineers and not of his own. About two years were consumed by these preliminary studies, and all the necessary information was secured even though some of it was obtained with great difficulty, and at considerable expenditure of time and money.

The outstanding difficulty in connection with the solution of the Mississippi River problem is to secure all necessary information that has a bearing on its proper solution. Strange as it may seem, the basic information, such as is required for the development of a comprehensive plan, does not seem to be available. There is no possibility that it can be secured in a few months. It will take several years at best to obtain the necessary data and to make intelligent analyses. It would be most unfortunate if the country were to become committed to a plan, and the large expenditures that necessarily would go with it, until after all such information is assembled and digested, and the best possible scheme is developed. There is need, of course, for immediate appropriations to take care of the reconstruction of works that existed before the 1927 flood.

F. G. JONAH,* M. AM. SOC. C. E.—The recent flood in the Mississippi Valley wrought great damage to the railways in that region, and they are vitally interested in any plan for flood control that will minimize, if not wholly prevent, the tremendous losses that they sustain from these ever-recurring overflows.

There are accounts and records of many floods in the Mississippi River, the earliest being that given by Garcilasso de Vega, who wrote a history of De Soto's explorations. This he based on interviews with men who had been with De Soto on his great expedition. The flood occurred in 1543, and reading the account of it is very much like reading the account of any of the recent floods. One observation might be made with respect to that flood, and also to the others up to and including that of 1844, namely, that the forest growth then covered the entire valley, and apparently had no influence in lessening the flood. This is a fact that should be borne in mind when the project of reforestation is discussed.

Each succeeding flood will be, generally speaking, more destructive than the previous ones for the simple reason that there is more valuable property that can be destroyed. In 1882, when the railway companies first experienced

* Chf. Engr., St. L.-S. F. Ry., St. Louis, Mo.

trouble, there were about 200 miles of line in the delta. At present, there are 7 500 miles, and other developments have multiplied in proportion, towns, cities, improved highways, increased acres of land in cultivation, and a largely increased population.

From the earliest day of railway construction in the delta to the present there has scarcely been a year when the lines have not been subject to trouble from high water, and it appears that major floods may be expected to occur about once in every five years. The floods affecting railways seriously were those in 1882, 1890, 1892, 1897, 1903, 1912, 1913, 1916, 1920, and 1922. Certain lines sustained great damage, but in the flood of 1927, every road running through the valley below St. Louis, Mo., sustained enormous damages and losses. Due to the flood, train service was suspended on lines aggregating 3 000 miles, and in periods of from 10 to 120 days. The physical damage to these lines has been not less than $10 000 000, and in addition there is a loss, hard to estimate, growing out of the interruption of traffic and the general paralysis of business in the flood sections. These sections equal an area of 18 000 sq. miles, covering more than 100 counties and parishes, in several States, which is equivalent to the area of several States.

Unlike other calamities of Nature, such as earthquakes, cyclones, tornados, and tidal waves (which come without warning), a flood in the Mississippi Valley can be predicted, and with a remarkable degree of accuracy. The U. S. Weather Bureau and the Mississippi River Commission have predicted the passage of the crest of the flood and its highest stages at the several important points along the river to within a few hours of the actual time and a few tenths of a foot of the actual heights attained. It is true that these predictions are revised from time to time during the flood, by reason of the breaks in the levee lines or continued and heavy rainfall. Thus, during the recent flood, there was an unprecedented rainfall over the water-shed of the Arkansas River, which brought that river to one of the greatest stages of record. This made necessary the revision of the predictions for the heights attained by the river at lower points, but these forecasts are so reliable that the railways know what to expect and make preparations accordingly.

The work of fighting the water during inundation is done in three general phases:

First.—To take all possible precautions to prevent overflow and to minimize the damage to track and structures when such overflow occurs.

Second.—To remove the inhabitants and as much of their household goods and live stock as possible from the overflow areas to places of safety.

Third.—To restore track and bridges to service and to resume train schedules in the shortest possible time.

The precautionary measures are the patroling and guarding of the levee lines, and building up the weakest spots with sandbags. In many cases the railways recruit large gangs of men for this work. They place them under the directions of the Government engineers and the municipal authorities, and they transport thousands of sandbags, planking, and laborers to those places that require this emergency work.

There are going on, at this same time, other precautionary measures, such as the cutting in of steam shovels for producing rip-rap, which is always needed in great quantities, and the assembly of work trains, extra gangs, pile-drivers, piling, ties, bridge timber, and rail and fastenings. The track is anchored where it is likely to wash off the embankments, and the ends of openings are protected with rip-rap.

The removal of the inhabitants and live stock is undertaken as soon as the danger is imminent. Many of the people remain until their lives are actually in danger. The railways haul them out to places of safety, furnish hundreds of camp cars and box cars for their temporary shelter, haul water and food-stuffs for them, and provide, in many cases, doctors and medicine. After the flood subsides they haul them back to their homes, and haul seed for their planting, and these services are performed without charge. The railways co-operate with the Red Cross and municipal authorities very closely.

After these precautionary measures are taken, and, when the flood is on the lines, the first effort is to maintain communication as long as possible. Train service is carried on many days when the trains travel through water for many miles at slow speed, and then, after they can no longer run, the plan is to get the work trains in just as soon as the water goes down and restore the tracks for safe operation as quickly as possible.

The railway lines operating in that territory have developed a body of high-water fighters, who, by long experience, are capable of doing great work in these emergencies. Many miles of track are kept in service by raising it on slag, rock, or cribbing, securely anchored; but it is impossible for the companies to raise all their track above flood heights. The cost would be prohibitive. The delta country comprises about 30 000 sq. miles, in which there is now 7 500 miles of railway line, and the railway officials have long since concluded that it would be impossible to raise these lines above flood levels, and, were it possible to do so, they would not serve the country as well as they do now on their present elevations, because they are now adjusted to the industrial situation. Therefore, the railway companies rely on the protection of the levees and take their chances along with the other property owners in the affected districts.

Since the 1927 flood, there has been a mass of literature and discussion in the technical journals and the public press, advocating every conceivable method of control. There have been some suggestions of impounding reservoirs or detention basins in the valley itself. It has been suggested that the St. Francis Basin be used for this purpose, and this entire area of 4 000 sq. miles converted into a catchment basin. Some mention was made of the possibility of this as far back as the report of Humphreys and Abbot, in 1861, but at that time it was swamp land covered with primeval forest growth. It was public domain and the lands could have been segregated by the Government, but now conditions are different. This land comprises the most fertile region of Southeast Missouri and Northeastern Arkansas, in fact, the best agricultural portions of those two States. Statistics will show that, while certain counties in these States either lost population, or were stationary in

growth, in the last two decades, the counties in the St. Francis Basin rapidly increased in population. It is now covered with prosperous cities and towns, farms on every 160 acres almost, and it is one of the few spots in the world where wheat, corn, cotton, and rice can be grown on adjacent fields. Within this basin there are 800 miles of railway lines, and hundreds of miles of concrete highways. These lines could not be abandoned under any circumstances, as they are necessary to keep up communication between Memphis, Tenn., and the great region to the west. The cost of raising any of these lines above the suggested reservoir level would be absolutely prohibitive.

It seems that a more reasonable solution for relief in the St. Francis Basin would be to make a controlled spillway below Cape Girardeau, Mo., leading the water into the St. Francis River, putting levees on this river as well as on the Mississippi. This water, of course, would again reach the Mississippi at Helena, Ark., but it could be carried around in this new channel or by-pass much more quickly than it would come down the main channel of the river, a much longer distance, and thus the crest of the flood might be divided or broken.

A part of the flood waters of the Arkansas might be diverted through a controlled spillway to the Tensas Basin and down the Tensas and Black Rivers to the Red River and the Atchafalaya, through which the Red River discharges when the Mississippi is at flood stage. The main channel might thus be greatly relieved by the diversion of these flood waters of certain of its tributaries.

The settlement of the Mississippi River Valley proceeded along the river itself. The towns and villages are built close to the river bank, because when the country was settled the only means of communication was by the river. Traffic was carried by the steamboats, and towns grew up around the steamboat landings. The highly developed farms front on the river bank because the lands are higher there than elsewhere in the delta. The highways are along the river bank, and the railway lines are likewise very close to the river as they run from town to town. In the proposal of setting certain portions of the levee lines back from the edge of the bank, the railway lines will have to be adjusted to new conditions. There is no doubt that many miles of levee have been built too close to the bank and are subject to the scouring and undermining of the river currents.

It is assumed, of course, that New Orleans must be protected at all hazards, and it would seem that the city can be made secure by converting the Atchafalaya into a permanent controlled spillway, opening up another one through Bayou Manchac, Lake Maurepas, and Lake Ponchartrain, and the removal of many miles of levee lines below the city. As emphasized in Colonel Townsend's admirable paper, the present law creating the Spillway Board, prohibits the discharge of overflow water into Mississippi Sound. This doubtless is due to the objection that New Orleans has always had to the discharge of silt into Lake Ponchartrain, but many engineers believe that it would be a very long time indeed before this occasional discharge would effect the lake. The silt would be deposited in Lake Maurepas and in the

surrounding swamps, and by the time the discharge reached Lake Pontchartrain it would be comparatively clear. This Act could be amended when conditions warrant it.

C. S. JARVIS,* M. AM. SOC. C. E.—It has been the speaker's privilege to glean in broad fields, long since harvested, and to discover values among material habitually overlooked, neglected, or discarded. This opportunity resulted from a co-operative arrangement between the Secretary of War and the Secretary of Agriculture, fostered by the Corps of Engineers, U. S. Army, and the Bureau of Public Roads. In the course of this work it has been demonstrated that the earliest and rarest hydrographic records, far too meager at best, are largely lying dormant as an undigested mass, or as detached and unrelated fragments, although they are capable of being assembled and utilized to great advantage. American engineers have been accustomed to think that the longest periods of meteorological and hydrographic record were for about 60 years, when as a matter of fact they exceed a century.

Fig. 39 depicts the relation of run-off to precipitation on two of the water-sheds supplying New York City. The habits of the Esopus area are portrayed from 1906 to 1926, inclusive. The monthly precipitation, which is platted above the axial line, occasionally produces run-off at nearly the same rate; but it lags behind the stormy period as required for percolation, thawing, or concentration. The average monthly precipitation ranges from 3.5 to 4.5 in., and the depth of run-off to be expected during March or April is fully 6 in. Even though the rainfall is greatest during the summer months, the yield is the least, due to the higher temperature, rates of evaporation, absorption by the soil, interception by foliage, and the demands of vegetation during the season of growth. The run-off from the 257 sq. miles of drainage area during the period of record was 31.2 in. in depth yearly (if considered evenly distributed over the water-shed), or 65.4% of the precipitation.

The hydrographs for the Croton drainage area extend from 1868 to 1926. The orderly behavior of the run-off since 1875 would be an excellent argument for reducing or controlling floods by forestation and wise supervision of the water-shed, were it not for such years as 1902 and 1920. The monthly run-off during the spring thaws in each of these years was double or treble the average monthly precipitation, and this could not fail to produce violent floods above the reservoir. The average annual run-off during the 59-year period of record was equivalent to a depth of 22.6 in. over the 375 sq. miles of water-shed, or 47.2% of the average annual precipitation. Only two meteorological stations were maintained for the first few years on this area, but the number was periodically increased, and for the past 20 years nine stations have given daily reports. The maximum annual rainfall recorded for this entire area was 63.76 in. in 1901; the minimum was 37.62 in. in 1880. As might be expected, those years marked the extremes of annual run-off, 34.4 and 11.8 in., respectively. The observed monthly precipitation frequently reaches double the average and rarely if ever attains three times the average for a given month.

* Highway Engr.; Chf. of Hydrographic Section, U. S. Bureau of Public Roads, Washington, D. C.

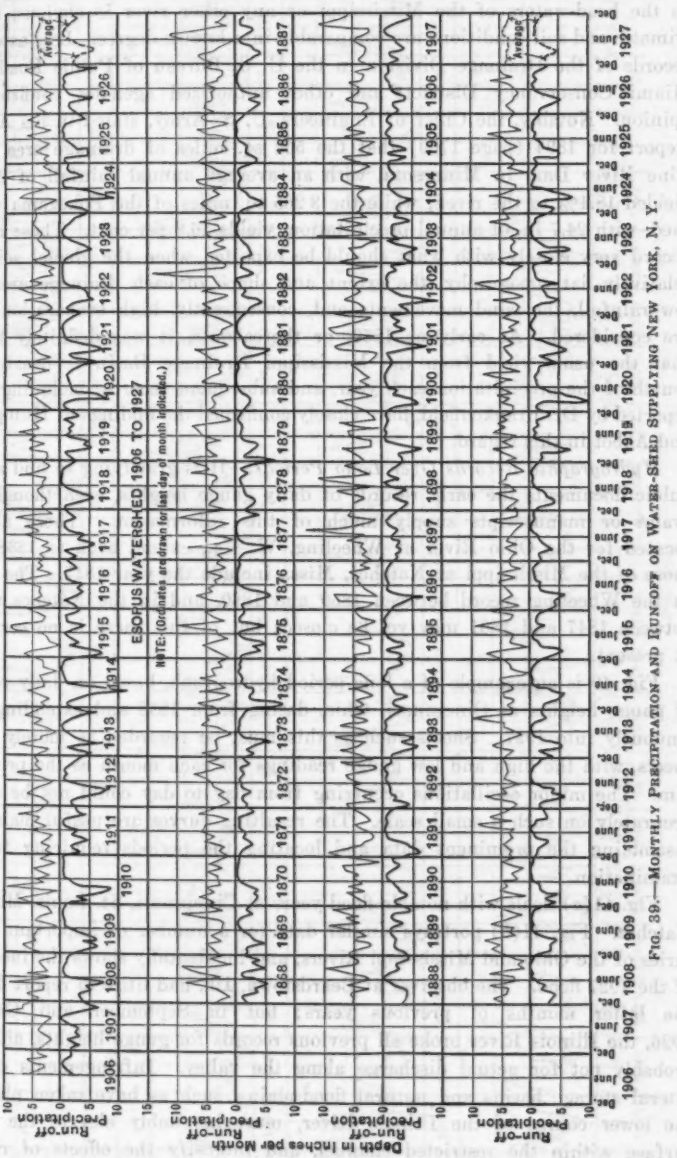

FIG. 39.—MONTHLY PRECIPITATION AND RUN-OFF ON WATER-SHED SUPPLYING NEW YORK, N. Y.

Application of Basic Data to Other Drainage Areas.—The application to the head-waters of the Mississippi or any other river is obvious, if the climatic and soil conditions are comparable in a known degree. Less extensive records of the Drainage Division in the U. S. Bureau of Public Roads, the Miami Conservancy District, and other authorized agencies confirm this opinion. Notably, the Chief of Engineers, U. S. Army, stated in his Annual Report for 1894 (page 1709) that the 562 sq. miles of drainage area above Pine River Dam in Minnesota, with an average annual rainfall of 23 in., yielded 18.4% to the river; while the 3 265 sq. miles of the Pokegama watershed, with 24.7 in. of annual precipitation, yields 16.8 per cent. These results accord very closely with what should be expected when the glacial soil, the relatively flat topography, the extent and shape of each drainage area, the low rainfall, the wind movements and, consequently, high evaporation rates are considered. As early as 1850, or thereabouts, it was definitely known that the usual yield from the Mississippi Drainage Basin is nearly one-fourth of the precipitation each year, and subsequent records, including those reported by Dr. Frankenfield, have closely confirmed the findings of Humphreys and Abbot in this regard.

Hydrographic Records Over Long Periods.—It is gratifying to find among public documents the early records of daily gauge heights, even though diagrams or manuscripts supply much of this information. Those already located for the Ohio River at Wheeling, W. Va., extend back to 1838; and those of the Mississippi at Natchez, Miss., include the year 1817. The break in the Wheeling record between 1850 and 1860, and in the Natchez record between 1847 and 1861 may yet be closed; but of this there is no certainty at present.

Fig. 40 is an example of a long-period hydrograph, based on daily records of gauge heights at Cincinnati, Ohio, dating from 1858 and extending continuously into 1927. Sheets such as this must be regarded as merely index sheets, with the high and low gauge readings for each month as the principal aim. The minor oscillations occurring from day to day could not be shown accurately on such a small scale. The resulting curves are useful mainly in assembling the prominent data and locating the periods requiring further examination.

Fig. 41(*a*) deals with notable flood years at Cincinnati, St. Louis, Mo., and Natchez. Fig. 41(*b*) portrays similar data for a number of important tributaries of the Ohio and Mississippi Rivers, and incidentally shows the inception of the 1927 flood. The observer at Beardstown, Ill., had little to report during the latter months of previous years; but in September and October, 1926, the Illinois River broke all previous records for gauge heights, although probably not for actual discharge along the valley. Infringements on the lateral storage basins and natural flood-plains, such as have taken place on the lower course of the Illinois River, must inevitably elevate the water surface within the restricted channel, and intensify the effects of record-breaking storms such as occurred in September, 1926.

FIG. 40.

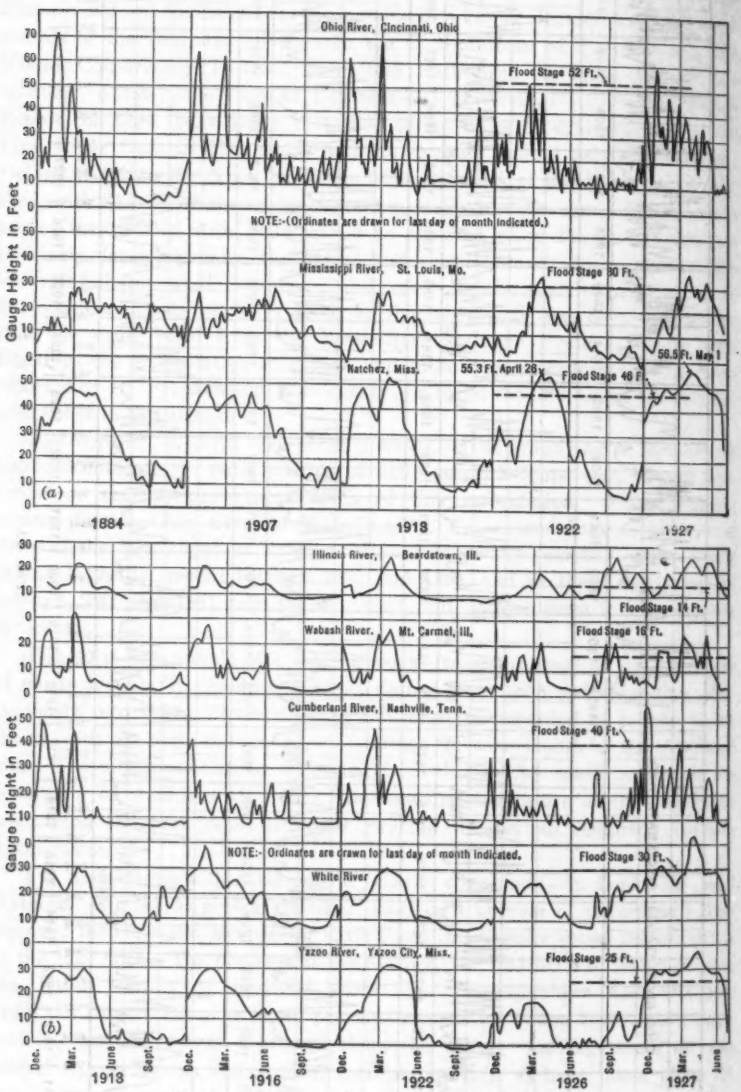

FIG. 41.—NOTABLE FLOOD-YEAR HYDROGRAPHS.

The depression of the Beardstown hydrograph during the early winter does not mean that the danger had passed, but that the flow had been checked, largely by freezing in the channel, in the soil, and in valley storage.

The Wabash, Tennessee, Cumberland, White, and Yazoo Basins all contributed unusual amounts during the latter part of 1926, setting the stage for the tragedy that was to follow. The same is true regarding the Ohio, the Missouri, and the Arkansas Basins. It is significant that the Ohio River receded to a moderate stage early in 1927; otherwise, additional chapters would have appeared in this year's history of disaster.

Fig. 41 helps to explain the forecast of the U. S. Weather Bureau some months in advance of the happening.

United States Weather Bureau Forecast of Flood Stages.—Early in January, 1927, Dr. Frankenfield, of the U. S. Weather Bureau, remarked, in the speaker's hearing, that conditions were shaping themselves for a Mississippi River flood that would far surpass all previous records. During succeeding weeks, as he anxiously noted the development of initial stages, he lamented the lack of publicity accorded the warnings of impending danger. When at length the catastrophe was recognized and accorded front-page prominence, the forecast of flood stages proved to be of incalculable benefit and unfailing reliability for the guidance of patrols and rescue organizations. One aggravating factor was apparently beyond the range of accurate prediction, and that was the intense torrential rainfall in the Lower Mississippi Valley. This occurred at the worst conceivable time for depleting the lateral storage and soil moisture capacity, augmenting the flood wave, increasing its velocity, and impeding the efforts aimed toward human safety, rescue, and relief.

Relationship Shown by Hydrographs.—Fig. 42 portrays the hydrographs of a river system. The Ouachita at Camden, Ark., has the sharp variations so commonly observed on head-waters, or in semi-arid country, while at Monroe, La., representative of the lower valley, the curve is fairly smooth. The records of the Red River, at Shreveport, La., and at Alexandria, La., show a closer relationship. Those for the Mississippi, at Red River Landing, La., and for the Atchafalaya, at Melville, La., nearly 40 miles distant, as well as for the intervening station at Barbre Landing, seem to be nearly identical in form.

The explanation for such a coincidence is to be found in the Old River channel which conveys water from the Red to the Mississippi, or reverses the flow, according to their relative stages. When the 1927 flood was at its highest, the relief afforded through this one outlet ranged between 100 000 and 200 000 cu. ft. per sec., reducing the flood height at New Orleans, La., from 1.7 to 3.0 ft., an effect nearly equal to that of the artificial crevasse below the city. Recalling the $1 313 000 000 estimated cost of reservoirs capable of lowering the flood crest 3.36 ft. at Red River Landing, the effective relief afforded by the Atchafalaya outlet is worth more than has been expended to date (1927) on Mississippi flood control.

According to official current meter measurements,* the discharge of the Mississippi River through or adjacent to Old River channel has exceeded 250 000 sec-ft. at some time during each of the 1912, 1913, 1916, 1917, 1920, and 1922 flood seasons. The same authority indicates that other notable measurements were as follows: 154 000 sec-ft. in February, 1907; 347 000 in April, 1912; 317 000 in April, 1920; 447 000 in April, 1922; and 206 000 in April, 1923.

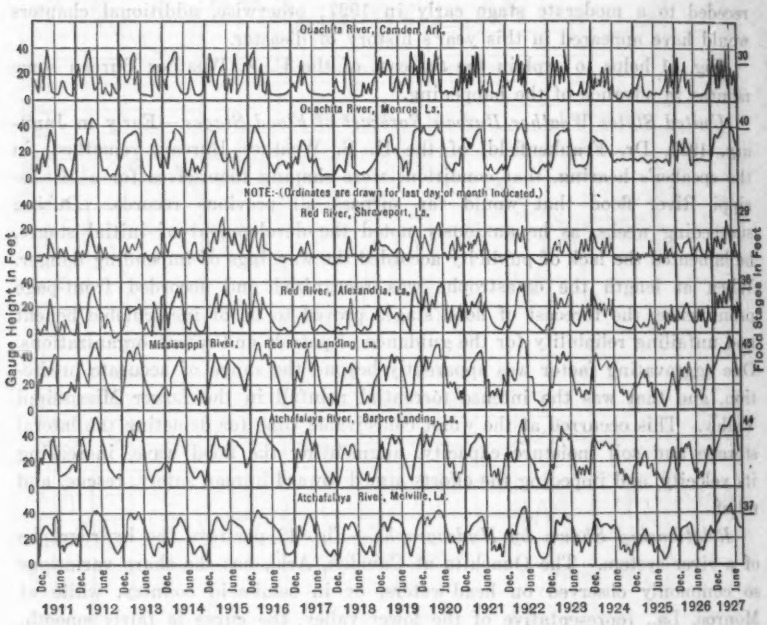

FIG. 42.—HYDROGRAPHS OF A RIVER SYSTEM.

Examples of Relief Outlets and Automatic Spillways.—In spite of the sporadic notions promulgated during the past eighty years for divorcing the Red and the Atchafalaya from the Mississippi drainage, or for closing the Atchafalaya at Barbre Landing against the Red River, this great relief outlet has been consistently maintained and improved by the U. S. Corps of Engineers. Log rafts and other obstructions have been removed, inducing the current to enlarge its own channel until the capacity now exceeds 400 000 sec-ft. for a 50-ft. stage at Barbre Landing. This represents an increase of fully 50% since 1882. Meantime, some revetment and sills had to be provided near Simmesport, La., to insure against the possible depletion or capture of the main river. Thus, doubtless, originated the belief that the engineers were gradually closing the outlet.

* "Results of Discharge Observations. 1838–1922," Pamphlet compiled and issued by the Mississippi River Commission, 1925.

Automatic spillways of the most expensive and wasteful type have operated at intervals ever since the first levees were established; and these crevasses will recur until adequate spillway facilities are provided to protect the levee system.

The Fiction of "Levees Only".—Because the engineers employed in controlling the Mississippi have consistently sought to complete the levees to standard grade before diverting funds and energies to other expedients, they have been regarded as the sponsors of "levees only" as the means of control. The reports of the Chief of Engineers are replete with discussions of divergent views on this subject. Similarly, the report of the State Engineer of Louisiana for 1850, page 39, advocated outlets or spillways; the Annual Report for 1861, page 38, condemns such a proposal. After additional years of investigation the conclusion was recorded* that:

"Outlets of sufficient magnitude to appreciably depress the floods, must either deluge vast areas of our State, as the Ashton and Grand levee or Morganzia, or be most expensive and injurious, as would be the Bonnet Carre and Lake Borgne, and therefore I oppose them, Lafourche and all, and turn for safety to our present levee system."

Despite such sentiments among local residents and officials, it is significant that the main reliance continued, not as "levees only", but levees aided by a great relief outlet and overflow sections or the inevitable crevasse within the uncompleted structure. Furthermore, extensive storage was proposed, accomplished, and operated on some of the head-waters as an aid to flood control and its natural corollary, namely, increased flow during the low-water season.

The "levees only" policy is fiction at best; for actually other means have passed the experimental stage. A relief channel operated throughout American history has convinced most of the former opponents of spillways.

Regarding Physical Limitations.—Try to imagine the 1927 flood confined between levees, 10 or 15 ft. above the completed embankments of recent years, resisting a current velocity of 12 ft. per sec., or 8 miles per hour, double or treble the safe velocity along unrevetted banks of silt; and then return to reasonable measures.

The proposed location of the levees a few miles back from their present location would encounter the same difficulties because of the lateral slope of nearly 7 ft. per mile away from the main channel. Considerations of foundation pressures, structural security, and the safeguarding of communities, all seem to forbid a great increase of levee heights. Unless adequate detention or spillway facilities are provided, the river assumes the mastery and Man becomes the fugitive.

A Résumé of River Habits.—Fig. 43 illustrates a device originated by the speaker for condensing hydrographic data and transforming it into convenient units. Such a system of parallel scales would present on a single page the most essential elements of voluminous records and extensive research, forecasts as to probable future recurrence, and a convenient means of comparison. Thus, the 1927 flood at Red River Landing with a gauge height of 57.5 ft.,

* Annual Rept., State Engr. of Louisiana, 1871, p. 20.

discharged nearly 1 600 000 sec-ft., or 1.3 sec-ft. per sq. mile of drainage area; or at the rate of 1.5 in. depth per month over the entire water-shed. The probable frequency of recurrence, judged by the whole unweighted record, is once per century; or in the light of the river's aggravated habits during recent years and their prospects for continuance, it may better be classed as a 25-year flood. The rating on the Myers scale is 14.5 per cent. Fig. 43 is based on 57 years of continuous record to 1927.

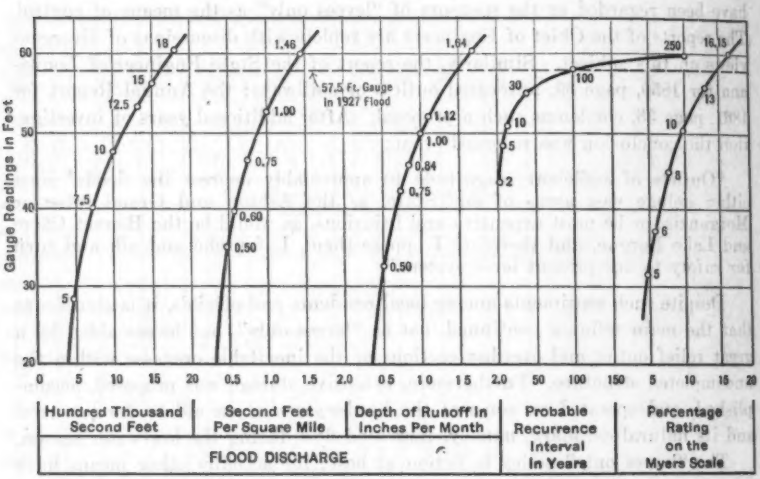

FIG. 43.—ANNUAL FLOOD RATINGS OF THE MISSISSIPPI RIVER AT RED RIVER LANDING, LA.

Using the same general method of analysis in 1923 and 1925, the speaker reached the conclusion* that the rating at Helena, Ark., for rare floods should be 25%, corresponding to a discharge of 2 500 000 sec-ft. He also urged the adoption of spillways to afford relief, and suggested a general re-appraisal of the flood situation to meet the changed conditions wrought by Man. Information disclosed after months of research seems to confirm both the estimate and the recommendations. The main significance of the 25% rating lies in the probability of discharges exceeding 2 500 000 sec-ft. at Red River Landing if the levees hold. The net accretion at this station from below Helena, should be measured approximately by the maximum concurrent contributions from the White, the Arkansas, the Yazoo, and Red Rivers, minus the outflow through the Atchafalaya. As this depends on the stage of the Red River it seems advisable to investigate the feasibility of diversions above Alexandria, into such neighboring drainage as the Sabine River, where local benefits would accrue. Likewise, it has been suggested that, during emergencies, part of the Arkansas River run-off should be conducted southward through bayous and never be allowed to reach the Mississippi.

* "Flood Flow Characteristics," by C. S. Jarvis, M. Am. Soc. C. E., *Transactions*, Vol. 89 (1926), p. 1023, Item No. 947.

Need for Topographic Maps.—The need for topographic maps of this region, to facilitate the location of auxiliary channels and lateral storage basins, or detention areas, was never more imperative than at this time. Fortunately, the 1927 flood-plane can still be traced, and there has been a demonstration of how much spreading is required to dissipate a major flood.

A Graphical Solution of Flood Probabilities.—Fig. 44 illustrates the speaker's method of determining flood periodicity by analyzing the trend of existing records. This has been described in detail* and has thus far satisfactorily withstood tests and comparisons of results with the various approved analytical methods. In addition to being much less laborious and involved, the graphic solution seems to be more readily interpreted. It is to be observed that, for Red River Landing, the same result is obtained whether the gauge readings or the distances above the flood stage of 45 ft. are plotted. For a 400-year period both curves indicate a probable stage of nearly 61 ft., if the entire unweighted record is considered.

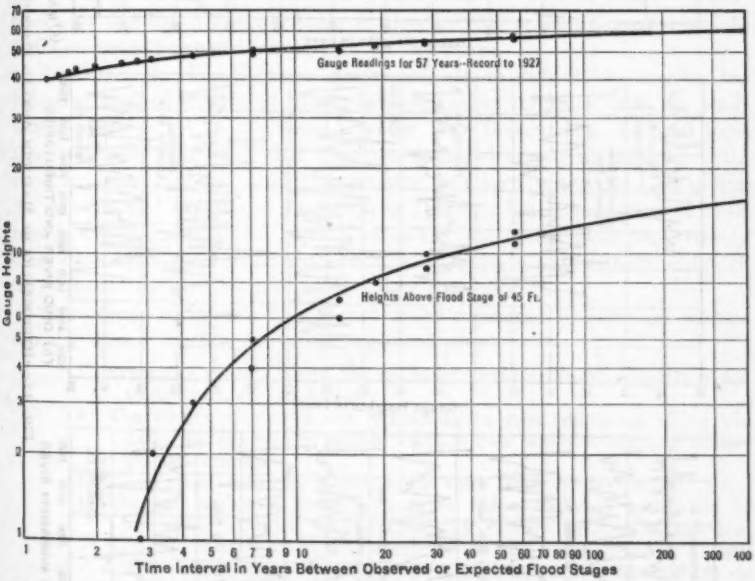

FIG. 44.—TIME INTERVAL, IN YEARS, BETWEEN OBSERVED OR EXPECTED FLOOD STAGES, ON THE MISSISSIPPI RIVER, AT RED RIVER LANDING, LA.

Maximum Annual Flood Heights.—Fig. 45(*a*) represents the maximum annual stages attained on important tributaries of the Mississippi. The unmistakable upward trend of the Illinois River, at Beardstown, has been observed with alarm for several years; this is also true of the Yazoo and other rivers under similar treatment.

* Discussion by C. S. Jarvis, M. Am. Soc. C. E., of paper entitled "Probability of Flood Flows," by F. G. Switzer, Assoc. M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., October, 1927, Papers and Discussions, p. 2027.

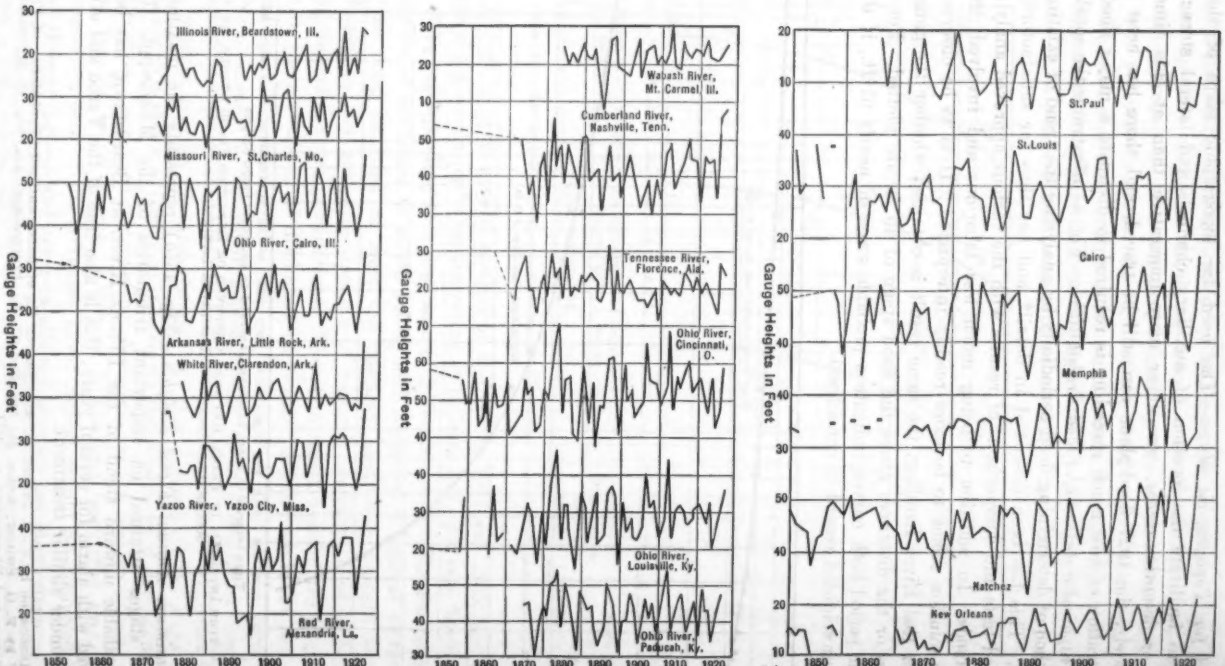

FIG. 45.—HYDROGRAPHS OF MAXIMUM ANNUAL FLOOD-STAGES.

Fig. 45(*b*) indicates that the Ohio River and its principal tributaries are gradually yielding to some form of restraint and regulation. Among these influences, not yet evaluated, but generally under-estimated, are channel improvements, detention basins, and numerous reservoirs operated solely for local protection or enterprise.

Fig. 45(*c*) displays the definite upward trend so characteristic of all Mississippi River stations between Cairo, Ill., and the Gulf. It also shows the neutral tendency at St. Louis, and the evident downward trend at St. Paul, Minn. There has been no progressive diminution of precipitation in this area throughout the period of record; the brief cycles of either sub-normal or excessive rainfall are readily traceable (Fig. 45(*c*)). The record of gaugings by current meter between 1866 and 1917 indicates that the cross-section has remained fairly constant, so that the diminution of flood crests at St. Paul means a decreased rate of discharge, not only apparent, but real. The effective lowering amounts to several feet during the past 50 years. Translated into discharge, this reduction is about 40 000 or 50 000 sec-ft., which, at Cairo, would represent nearly 1 ft. on the gauge.

Regulation by Head-Waters Reservoirs.—It is difficult to ascribe the reduction of flood heights at St. Paul to any other influence than the head-waters reservoir system established by the War Department. So well have these reservoirs functioned that observers doubt whether they have yet withstood a severe test. A similar impression has been entertained regarding the structures of the Miami Conservancy District; but examination of their records will prove that they have been called into action more than twenty times since 1922, and have averted material damage in that district, although the recent storms have attained only moderate severity.

This regulation of the flow is not to be measured by nominal storage capacity alone. Factors too often neglected are:

(1) Reservoir storage above the spillway level; ordinarily nearly equal to that which lies below.
(2) The effects of back-water, extending to great distances along the main valleys and retarding surface flow while promoting underground storage.
(3) Percolation into the lateral areas thus temporarily flooded.
(4) The soil moisture capacity reserved below the dam by reason of the delay afforded by the foregoing factors against inundation.
(5) The lag in movement of water outside the main channel, always subtracting from the flood crest and extending the period as well as the losses in transit.

Due to these factors, the actual retardation accomplished by a reservoir with an adequate spillway is a multiple of the apparent capacity. This has been demonstrated repeatedly on various streams, under conditions and control roughly simulating those of the laboratory.

Salvage of Fragmentary Records.—Investigators have been richly rewarded for applying the winnowing process to old records. The observations at Natchez, extending intermittently from 1770 to 1802, and each year thereafter, are outstanding examples. No doubt, there are other data to

be uncovered in the reports of the Chief of Engineers, U. S. Army; the Weather Bureau; the Geological Survey; State and municipal engineering departments; power and irrigation companies; and occasionally in private files or libraries.

A commendable spirit of co-operation in meeting the immediate demands of various governmental departments recently produced results far beyond original expectations. The foregoing illustrations are representative of a great mass of information hitherto unassembled, but reposing in hundreds of volumes, or in manuscript form.

To accomplish what is required in this broad field, some competent agency must be financed and set to work, with powers commensurate with its difficult task. After the records have been interpreted and co-ordinated their most essential elements should be reduced to graphic form and summarized in some convenient manner for each station, as has been shown on Fig 42.

The Flood-Control Problem Defined.—The problem of flood control is simplified by consideration of the relatively large volume for which provision has already been made in channels and in some form of storage. The relatively infrequent flood stage attained on large rivers, and the few days or weeks that it continues above the danger line, reduce the difficulties proportionately.

Definite, tangible, and positive control projects are needed immediately. These require popular support which cannot be had by antagonizing, but by recognizing, every commendable theory or movement. Therefore, every reasonable means of improving or maintaining soil structure, fertility, and vegetative covering, stabilizing drainage channels and reducing erosion, promoting the passage of surface water to soil storage, and allowing for its orderly release therefrom, should be encouraged as steps in the right direction. No matter how remote and indirect may be their influence, they benefit the locality; they enlist conscious support and sympathy; they combine free-will offerings with taxation toward a solution of America's foremost problem. They bear the same relation to effective flood control as do war-savings, abstinence, and speeding up of industry to the winning of a foreign campaign.

Checking of soil erosion in Alpine regions, for example, seems to be as imperative in Switzerland as the defense of the fatherland; or perhaps it is one means of defense which is worthy of adoption in other mountainous districts included in American problems.

Only one-fourth of the total rainfall appears as run-off in the Mississippi River. This is accommodated without material damage on an average of three years out of every four. The minor portion of the highest known flood is the destructive element, and that is susceptible of control.

Conclusions.—

1.—"The Mississippi needs more room", as aptly expressed by Col. George R. Spalding, Corps of Engineers, U. S. A., after conducting the campaign of rescue.

2.—Its control is a National problem and should be accomplished as the nation would repel an invasion.

3.—Wherever human life is at stake the protection should be positive and enduring. Where only inconvenience and slight damage would accrue from temporary flooding, this means should be encouraged and insured during emergencies such as the 1927 flood, as a means of dissipating the power of the flood. Such automatic relief is as essential to storage basins and river channels as are safety valves for steam boilers.

4.—Levees and other barriers as a first line of defense, assisted by reservoirs and regulating basins, auxiliary channels and spillways, additional outlets and diversion into adjacent drainage areas, all correlated, under intelligent supervision and control, must be utilized in any effective plan for the mastery of the Mississippi River.

EDWARD H. SCHULZ,* M. AM. SOC. C. E. (by letter).—The continued and heavy rains of the fall of 1926 and spring of 1927, brought about an extraordinary flood in the Mississippi River and its tributaries, from Rock Island, Ill., to the Gulf of Mexico. Rains were exceptionally severe on the watersheds of the Illinois, White, and Arkansas Rivers and in the valley below Cairo, Ill. There was much damage to property, much flooding of land, a large loss of farm animals and crops, and complete interruption of rail and highway traffic. Above all, there was acute suffering among the people, although fortunately not a heavy loss of life, thanks to the relief measures of the Red Cross, of the Army—the Quartermaster, Air Corps and Engineers—and of other Governmental agencies.

Protection Against Future Floods.—The Mississippi River Commission, with the approval of the Secretary of War and the President, was directed by the Chief of Engineers to prepare a revised plan of protection against a probable flood on the main river and its tributaries, as far as they are affected by the back-waters of the Mississippi River floods. Public hearings were held, and investigations of rainfall, gauge heights, and discharges have been made with a view of presenting a comprehensive report, a plan, and an estimate for the action of the Chief of Engineers, the Secretary of War, and for presentation by the President to Congress. Committees of the Commission and the District Engineers in charge of local work have studied and reported on auxiliary means of help, such as dredging, reservoir, diversions, and outlets, as well as on the general subject of levees, including greater free-board and larger sections.

Present Levee Jurisdiction.—The Commission's jurisdiction is limited by law, for levee and other protection work, to the Mississippi River below Rock Island, and the tributaries as far as they are affected by Mississippi River floods. The subject of a general survey of all tributaries, as well as of other rivers of the United States, covering floods, irrigation, water power, and navigation, was authorized by Congress, January 21, 1927, based on a report in House Document 308, 69th Congress, First Session.

* Col., Corps of Engrs., U. S. A.; Div. Engr., Lakes Div., U. S. A., Cleveland, Ohio.

Physical Characteristics.—The distances along the Mississippi River and the slopes at low water are as follows:

Rock Island, Ill., to mouth of Missouri River.....302 miles, slope 0.4 ft. per mile.
Mouth of Missouri River to Cairo, Ill.....209 " " 0.6 " " "
Cairo, Ill., to mouth of the Red River .....772 " " 0.35 " " "
Mouth of Red River to the Gulf .....309 " " 0.02 " " "

The alluvial valley begins about 52 miles above Cairo near Cape Girardeau, Mo. From this point to the Gulf the river flows in a valley varying from 20 miles in width near Natchez, Miss., to 80 miles near Greenville, Miss., the average being about 45 miles. Below Plaquemine, La., the valley merges into the fan-shaped delta with a radius of 60 to 100 miles.

Rock is found not far below the bed at St. Louis, Mo. From St. Louis to Cairo, the average depth to rock is about 92 ft., varying from near the bed to 130 ft. below. The general drop is 105 ft. in this distance. Below Cairo, the dip is rapid. No difficulties with rock would occur therefore in any river or flood improvement.

The Water-Shed.—The area of the whole Mississippi water-shed is 1 240 000 sq. miles, or about 41% of the United States. The extreme dimension in longitude is 1 900 miles, extending from the States of New York to Montana, and in latitude 1 400 miles, from Canada to the Gulf. Of the total area, 390 000 sq. miles are arid, 190 000 sq. miles, semi-arid, and 660 000 sq. miles are humid.

The distance from the head-waters of the Missouri to the Gulf is 4 200 miles, from Lake Itasca, 2 475 miles, and from the head-waters of the Ohio, 2 370 miles.

The six natural divisions of the drainage and normal rainfall are as given in Table 35.

TABLE 35.—THE MISSISSIPPI WATER-SHED.

Division.	Area, in square miles.	Ratio to entire basin.	Normal precipitation, in inches.
Upper Mississippi	165 900	0.13	30.9
Missouri River	527 100	0.43	20.7
Ohio River	201 700	0.16	44.2
Arkansas Basin	186 300	0.15	29.8
Red River	90 000	0.07	38.3
Central Valley	69 000	0.06	48.8
Total	1 240 000	1.00	30.1

It will be noted that the average rainfall is about 30 in. During March and April, 1927, 25 in. of rain fell, and in January to April as much as 35 in.

in some parts of the lower valley, more than 23 in. above the normal for those months.

The Delta Basin.—In general, floods on the Lower Mississippi occur from February to May, and low water from August to December. The delta area, normally subject to overflow (except for the levee system), is 29 790 sq. miles in extent. This is equal to about 19 000 000 acres, divided, as follows:

By States:	Square miles.
Illinois	65
Kentucky	175
Tennessee	453
Arkansas	4 652
Mississippi	6 926
Louisiana	14 695

By Basins or Districts:	Square miles.
St. Francis and miscellaneous in Illinois, Kentucky, and Tennessee	6 706
Yazoo	6 648
White	956
Tensas	5 370
Atchafalaya	6 085
Pontchartrain	2 001
Lafourche	2 024
Total	29 790

The flood of 1927 covered a great portion of these areas. The previous large floods occurred in 1828, 1844, 1858, 1862, 1882, 1883, 1893, 1897, 1903, 1912, 1913, and 1922.

Discharges and Gauge Heights.—The maximum discharge at Cairo for 1927, was 1 800 000 sec-ft., the actual height was 56.3 ft. on the gauge, and the confined height was estimated at 58.5 ft. The actual height at Vicksburg, Miss., in 1927, was 58.5 ft., which was 3.65 ft. above any previous flood, with a discharge of 2 278 000 sec-ft.—more than 20% greater than any previous flood.

Three waves passed Cairo in the last flood. The first was early in January with the Cumberland and Tennessee Rivers at high stage; the second early in February, with the Ohio River high; and the third in March and April, with the Upper Mississippi River high, and the Arkansas and White Rivers both at extraordinary stages.

In 1927, during maximum gauge at Cairo, the Ohio River contributed 814 000 sec-ft., whereas in 1913, it gave 1 395 000 sec-ft. One method of arriving at a future maximum flood has been to add the excess Ohio flow of 1913 to the Upper Mississippi flow of 1927. While this may be taken as the maximum possible, the maximum probable may be taken as somewhere between 2 150 000 and 2 250 000 sec-ft. at Cairo.

The average number of days of extreme flood heights is about 9 at St. Louis, 14 at Cairo, 13 at Memphis, Tenn., 19 near Arkansas City, Ark., 24 at Vicksburg, Miss., and about 25 at New Orleans, La. The number of days above ordinary high water is as much as five times this period.

The maximum discharge of the Missouri River is about 1 sec-ft. per sq. mile, that of the Ohio River is about 6½ sec-ft., and that of the Mississippi at Vicksburg, about 2.0 sec-ft. per sq. mile of water-shed.

The extreme range of gauge readings to date at Cairo and below, has been listed in Table 36.

The maximum flow at the latitude of Arkansas City in 1927 was 2 662 000 sec-ft., including overflow, and the actual discharge in the main river was 1 712 000 sec-ft. At Old River, the inflow was 2 010 000 sec-ft. and the outflow 1 461 000 sec-ft. in the main river, and 592 000 sec-ft. down the Atchafalaya River.

The 1927 flood was on the average 1.3 ft. higher from Cairo down, than the previous highest, or 1.7 ft. below levee grade. It exceeded the previous high gauge by 3.4 ft. at the mouth of White River, and was 2.2 ft. below the previous high at Cottonwood Point, Mo.

TABLE 36.—Range of Gauge Readings in Mississippi River.

Location.	Extreme low.	Extreme high.	Range, in feet.
Cairo, Ill.	−1.0	56.3	57.3
Memphis, Tenn.	−2 65	46.55	49.2
Arkansas City, Ark.	−3.6	60.55	64.15
Vicksburg, Miss.	− 6 5	58.5	65.0
Red River Landing, La.	−0.6	57.5	58.1
New Orleans (Carrollton), La.	−1.6	21.27	22.9

Since the Mississippi has no natural reservoirs, it is not surprising that there should be great variations in stage and flow, and that the river heights did exceed the previously expected maximums. The reservoir area of the Great Lakes gives the St. Lawrence a storage of more than 100 000 sq. miles. The Mississippi River has an average flow three times as large as the St. Lawrence, and a maximum flow nearly eight times as large.

The Levee System.—The present levee system had its beginning in the small mounds, about 2 ft. high, built at New Orleans as early as 1717. With each succeeding flood these small protections were built higher and took in more territory, so that gradually a levee system was created. This work was first done by private plantations, then by groups, and, finally, by levee districts and States. In 1859 the levee grade was only about 5 ft. above the banks. The United States as early as 1824 appropriated funds for river snagging, etc., and up to 1879, about $10 000 000 had been spent. It was not until 1879 that formal assistance on a large scale, both for levees and revetments, was given by the Federal Government.

At present, the levee system is about 1 815 miles long, of an average height of 17 ft., and about 472 000 000 cu. yd. in volume, which is about 260 000 cu. yd. per mile.

The expenditures to date (1927) have been as follows:

	Levees.	Revetment.	
United States.....	$71 000 000	$61 000 000	
Local co-operation	167 000 000	3 000 000	
Total	$238 000 000	$64 000 000	
Grand total			$302 000 000

The most recent authorization by the United States was in 1923, the project covering $60 000 000, of which about $30 000 000 had been spent at the beginning of the 1927 flood. The 1914 project was thus about 90% completed. The present local co-operation required by law is one-third of levee costs, and all right of way and maintenance. The United States constructs all revetment, except on tributaries, where local interests are required to co-operate.

The Mississippi River Commission.—This Commission was organized in 1879 to make complete surveys from the head-waters to the Gulf, and to prepare plans and execute works for navigation and protection against floods from Cairo to Head of Passes, La., including outlets, levees, closing chutes, bank revetment, and dredging. Jurisdiction was later extended to Rock Island, and to include tributaries in the flood back-water of the main river. The levee grade line established in 1914 was placed 3 ft. above the 1912 confined flood, the greatest to that time. The characteristics were: Free-board, 3 ft.; crown width, 8 ft.; river slope, 1 on 3; land slope, 1 on 3, to banquette, and 5 to 8 ft. below crown; and banquette, 20 to 40 ft. wide, with 1 on 10 slope and back slope 1 on 4.

Studies and plans are now being made to provide greater free-board, larger crown width, and flatter slopes. The new section would thus be much greater in volume for this average height.

Crevasses.—There were twelve principal localities where crevasses occurred. Counting the smaller breaks and those on tributaries, there were twenty-four all told under Commission plans. The first occurred at Dorena, Mo., 33 miles below Cairo, on April 16, 1927, and the last at McCrea, La., on the Atchafalaya River, on May 23. All breaks occurred on the right bank except two, one at Mound, Miss., on April 21, flooding Greenville, and the other at Caernarvon, La., on April 29, opened by the local interests to reduce the flood heights at New Orleans. There were heavy rains and high winds on April 20, with a rise of 1.1 ft., in 24 hours at Arkansas City. The Mound crevasse opened to ½ mile in 4 hours, and eventually flooded more than 700 000 acres, destroying many farm animals and flooding many towns. Mail placed in the street box at Greenville on April 24, was not delivered in Chicago for more than three weeks, showing the disruption of communication and transportation service. Four breaks occurred on the Arkansas River, and seven on the Bayou des Glaises and Atchafalaya Rivers. Many of the levees were not up to grade, nor under Commission jurisdiction. Some of them were undermined or cut by wave-wash and in spite of all the efforts of the local levee districts and

the United States District Engineers, they were overtopped or undermined and destroyed.

The flood has shown that protection must be given for greater floods, that levees in the geographical jurisdiction must be under Federal control, that the problem is National, and that participation by local interests must be made more liberal.

Caving Banks and Revetments.—The present average bank height is about 44 ft. above low water at Cairo, and about 45 ft. at Red River Landing, with an average slope down stream of 0.35 ft. per mile.

Caving banks are a notable characteristic of the lower river and can be prevented only by revetment. There are about 127 miles of revetment now built, consisting formerly of mattress and rip-rap, but more recently of concrete slab type. Several hundred miles of additional revetment will be needed. The cost is $300 000 to $400 000 per mile. The caving at times has equalled 1 000 000 cu. yd. per mile, in certain sections, the total amounting to 400 000 000 cu. yd. per year.

The lack of this revetment protection causes the need of expensive setbacks and relocations in the levee line, often costing more than $500 000 per year. At times, setbacks have a benefit of their own in providing more cross-section area for floods. Fixation of the bank line is an important part of regulation and flood control.

Suspended Matter (Sediment).—The amount of suspended matter present depends on the velocity, character of bed and banks, whirls, and eddies. It has been found to equal $\frac{1}{1\,500}$ of the discharge by weight and $\frac{1}{2\,000}$ by volume. There is also material rolled along the bed. The total quantity carried to the Gulf is estimated as equal to a volume of 1 sq. mile, 268 ft. high. The banks of the Southwest Pass have advanced at times at a rate of 1 mile in 20 years. The sediment deposited on the delta is estimated to average 0.01 in. in thickness annually.

Property Values and Damages.—The valuation of properties in the Delta Basin is estimated at $4 000 000 000 to $6 000 000 000; the damages of the 1927 flood at $200 000 000 to $400 000 000, of which $10 000 000 was physical injury to the railroads. The delta was overflowed over 50% of its area. More than 600 000 people were made homeless. The expense of the flood fight, for closing levee gaps and crevasses, and repairs, was more than $7 000 000. In addition, the levee districts spent more than $1 300 000 for the flood fight. The estimated cost of raising the wharves at New Orleans, and of right of way for necessary levee setbacks must also be considered. In addition, a thorough study of the economic considerations should be made at the earliest practicable date.

Future Protection.—Suggested remedies are control of drainage and contour plowing, reforestation, additional levee heights, dredging, reservoirs, outlets, diversions, and spillways.

Contour plowing and land drainage would give but meager help; they are impracticable because there is no law to enforce such a measure, and, as stated, the relief would be insignificant.

Reforestation should be done on its own merits. There is great need for such work. The benefit to flood control is problematic. An examination of the water-shed records in Minnesota shows that forests caused greater floods than cultivated land, but probably less than deforested scrub land or pasture. To include any forestation for flood control would require many years, even if the benefits were certain.

Any material raising of levee grades should be avoided, if possible. To hold in check the probable future flood would require a considerable raise unless auxiliary means can be used. These additional heights not only become very costly, but add a greater menace to the property and people behind the levees.

No particular change of the bed has been noted. If anything, there has been a lowering of 2 to 4 ft. between Cairo and Helena. The average depth of the thread of the stream at low water, taking both the pools and bars, is 31 ft. at Cairo, 48 ft. at Red River Landing, and 84 ft. at New Orleans. Dredging is necessary to maintain the present navigation project of 9 ft. by 250 ft. at all stages above Red River, and it costs about $600 000 per year. An enlarged channel width is advisable in view of the recent large increase in river traffic.

To dredge for flood control would require several hundred million cubic yards per year at an enormous cost. This would lower the bed only a few feet, and it would be filled again with the next flood.

Cut-offs would reduce the length of the river, but would increase the slope and velocity, and require new levees and revetments in the vicinity. On the whole, they would be a detriment to the river and are decidedly inadvisable.

At first thought, reservoirs seem to offer help. To be of real benefit, they should store water at least three months, from February to May; 1 000 000 acre-ft. of storage will hold back about 5 600 sec-ft. for 3 months, which is equivalent to about 1.07 in. of gauge on the main river. (About 60 000 sec-ft. corresponds to 1 ft. on the gauge.) Reservoirs are naturally divided into those above Cairo, those below Cairo, and those in the valley itself. To take care of 4 ft. of river height will require about 44 000 000 acre-ft. at a cost of more than $500 000 000. Additional storage becomes more expensive, since the most available and economical sites would be used first. The storage nearest the lower valley is the most advantageous, both in rainfall and in control. Storage for local flood control although simpler is nevertheless very expensive. The Dayton flood control, as an example, has cost $30 000 000.

In general, it is difficult and at times impractical, except at great cost, to use reservoirs as a direct means of flood control for the lower river. Where power is involved the benefits are necessarily divided, although still valuable especially to local flood control. Further study should be made of sites on the tributaries of the Lower Mississippi and of basin storage along the main valley below Cairo. Here, real benefits may be possible.

Outlets, diversions, and spillways seem the most promising remedies. A diversion channel from the main river near Arkansas City to the Red River is

possible, and an increased discharge is practicable through the Atchafalaya Outlet. Also, spillways are feasible above and below New Orleans. Any diversion above Arkansas City becomes much more expensive than the corresponding levee protection. The diversions mentioned will materially lower levee heights and will reduce the total cost over any plan without such diversions, in addition to giving greater security. It is reasonable and practicable that some solution based on revetment, on levees of proper section and free-board, and on diversion and outlets and possible reservoirs on the lower tributaries will secure the necessary protection.

Conclusions.—Complete protection against floods such as that of 1927, and of future probable floods, is vital to the security and prosperity of the Mississippi Valley. The business and transportation interests, not only of the valley, but of the nation itself, cannot be harassed by recurring floods. The cost of the protection may run into hundreds of millions of dollars. The economic conditions should be studied, and a comprehensive plan submitted, based not only on sound engineering, but on considerations of National obligation and of lasting benefit to the whole country.

Q. C. Ayres,* M. Am. Soc. C. E. (by letter).—Like many another engineer whose livelihood does not depend, directly or indirectly, upon the methods used in the control of the Mississippi River, but whose inclinations lie within the general field of hydrology and hydraulic engineering, the writer has read with intense interest the very valuable and illuminating papers contributed to the Flood Symposium. He recalls the many perplexing questions that assailed his mind in 1913, when he took part in the memorable high-water fight of that year at Greenville, Miss., and he notes that most of these questions still remain unanswered. Also, the many months of strenuous activity in connection with swamp surveys in the shadow of the mighty river are not forgotten.

An outstanding feature of this Symposium seems to be a sharp difference of opinion, accentuated to an extent not commensurate with the large amount of attention devoted to this subject in the past. A moderate degree of such variance is, of course, a normal, stimulating, and desirable thing, but it would seem that radical differences would have been ironed out before now. If the recognized leaders of the profession, both within and without the Mississippi River Commission, can not agree among themselves on fundamental conceptions of river control, how can they expect anything but exaggerated disagreement among the rank and file? And what can that breed but still more accentuated misunderstanding in the mind of the voting public? Since the Congressional mind is nothing more or less than a composite cross-section of public beliefs, inflamed by diverse political and partisan interests, it would seem that flood legislation in the past has been all that could have been reasonably expected. After all, under the American system of government, no matter how competent and ingenious an engineering body may become, any program that might be devised must be patterned to fit the specifications of purse-holding laymen.

* Associate Prof., Agricultural Eng. Dept., Iowa State Coll., Ames, Iowa.

It is the writer's belief that, when all the facts are considered, the record of the Mississippi River Commission in the judicious handling of a very difficult and many-sided problem will measure well up to the standards of contemporary engineering practice.

The writer particularly has in mind Mr. Morgan's paper. The case he makes against the Commission seems just a little bit too plausible. For example, he quotes the President of the Commission as having stated in 1912 that $73 000 000 was ample to do all the remaining necessary work on the levee system. This is no doubt a correct statement of majority opinion, but the writer happens to recall that the individual estimate of a civilian member of the Commission—C. H. West, M. Am. Soc. C. E.—at that time was $250 000 000.

This circumstance would seem to blunt the point of Mr. Morgan's sweeping denunciation on one score at least and leads to the belief that perhaps other scores would be similarly relieved of harshness if all the pertinent details were known. The impression of blind "ancestor worship" so artfully created by Mr. Morgan as the outstanding trait of the Commission personnel seems subject to discount on its face. Furthermore, it is an anachronism to state that the Commission failed to apply 1927 methods to the problems of the preceding century.

Happily, engineers are agreed upon one matter of transcending importance —the need for accurate and comprehensive data. It would seem almost self-evident that the first step in the solution of any scientific problem is the collection of adequate and indisputable facts; yet this basic phase of the Mississippi question has been undeniably neglected to a large extent, under pressure of restrictive legislation and limited funds. Lack of conclusive information doubtless explains in large measure the divergence of opinion so regrettably apparent, but for this, any indictment of the Mississippi River Commission must be leveled also at the entire profession.

There is reason to hope, however, that Congress will enact new legislation substantially in accord with the latest recommendations of the many agencies now at work on the problem. Facilities may thus be provided for the first time to gather a great mass of physical data, to enlarge the vision and diversify the engineering talent at the disposal of the Commission, and to enable many important controversial theories to be definitely proved or disproved. In such an event, the present moment may mark the end of a long period of pioneering with expedient disbursements, and the beginning of a new epoch more in keeping with the ideals of the profession.

H. S. Gladfelter,* M. Am. Soc. C. E. (by letter).—The paper by Major Godfrey is of much interest in presenting briefly, the extent of the development of modern transportation on the Mississippi River and the extent to which flood protection measures may be aids to navigation.

With the gradual building up of rail-transportation systems, running parallel to the Mississippi River, old-time steamboats gradually disappeared. These old steamboats had no regular schedules, and their rates were whatever

* Engr., U. S. Engr. Office, Memphis, Tenn.

the traffic would bear. They offered no insurance that freight entrusted to them would ever reach its destination. No adequate terminals were provided for the exchange or storage of freight after it was delivered. The designs of boats and their mechanical equipment did not change materially in the period from 1850 to 1900. In 1852, when steamboating was at its height, 3 100 boats docked in the Port of St. Louis, and the average load of these boats was only 26 tons.

Contrast this condition with that now existing. The Federal Barge Line operates 13 powerful boats that handle tows of 8 000 to 12 000 tons. These vessels are equipped with modern propellers and triple-expansion condensing engines. The American Barge Line (referred to as the W. C. Kelly Barge Line) with four high-powered Diesel towboats, handles tows of from 3 000 to 4 000 tons, and the giant stern-wheel towboat, *Sprague,* with modern machinery, having a power plant of exceptionally high efficiency, handles tows consisting of 224 000 bbl. of crude oil, or about 40 000 tons.

Major Godfrey refers to experiments now being conducted with pulverized coal as fuel on one of the boats of the Federal Barge Line. If these tests are successful a new field of cheap fuel will be available for use on the larger vessels. With high labor costs, it is essential, in the operation of river boats, that machinery of the most efficient type be adopted. The old days of inefficient machinery are gone.

The use of modern terminals with machinery for handling the freight is emphasized. Modern terminals have been erected in a number of cities from St. Paul, Minn., to New Orleans, La. These have car interchange facilities. In some cities even store-door delivery is attempted by motor truck, in order to compete with rail transportation. River transportation, to be successful, must give all that rail transportation offers and more.

Considerable interest has been taken in the statement in the message of President Coolidge to Congress that the Federal Barge Line, having demonstrated that it can make money, should be turned over to private interests as soon as possible. With the competition offered the railroads by water transportation interests, the question naturally arises, as to whether the railroad companies will be allowed to acquire control of the water transportation and, in order to protect their rail interests, gradually throttle the water transportation as was done in the past.

The earliest system of aids to navigation consisted of regulation works in the form of permeable dikes. These seem to have been effective for a short time in improving channel conditions, but due generally to insufficient funds, were not properly maintained, and, eventually, all the dikes failed. This system of regulation, if applied to the entire length of the river and properly maintained, would probably have resulted in good channel conditions, but the expense of maintaining a channel in this way would be very much greater than the cost of maintaining the dredged channel, adopted later.

The assistance offered to navigation by dredging, channel-marking, and channel charts, has been effective in providing a channel suitable for present requirements. Under this system, the commerce on the river has increased

rapidly. The constantly increasing volume of navigation and the economic size of tows will undoubtedly, in the future, demand a less restricted channel and one of greater depth and width. Dredging alone will not be effective in producing the required channel economically.

The plan of flood control of the Mississippi River presented by the Chief of Engineers to Congress recognizes the limitations of dredged channels and provides for a system of regulating works similar to that used successfully on the Mississippi River between St. Louis, and Cairo, Ill. This system of regulation would serve the dual purpose of bank protection and channel improvement.

With the work embraced in this flood-control plan, navigation interests are assured that channel conditions will be improved; and while flood control and improvement of navigation are entirely different problems, it will be found that many of the solutions of flood control will also be solutions for providing improved navigation.

Byron E. White,* M. Am. Soc. C. E. (by letter).—The excellent and authoritative papers presented on this subject have done much toward clarifying the atmosphere of uncertainty which has shrouded the Mississippi River problem. It is fortunate that it has been so fully treated, in its various phases, by eminently qualified engineers.

A careful reading of all the literature bearing on the question, leads to the conclusion that there is no escape from the construction of levees along the lower river, as the main line of defense against floods. It is also quite clear that the raising of levees to greater heights cannot go on indefinitely. Some auxiliary means, therefore, must be adopted to care for the excess flood waters, beyond the safe capacity of the channel formed between the levees.

The only means which has been more or less generally accepted as practicable are spillways and auxiliary flood channels. This is the plan so well described and advocated by Mr. Garsaud. The greatest objection raised to spillways is the formation of bars or shoals down stream therefrom in the main river channel and the resulting reduction in carrying capacity, etc. If such spillways are controlled, so that the flow in the river down stream may be kept at a safe height below the tops of the levees, and only the excess water diverted, such shoaling should be effectually prevented. Colonel Kutz states his belief that such will be the case.

Such spillways or sluice-ways (as they may properly be called) will be of unprecedented dimensions and capacity, but, otherwise, not unlike hundreds of similar structures. They should present no unusual difficulties in construction or operation. Their proper use should be of great assistance in maintaining the main river channel during and after floods and minimizing the work necessary to maintain navigation channels after a flood has subsided.

Any doubts as to the proper arrangement, location, and performance of such controlled spillways could be rather quickly, cheaply, and easily proved or dispelled by carefully conducted tests of models in a hydraulic laboratory, such as has been so strongly urged by John R. Freeman, Past-President,

* Gen. Engr., Utica Gas & Elec. Co., Utica, N. Y.

Am. Soc. C. E. Many other detail problems of levee construction, control of erosion, and channel control could be studied in such a laboratory. Such immense sums of money spent in construction, and such vast interests, both financial and human, are involved in the success or failure of the plans and structures necessary to control the destructiveness of floods, that the relatively small cost of model tests fades into insignificance when the certainty of results and other advantages are weighed against it. The study of these problems in a laboratory should do much to popularize model testing among engineers and executives and aid immensely in putting American design and construction work on a more sound and satisfactory basis, especially where novel designs are involved.

While this may cause some delay in the preparation of final plans and the execution of the work, the certainty of results should more than compensate for it, especially if the existing levees and other structures are promptly repaired and made ready for service before the next flood season. It would be almost criminally wasteful to embark on a radical change in plan, without first making sure of its efficacy in detail. Unless there is a real threat to the stability of the levees, the writer is also strongly in favor of the construction of wide, paved highways along them, for ease of access, inspection, and repair.

Much doubt as to the feasibility of reservoir control as a means of preventing, or even materially reducing the height of floods in the lower valley is expressed by practically all who are familiar with the river. The physical dimensions of a dam which would impound the requisite volume of water might be very great, without exceeding the value of a large regulating capacity. Hence, it is just possible, even if a little improbable, that, on account of the great length of dam which would be involved, some feasible site may have been overlooked in all the investigations made thus far. Another search for such sites may well be in order, before definitely abandoning all idea of partial control by means of reservoirs.

In view of the assertion that only a relatively small part of the lower valley has been topographically mapped, it is not difficult to conceive that some, perhaps several, feasible dam and reservoir sites may have escaped proper attention. A survey by the rapid methods of the U. S. Geological Survey, covering those areas which hold forth any promise, would give quick results and disclose any sites, worthy of further and more detailed investigation. It is, of course, possible that such studies have been made and that there are no potential dam sites which are not known and have not been studied, but the discussion has not shown this to be the case.

The almost infinitesimal effect of reservoirs located on the Upper Mississippi and Ohio Rivers on flood heights at Cairo, Ill., cited by Colonel Kelly, may seem astonishingly small, yet they are probably not far from the truth. Therefore, any effective reservoir control must be located (as stated by some of the authors) much closer to the region to be protected and must store vast quantities of water and cover immense areas of land. Whether such areas exist, and whether they are of small enough property value to warrant their use for this purpose, does not appear to have been authoritatively stated.

The study of reservoir possibilities referred to by Colonel Kelly does not offer much encouragement for the hope that economical reservoir sites, effective for flood control, may exist in or near the lower valley. It is, of course, possible that in the haste with which the investigations and report had to be made, something of value has escaped attention or has not been properly investigated or evaluated. The case should not be considered closed until every possibility has been completely studied and its value deliberately weighed.

Reforestation has also been frequently advocated as a means of reducing the height of floods on the Lower Mississippi and elsewhere. It is generally recognized that forest cover is quite effective in limiting or preventing soil erosion, as well as helping to retain the water absorbed by the soil. Record floods, such as that of 1927, are the result of prolonged, intense rainfalls, and often (although probably not in this case) the rapidity of run-off is augmented by frozen ground. Under these conditions the effect of forest cover on holding back the water must be very small, especially when the ground is already thoroughly saturated, as was the case in 1927.

The work, time, and expense involved in reforesting, say, 20% of the total drainage area (1 250 000 sq. miles) of the Mississippi, or 250 000 sq. miles, are enormous. At the rate of 1 200 trees per acre, there would be required 192 000 000 000 trees and the cost would be from $1 500 000 000 to $2 000 000 000.

It is hardly possible that a much greater area, aside from that already forested, could be devoted to that purpose, without encroaching on lands which are more suitable for agriculture and grazing. When the percentage of the total area available for reforestation is taken into account, together with its inability to greatly limit run-off under exceptional conditions, this does not appear to offer much encouragement as a means of flood control. Since the effect of such reforestation as may be practicable will not be great, it would be advisable to consider it as another line of defense against the possible maximum flood.

These remarks must not be misconstrued as opposing reforestation. The immense value of an adequate timber supply, about 30 to 50 years hence, is of itself sufficient reason for encouraging the reforestation of all areas where trees can be grown, as a crop, to better advantage than anything else. The comparatively small benefit of forests as a means of flood prevention, the percentage of the drainage area available for forest planting, and the length of time and the difficulty of getting an effective reforestation program started and carried to completion, all rule it out as an immediate or major factor in this situation.

The events of 1927 emphasize the desirability and, indeed, the necessity for placing the planning and supervision of the construction of all works for the control of the Lower Mississippi in the hands of a single agency of the United States Government. Further, in order to stem the rising tide of paternalism and the reliance on the Federal Government in all kinds of major projects involving local benefits, the States, cities, and business interests should be required to shoulder a reasonable portion of the costs. To do other-

wise will constitute a precedent which will be used as an argument in unnumbered future (as well as present) projects. Once the principle of local sharing of costs is abandoned, there will be no end to the calls for contributions from the Federal Treasury to do that which is the duty of individuals, communities, and States. While the nation should help, where navigation and national interests are involved, its generosity should not be imposed upon. The loaning of the credit of the nation in an emergency is a different matter.

In regard to Mr. Scheidenhelm's excellent paper, on "Power as Affecting Flood Control", there are a number of points which might well be amplified.

In the face of the already low and constantly declining cost of fuel-generated energy, the value of stored water for power generation is so small that, unless the cost per unit of volume is exceptionally low, storage reservoirs, exclusively for that purpose, are not economically feasible; that is, unless there exists a large aggregated head down stream from them, which it is economical to develop for power production. In the usual case, this means that, unless the available head, or fall, below the reservoir site amounts to several hundred feet, the cost of the reservoir may be prohibitive. This fact eliminates many apparently promising streams from consideration as power producers. As steam power costs go lower (and further economies are constantly being effected), this effect will be greater and will continue to narrow the choice of streams on which economical hydro-electric plants may be constructed.

In the many cases where suitable reservoir sites are found above large available heads, the head at the reservoir dam itself will usually be found to be a small part of the total involved. If generating equipment is connected to the outlet conduits, in many cases, it will be a producer of secondary energy, only, as and when water and a suitable head are available. When such an installation is a part of a large interconnected system, this arrangement is usually entirely feasible and practical, provided the costs are not too great.

In favorable locations, an additional head, immediately down stream from the storage dam, may often be combined with that at the dam by extending the outlet conduit down stream. When this additional head is equal to, or in excess of, that at the dam, power and energy, with properly designed equipment, may be generated from any water released, down to the practical drawdown level in the reservoir.

In this as well as in the other case, previously described, a firm value can only be attached to such power and the corresponding energy, as is produced from the minimum quantity of water released from the reservoir, either continuously, or at all times when firm or dependable capacity is required. If, at any time when firm power is needed, water cannot be released, or the head is so low that no power may be produced, then the connected power plant will have no firm capacity value. The value of such a plant when incapable of producing firm power and energy is much reduced, because it must be based on the value of secondary, or intermittent, energy only. Where steam or fuel-generating plants are connected to the system, the upper limit of this value is the cost of fuel per kilowatt-hour, plus the additional labor and other charges caused by operating the steam plant, less the cost of trans-

mission to the market which would otherwise be supplied by steam power or other alternative source. In many cases there are other conditions or costs which still further reduce the value of the available power and energy.

In the case of reservoirs, where such additional head is not available, and it is desired to draw the water as low as practicable, the installation of a power plant is only justified when the intermittent supply of energy has a value sufficient to pay the charges on the plant, plus a reasonable profit. In such cases, therefore, the installation and operating costs must usually be exceedingly low, if the plant is to be justified. Herein lies the best reason why power plants are not usually found at the foot of storage dams.

Where storage for flood control and storage for power are sought to be combined in a single reservoir, the flood-control requirement will usually intensify the conditions unfavorable to power generation at the foot of the dam; and where additional head is available immediately below, it will, of course, operate to reduce the power and energy output, and, consequently, the value of a connected hydro-electric plant. Also, where both flood control and storage for power are combined in the same reservoir it is sometimes, although not frequently, possible to increase the height of the dam and utilize the upper portion, where the proportion of volume to depth is greatest, for flood control. If, in this, as in the preceding case, the contemplated total drawdown of the reservoir is too great a part of the total head available, the head will finally become so small that no power can be generated. The value as a power site is then greatly reduced, if not altogether wiped out.

Many of the reservoirs at the head-waters of the Mississippi, the Ohio, and other tributaries of the Mississippi, will be beneficial to power development, especially those in the mountainous regions. They will also exert some slight effect on floor reduction in the lower valley, as described by Colonel Kelly. Those lower reservoir sites, which would exert the greatest influence on flood control along the lower river, will be practically, if not entirely, useless for the production of power. It is unlikely that basins will be found at proper locations, the capacity of which will be sufficient to accomplish completely the desired purpose, even if designed as retarding reservoirs, like the Miami Conservancy District structures. It will be essential, therefore, to empty them as rapidly as possible, after each filling, in readiness for the next flood. The head, therefore, will be extremely variable, and power will be available only at long intervals, and for short periods of time. Hence, there is slight possibility that power will be a by-product of their construction.

Favorable effects of reservoirs on flood heights are, of course, most noticeable immediately below the dam, and it is possible that the sequence of arrival of flood crests from different tributaries at some point down stream, as, for instance, at Cairo, may be such that the flattening and lengthening of the flood peak above the crest of a storage dam may have unfavorable results far down stream. Hence, reservoir control at distant points does not have the beneficial effect that the same capacity would have, if concentrated near the point where its effects are most desired.

The recent development of large interconnected power systems has made it feasible and economical in many cases to utilize the intermittent power and energy available at the foot of reservoir dams, when conditions for them are favorable, and when within a reasonable distance of existing transmission systems and markets. Interconnection on a large scale has also made it economically possible to combine storage for flood control and for power in many instances, where it would otherwise be uneconomical for either purpose alone. Where such cases exist, the just allocation of costs between these uses is a matter of great importance in order that neither interest may be unjustly treated or taxed. The proportion of the cost which power interests can afford to pay is strictly limited by economic conditions. Expert engineering, legal, and business advice, as well as a sense of fairness and open-mindedness, are, therefore, essential in dealing with such a problem. With such an approach, a reasonably harmonious compromise of the conflicting interests of storage for power and flood control, may often be reached, to the benefit of all interested parties.

The degree of conflict between the requirements of storage for power and for flood control, are proportionate to the relative extent of stream-flow regulation which may be effected by the reservoir or system of reservoirs in question. If complete, or nearly complete, regulation may be attained, the interests need not seriously clash. It then becomes merely a matter of draining the reservoirs well down in advance of the usual flood seasons. From this case to that of the relatively small reservoir effecting little regulation, the interests become more diverse. Nevertheless, large benefits may usually be obtained by both interests, by the exercise of fairness and common sense. Here, the connection of the power plant or plants to a large interconnecting system may likely be the saving grace which makes the generation of power at all practical and economical.

In general, the writer believes that while the requirements of power and flood control in a reservoir are more or less at variance, unless the necessities of one or both are decidedly fixed, both may be reasonably well accommodated, to the economic benefit of the community and the interests involved. A factor of equal and prime importance, which seems to be often overlooked or forgotten in some current discussions, is the existence of a satisfactory market, capable of absorbing the output in a reasonable time after the supply becomes available. If the anticipated absorption runs into too long a period of time, the interest and carrying charges on the unutilized portion of the investment, which must be added to the capital account, may make the ultimate cost altogether too high. If an adequate and fairly immediate market is not assured beyond a reasonable doubt, there is no justification for the construction of the project; and again, beyond a doubt, the output must compete in cost and dependability, with the other available sources of supply.

In the pressure for reservoir construction, it is often assumed that hydroelectric power supplies will be created which will assume a large proportion or all of the costs. It is sometimes asserted, also, that desirable reservoir or power sites are being allowed to lie dormant for ulterior reasons. It is well

to bear in mind at all times that, with few exceptions, every existing market is adequately supplied, and will continue to be well supplied, up to the moment when the output of a new development becomes available, barring unexpected and unusually large demands. The ancient law of supply and demand, coupled with good business and engineering judgment, may be depended upon to bring about the development of the most economical potential source of available supply.

There are projects of such magnitude, or remoteness from any adequate present market, that any corporation or other authority may well hesitate to embark on their immediate development and the assumption of the annually mounting carrying charges which must accrue before their entire output is successfully marketed. These facts and factors, affecting each project, must be carefully and conscientiously weighed before arriving at a final decision, or the results may be unhappy, if not disastrous.

W. G. PRICE,* M. AM. SOC. C. E. (by letter).—The Mississippi is a river burdened with clay and sand that has flowed in from its tributaries during the ages, to build land in an arm of the Gulf of Mexico.

Until Man began building levees much of the clay and sand was annually spread over the land which the river had built, and which was thus being continually raised. The river developed a channel sufficient to carry only its normal flow of water. Then Man built levees to stop the flood water from spreading over and further building up the land; and these levees, in order to be efficient, had to be high enough to carry all the water of the greatest floods, which is impossible. The engineers in charge reasoned that when the river was confined between levees the increased power of the resulting swifter current would erode and enlarge the channel and increase the carrying capacity so that the height of the levees need not be extended. This reasoning has been proved false.

In 1879 and 1880, during the low-water season, the writer measured, for the Mississippi River Commission, the sand waves in the river at Plum Point and Fulton, Tenn. Many of these waves, which closely followed each other at Plum Point (where the river was very wide and shallow) and at Fulton (where the river was narrower and deep) were as high as 10 ft., with a long slope on the up-stream side, and they moved toward the Gulf many feet each day.

A large quantity of sand was repeatedly caught in a trap bucket more than 5 ft. above the bottom of the river. The writer also measured the large quantity of silt and sand caught at the surface in the almost continuous boils (which are caused by the river running over the sand waves) in the Lower Ohio and Mississippi Rivers.

At Fulton, where the river was very deep, the many streaks of boiling water, spaced apart (which indicated the location of the crests of the sand waves and their stream lengths), could be seen extending nearly across the river. These data indicated that the scouring and material-carrying power of the Mississippi is very great at low water and immensely greater during floods when the river is confined between levees.

* Cons. Engr., Yakima, Wash. Mr. Price died on July 6, 1928.

Cross-sections of the Mississippi were made at many places in 1879 and 1880, and these, when compared with sections made since, indicate that the river bed is neither rising nor falling. These data also indicate that the quantity of heavy material being carried in by the tributaries and the quantity supplied by the caving banks are equal to that being dredged and carried out to the Gulf.

The river, by wandering about and digging away its banks as well as some of its levees, is now carrying to the Gulf an immense amount of material which it deposited and stored during past ages. The data also indicate that, if the river were stopped from wandering about, and thus scouring material from its banks, the present rate of erosion along the bottom would soon lower its channel and the heights of its floods.

There are only four ways that can be used to control floods in the Mississippi; these are, by the construction of levees, by-passes, spillways (also called outlets), and bank protection to cause the river to dig its bed deeper. Along the river from Cairo, Ill., to the mouth of the Arkansas, levees have failed and they will not give safe protection if built higher. The land has a downward slope away from the river and the flood currents are continually eroding the bank and following down this slope and, therefore, the new levees must be higher.

In this reach neither by-passes nor spillways should be located, therefore, the engineer is limited to the use of bank-protection works. Since 1883 much bank revetment has been constructed by the engineers in charge of this work and it has been destroyed wherever the swift current ran against it.

Practically all these bank-protection works have been of one type, which indicates that the engineers have been unable during forty-four years to produce new or better plans, but have continued to spend appropriations for the construction of worthless designs. The writer's experience in building a different type of durable revetment in the Mississippi indicates that works can be built to protect the present banks and also those against which the swift current from a cut-off would run.

There are several loops in the river where cut-offs can be made, thus creating an increase in the velocity and power to dig the bed deeper.

From the mouth of the Arkansas to the mouth of the Red River, a by-pass through the Tensas would carry enough of a great flood so that the levees along this reach of the Mississippi need not be excessively high and bank-protection works would not be needed, except to protect property and to avoid the continual expense of building new levees. This by-pass should take only the quantity of water required to keep the flood height safely below the top of the levees in the Mississippi; otherwise, it would defeat its object by causing the cross-section of the river to become smaller. It will really be an outlet since its waters will not return to the Mississippi. The by-pass will not close itself. It will form the size of its channel to correspond with the amount of flood water it has to carry, which is the law of all streams in material that is easily eroded.

If the Mississippi were permitted to choose its own route from the mouth of the Red River to the Gulf, it would go by way of the Atchafalaya; but for

commercial reasons and to avoid the flooding of valuable plantations along the latter river, this outlet must continue to take only the water that its channel can safely carry with its levees remaining at the present height.

No spillway should be permitted to take water from the Mississippi between the Red River and the Gulf when the water is below the safe flood height. If the spillway is permitted to flow when the river is lower, the section of the channel and the discharge capacity of the river below the spillway will be reduced by a fill and the spillway will not reduce future floods.

Sufficient water should be permitted to flow to the Gulf by way of the Atchafalaya or Vermilion Bay spillways, or by both, as proposed by Mr. J. P. Kemper,* to render spillways into Lake Pontchartrain unnecessary. A wide shallow spillway should be provided below New Orleans, La. This spillway should not lower the flood in the Mississippi enough to cause a fill in the river below the spillway; otherwise, the flood-lowering effect of the spillway at New Orleans would be eliminated. A river, in an alluvial land automatically digs or fills its channel to a size proportional to the quantity of water ordinarily flowing through it, and it will dig somewhat deeper if its outside curved banks are prevented from caving.

The writer is not familiar with the land through which Mr. Kemper's proposed Vermilion Bay outlet would flow. If it is to be opened, work on it should begin without delay to avoid another disastrous flood in Lower Louisiana. The Tensas and Poydras spillways can be opened quickly when another great flood is approaching.

In prehistoric times, the Red River was not connected with the Mississippi. It flowed to the Gulf by way of what is now the Atchafalaya. Great dams, or what were called rafts by steamboat men, were formed in the Red River and one in the Atchafalaya, above Melville, La. About 1875, the State of Louisiana removed these rafts, but did not make a good job of it, because later two steam tug propellers were broken while trying to pass through the Atchafalaya raft. These rafts were formed of great trees which had caved into the river. Their roots were buried in the bottom of the river and their upper ends were spears, pointing down stream and thus menacing the approach of steamboats. Forty years ago (1888) the remains of these rafts in sharp bends in the Red River, the writer noticed, were efficient bank revetments. The Red River, in prehistoric times, having clogged itself by a raft in the Atchafalaya, cut through into the Mississippi and, later, the Mississippi made a cut-off and thus formed Turnbull Island.

The combined outlet of the Atchafalaya and Vermilion must carry the excess of bank-full stage that can safely be permitted in the Mississippi. The Vermilion outlet should have a wide, shallow opening at its upper end so that it cannot take water from the Mississippi below that level, except that it should have a narrow canal deep enough for navigation. This outlet has a slope much greater than that of the Mississippi and, if not controlled, will become the great river, while the Mississippi with its lesser slope, will become a bayou, with a sand-bar filling its channel near Red River Landing.

* In a report to the National Flood Commission, entitled "Plan for Control in the Mississippi Valley," by J. P. Kemper, August, 1927, New Orleans, La.

OREN REED,* ASSOC. M. AM. SOC. C. E. (by letter).—This Symposium is the most thorough discussion of the Mississippi River flood control problem that has been published in recent years. The papers were prepared by engineers who have given many years of labor and thought to the control of a mighty river. An exceptional flood has given a full test to the measures of control that have been attempted.

The people of a vast fertile area are asking for relief and protection from flood damage. The country as a whole has at last realized the magnitude of the problem and is in the mood to demand the application of effective remedies for the control of floods in the Mississippi area. It is, in a measure, unfortunate that the engineering features of the problem could not have been more fully decided before Congressional action was started. It is generally admitted that the Mississippi River Commission has made good use of the funds available. Experience has shown that the use of levees has been well justified. However, for physical and economic reasons, levees probably should not be trusted to carry the maximum possible flood which might occur below Cairo, Ill. Reservoirs, spillways, and by-passes should all be studied and used where feasible.

Shortly after the Mississippi flood of 1927, a part of the Duchy of Liechtenstein was covered by the flood waters of the Upper Rhine River. Certain problems developed which were similar to those presented by the Mississippi flood. This Duchy is in the northeast foot-hills of the Alps, and the river at this point has a moderate slope and is bordered by a flood-plain of considerable width.

Levee construction was started about 100 years ago. Since the channel has been fixed between two parallel levees, the stream bed has risen because of the flat gradient and heavy load of débris carried by the stream. In places, the present stream bed is 23 to 29.5 ft. above the land on both sides. At Buchs, where the first crevasse occurred, the stream bed has been raised 11.4 ft. since 1848. Corrective work had been done in recent years in an endeavor to stabilize the channel at its present elevation.

Below Liechtenstein, the Rhine flows into Lake Constance. Above the lake there are two levees on both sides. The low-water channel is confined by a low levee, and the flood levee is set back far enough to give ample floodway. This system of levees is favored because the narrow low-water channel prevents the dropping of the silt and débris load.

The growing danger at Buchs due to the raising of the channel bed was fully understood. The levee on the Swiss side had been raised 1 m. (3.28 ft.) in 1926, and work had been started on the Liechtenstein shore. Two bridges crossed the Rhine at Buchs, a wooden highway bridge and a steel trussed railway bridge. These bridges had not been raised at the time of the flood.

The head-waters of the river were swollen by a severe two-day storm in the last days of September, 1927. At some places, precipitation equalled nearly 7 in. in 2 days. This is, however, not the greatest precipitation on record in Eastern Switzerland. The 2-day precipitation in 1868 at Barhardin

* Asst. Designing Engr., San Joaquin Light & Power Corporation, Fresno, Calif.

Pass was 18.4 in. In 1910, the rainfall was also more intense than in 1927 and covered a greater area.

The quantity of water carried by the Rhine above Lake Constance on September 25 and 26, 1927, was the greatest yet observed. At Buchs, the flood became dammed by the bridges, broke down the weaker highway bridge, and overflowed the Liechtenstein levee above the railroad bridge. When the crevasse occurred, the Swiss levee still had a free-board of 1.3 ft. The break widened quickly, so that a large part of the flood water flowed into the adjacent lowlands. After the high stage was passed, the full flow of the Rhine ran unchecked into the flood-plain, leaving the old river bed dry. The flood waters ran back into the Rhine near the mouth of the Ill River about 10 miles below the break at Buchs. The land side of the levee was washed by the flood waters, thereby causing three secondary breaks.

The influence of the flood on the level of Lake Constance produced no serious results. If a part of the flood had not been held back in the Rhine flood-plain, the level of Lake Constance would have been raised about 10 ft. The maximum discharge from Lake Constance was about 141 000 cu. ft. per sec., which was slightly less than in 1910.

It is planned to organize an international commission for the control of the Rhine from the source to Lake Constance and transfer all fees and facilities for river control to this body. A comprehensive plan can then be formulated, which will not be dependent on political boundaries. It is proposed to regulate the mountain torrents so that a large part of the débris will be retained by check dams.

HAROLD C. FISKE,* M. AM. SOC. C. E. (by letter).—Reservoirs have been created to store water for power purposes and they have been proposed and built for the storage of surplus water at times of flood. It now seems to be taken for granted by many that these two uses are necessarily antagonistic, and that if the reservoir is operated successfully for one purpose it will be a failure for the other. Furthermore, it is frequently concluded that the flood reservoir must be totally emptied immediately after local danger has passed, by discharging at the maximum rate which the channel below will carry. The large volume of water thus sent down stream will meet a flood wave in some section below and will increase instead of diminish the flood risks at and below that point.

Mr. Scheidenhelm has done a very valuable service in bringing up for further and more careful consideration the assumptions on which these conclusions are based. Very properly, he points out that Nature has given a perfect example of exactly the opposite argument in the Great Lakes, where the requirements of both flood prevention and power development are met to an ideal degree. Of course, this well-known example is commonly dismissed at once by comparing the size of the Great Lakes with that of any artificial reservoir that has been or could be constructed by Man, with the value of the territory that would have to be submerged to duplicate the lakes, etc.

What Nature seems to be suggesting is the value of studying her methods and of determining how far Man can go in any given case, not necessarily

* Lt. Col., Corps of Engrs., U. S. A., Fort Lawton, Seattle, Wash.

in duplicating her dimensions, but in securing her results. Since Man cannot hope to match her in all respects he seems sometimes to forget that flood damage may, in general, be prevented by the storage of a part of the excess flow. He forgets, also, that there is some chance to release this storage, not blindly the moment local conditions permit, but after a longer interval. It is clearly impossible to state a fixed rule that will solve this problem to the satisfaction of both flood and power interests under all conceivable conditions, but if each particular case is studied carefully on its individual merits it would seem reasonable to hope that in a certain percentage of instances a solution would be found that was satisfactory to all concerned.

As an example may be cited certain features of the survey of the Tennessee River and its tributaries, authorized by Congress in 1922 and on which a final report is expected early in 1928.* This survey is to cover the water resources of the Tennessee Basin and to include full consideration of the needs of navigation, power, flood control, and other allied topics.

One of the many different sections to be studied was the basin of a large tributary, the Clinch River. On this, prior to the survey, private power interests had in mind the construction of a dam 175 ft. high which would create the largest feasible reservoir for power purposes. The correct installation was found to be about 160 000 h.p. In studying this section the survey, in addition to power, gave careful consideration to the needs of flood control, navigation, etc. It may also be stated that due attention was given to all items of cost and to all sources of profit.

It was found that below this storage dam six other run-of-river plants were indicated in the next 250 miles, three on the Clinch River and three on the Tennessee River above the existing Hales Bar Dam. By diminishing or shutting off the flow from the Clinch storage during flood seasons the tendency to drown out the three Tennessee plants was reduced and their efficiency at such times was increased. By including in one unit the Clinch storage, the Clinch run-of-river plants, the three run-of-river plants above Hales Bar, the Hales Bar plant, and the plants at Muscle Shoals, there was obtained a development of tremendous size. Its value was greatly augmented by the volume which could be released at low water from the Clinch storage. At flood seasons discharge from the Clinch storage could be diminished or stopped, leaving only the Tennessee River plants in operation. Since the Tennessee would then be at a high stage there would still be ample flow for these plants to operate at full capacity, and the result was substantially the same as that obtained at low water with the entire system operating under the increased flow from the Clinch storage.

As for the flood situation, there were available the daily flow records for a period of twenty years, together with incomplete records going still farther back. No attempt was made to discuss or solve hypothetical conditions, but for each day of this 20-year period the output of power and the daily height of the water in the reservoir were determined. This period included one disastrous flood and several that did material damage at Chattanooga, Tenn., about 250 miles below the storage. For one short period, water flowed over the crest of the dam but, as far as floods are concerned, the quantity was

* This report was presented to Congress in December, 1927.

negligible. For the remainder of the time the discharge was controlled, and at all times the Clinch River was eliminated as a material factor in Tennessee floods. The height of the storage dam was increased from 175 to 225 ft.

To show the change in technical and general public opinion in this connection a few quotations from official documents may be convincing. House of Representatives Document No. 319* sets forth conditions as they were known before the survey was authorized. House of Representatives Document No. 463† contains a partial report on the survey and outlines some of the information obtained to that time. Referring to the Clinch storage, Document No. 319 gives the following (in terms of installed capacity):

Dam No. 3 (storage)	160 000 h.p.
Dam No. 21	80 000 "
Total	240 000 h.p.

In reference to the same section, Document No. 463 gives the following (also, in terms of installed capacity):

Cove Creek (storage)	200 000 h.p.
Clinton	15 000 "
Melton Hill	60 000 "
Kingston	50 000 "
Total	325 000 h.p.

From this it will be noted that, on this section of the Clinch River, combined navigation, power, and flood studies increased the apparent power possibilities by more than 33⅓% in addition to other flood and navigation benefits.

Reporting on the Tennessee River above Chattanooga and its possibilities for run-of-river plants, Document No. 319 gives the following (in terms of installed capacity):

Dam No. 29	36 000 h.p.
Dam No. 30	58 000 "
Total	94 000 h.p.

In addition, it states, "in the entire stretch of the river between Knoxville and Chattanooga, 188 miles long, there appear to be no other favorable power sites."

Concerning the same section, Document No. 463 gives the following:

Coulter Shoals	75 000 h.p.
Marble Bluff	70 000 "
White Creek	150 000 "
Soddy	150 000 "
Sherman	45 000 "
Total	490 000 h.p.

* 67th Cong., 2d Session, pub. in May, 1922.
† 69th Cong., 1st Session, pub. in June, 1926.

From this it will be noted that on this section of the Tennessee combined navigation, power, and flood studies increased the apparent power possibilities by more than 400%, in addition to the other important flood and navigation benefits. It developed, for power, the entire head between Knoxville, Tenn., and Chattanooga.

Prior to the survey, power companies were interested only in Dams No. 3 and No. 21 (Document No. 319 list) on the Clinch River, and this interest was largely academic. When Document No. 463 was published, power companies had already filed with the Federal Power Commission applications for preliminary permits for the nine sites listed for both the Clinch and Tennessee Rivers, as well as for others.

In conclusion, it is submitted that the effect of combined power and flood use of storage should never be prejudged, but each case should be investigated carefully and judged strictly on its merits.

CHARLES F. BROOKS,* ESQ. (by letter).—Dr. Frankenfield presents the average rainfall by water-sheds in the Mississippi Basin and details the rainfalls by months prior to some of the great floods. Comparing 1927 with 1922, he indicates that the first four months of both years had about the same excess of rainfall, but that the greater flood in 1927 was due to the greater excess in April. Such being the case, it seemed worth while to study these April rains in relation to the weather map situations, both local and general. The results of a small investigation on these lines jointly by Nesbitt H. Bangs, Graduate Student, Clark University, and the writer are summarized herewith.

Although the Mississippi flood, like the New England flood (1927), was caused by the importation of vapor from tropical waters precipitated in excessive amounts over a region that is extended in area, it was not the result of a single importation. Rather was it brought about by a series of such importations extending back to the beginning of August, 1926, but culminating in the astonishing amounts of rain which fell in the Middle Mississippi Valley in April, 1927.

For a large area comprising Southern Illinois, Eastern Kansas, Eastern Oklahoma, Western Tennessee, Missouri, Arkansas, and Louisiana, the rainfall averaged more than twice the normal. The precipitation on parts of this region was far more than this, as, for example, Arkansas with a rainfall of 12.93 in. compared with a normal of 4.88 in., and Western Tennessee with a rainfall of 11.35 in. compared with a normal of 4.40 in. Curiously enough, the State of Mississippi as a whole experienced only the normal rainfall, but certain stations in the northwestern counties recorded rainfall far in excess of the average, notably Greenville, with a rainfall of 13.67 in., an excess of 9.06 in. above the normal. Table 37 shows the rainfall in the various States and the departure from normal.

The rainfall for the month was not only intense, but was also remarkably persistent. From April 1 to April 22, rain fell in considerable amounts every day in some part of the region. Only on April 2 and 3 did Arkansas,

* Prof. of Meteorology and Climatology, Clark Univ., Worcester, Mass.

for example, report no precipitation during this period, but on those days rain was falling in Illinois. Table 38 shows the periods when the rainfall was general and copious in the different sections of the region.

TABLE 37.—RAINFALL, IN INCHES, APRIL, 1927.*

	April, 1927.	Normal.	Departure.
Arkansas	12.93	4.88	+8.05
Western Tennessee	11.36	4.40	+6.96
Eastern Oklahoma	9.48	5.47	+4.01
Missouri	8.46	3.73	+4.73
Southern Illinois	8.43	3.92	+4.51
Eastern Kansas	7.40	3.05	+4.35
Louisiana	6.85	4.70	+2.15
Mississippi	5.12	5.19	+0.07

* From *Climatological Data*, April, 1927.

Scrutiny of this table shows five well-defined periods of rainfall: the 1st, 5th to 9th, 7th, 11th to 16th, 18th to 21st, and 29th. A study of the weather maps for these periods indicates a close analogy between the conditions causing the rain on the 1st and 29th, the rainfall on the 5th and 18th to 21st, and indicates that the rainfall during the long period from the 7th to 16th was caused by a pressure distribution that remained persistently the same throughout the period.

Any conditions that will bring about the rapid ascent and consequent rapid cooling of warm moist air will cause heavy rain, and these conditions were particularly suitable during most of April. Pressure conditions over the United States and the Atlantic Ocean, as shown by maps,* were such that the southerly and southeasterly winds blowing up the Mississippi Valley originated, not merely over the Gulf of Mexico, but far to the southeastward over the Caribbean; hence they were warmer at the start, and passing as they did over such a great expanse of the warm Equatorial Current were given an amount of water vapor that was greater than normal through a considerable depth of winds. Arriving in the Mississippi Valley, these moisture-laden

* In *Monthly Weather Review*, April, 1927.

winds were forced to rise first over the mountains of Arkansas, and, more important, over great wedges of cold dense air pressing in from the northeast, north, and the northwest. No wonder the rainfall was heavy.

Given then this general picture of a vast flow of air from tropical waters meeting cold dense air from the higher latitudes, it is interesting to note under what local conditions heavy rainfall ensued. In general, the rainfall was of three types: (*a*) That which occurred in warm, southerly surface winds on the southeastern quadrant of a low-pressure area; (*b*) the warm-front type; and (*c*) the cold-front type.

(*a*).—In this case the lower wind coming directly from the tropics becomes warmer much more rapidly than the upper wind, which is usually from some westerly direction. Instability and consequent violent overturning of the surface air results, forming thunderstorms. At times, when the wind aloft becomes much colder from its source in a cold southwestern quadrant of the low-pressure area, the unstable overturning of the warm southerly wind below may reach cloudburst and tornadic violence.* The great number of heavy thunderstorms and tornadoes over the region bears witness to the frequency of this occurrence. Of forty tornadoes reported during the month nearly all occurred over the region discussed.

(*b*).—The second type of rainfall which fell when the warm southerly wind was forced to rise over a cold northeasterly surface wind flowing out from an area of high pressure to east and northeast, the so-called "warm-front" type, is usually a combination of general ascent and instability rainfall.

(*c*).—The third type occurred when the front of an energetic high pressure area pushed southeastward with cold northwest winds under-cutting or over-cutting it and forcing the warm, moist surface air upward. This is called the "cold-front" type and the rain falls with northwesterly winds at the surface and with rapidly falling temperatures. Where the over-cutting runs 50 or more miles in advance of the cold front at the surface, this type merges with the violent aspects of the southerly type.

What were the weather map situations of April that brought about the rainfall periods previously noted? On the morning of the 1st a low-pressure area of considerable intensity was centered over Missouri and Illinois and heavy rain fell with southerly winds over Missouri, Illinois, and Western Tennessee, averaging 1 to 2 in. in Southern Illinois. Here was an example of the first type; that is, heavy showers in southerly winds caused by overturning of the warm moisture-laden air.

On the 5th, an area of low pressure that had been centered over Oklahoma the preceding day had moved northeasterly to Lake Superior, and a wedge of cold air with moderately high pressure had cut in to the southwest of the low-pressure area. Heavy rain fell with northwest winds in Mississippi, Missouri, Arkansas, and Louisiana (Shreveport, 2.82 in.). This was an example of the cold-front type caused by the crowding in of cold air to displace the warm moist air of the preceding southerly winds.

* "Elementary Meteorology," by W. M. Davis, Bost., 1894, p. 258.

On the 7th an area of high pressure of great magnitude appeared over the Province of Ontario, Canada, and the Lake region. An ill-defined area of low pressure was centered over Texas, and this type of map persisted until the 16th. A great mass of cold air, constantly reinforced, was moving southeastwardly from Manitoba, Western Ontario, and the Lake region. Throughout this period there was a constant conflict between the cold surface northeast winds flowing from the high-pressure area and the warm southerly winds flowing northward in the Mississippi Valley on the easterly side of the low-pressure area in Oklahoma. It is difficult to indicate the exact point at which the northeasterly winds ceased and the southerly winds commenced, but at St. Louis, Mo., and Cairo, Ill., there were apparently seven days of rain with northeasterly winds; at Memphis, Tenn., four; and at Vicksburg, Miss., one, showing that the line of maximum rainfall with northeasterly winds was somewhere between Cairo and Memphis.

North of this line the surface wind was northeast and the rainfall was of the warm-front type, caused by the warm wind ascending above the cold wedge flowing out from the northeast high-pressure area; but south of the line, the rain that fell was of the instability type, (*b*).

An interesting variation of these types occurred during this period, especially on April 13-14, when the Oklahoma low-pressure area shifted slightly to the northward, as a tongue of cold air swept over Texas. Heavy rains of the cold-front type fell with northwest winds over Texas on these days (Dallas, 2.06 in. on the 13th). In the period, April 10 to 14, twenty tornadoes occurred, most of them in Texas. When the cold front, now in the free air, reached New Orleans, La., on the 15th, 14.00 in. of rain was precipitated.

On the 19th an energetic area of high pressure commenced to speed southeastward from the Northern Rocky Mountain region toward the Gulf of Mexico, and for the next three days (19th, 20th, and 21st) during its passage, extremely heavy cold-front rains (5 to 12 in.) fell in Arkansas.

The final period of heavy rain came on the 29th when an area of low pressure very similar to that of the 1st passed eastward over Missouri. The rainfall was particularly heavy in Illinois, Missouri, and Tennessee (on the 30th).

Thus, from the general description just presented, it can be seen that the rainfall periods bore certain resemblances to one another. For instance, those of the 1st and 29th occurred with southerly winds; those of the 5th and 18th to 21st were of the cold-front type, falling with northwesterly winds; and those of the 7th to the 16th were generally of the warm-front type, falling along the line where the warm winds on the eastern side of the low-pressure area began to override the cold air from the high-pressure area to the eastward. An attempt has been made to separate the total precipitation at a group of selected stations into the amounts that fell with northeasterly, southerly, or northwesterly winds.*

* Acknowledgment is made to Mr. A. J. Henry, of the U. S. Weather Bureau, for the manuscript 12-hour precipitation charts, and to Mr. Thomas R. Brooks, of the Weather Bureau, for kindly copying a number of the 8.00 P. M. weather maps for April, 1927.

To assume that all the rain which fell during the previous 24-hour or 12-hour period fell with the wind from the direction indicated at the end of the period is possibly to stray appreciably from the actual facts, although the persisting character of the weather map situations from day to day in these rainy periods make the results seem probably significant.

Over the flooding rain region as a whole, as represented by nine stations, 43% of the 12-hour rainfall (8:00 P. M. to 8:00 A. M.) came in the region of southerly surface winds, 35% in the northeasterly sector, and 22% in the region of northwesterly winds. The corresponding 24-hour values are almost exactly the same, 42, 34, and 23 per cent.

It is interesting to note that the more northerly stations had the greater amount of rains of the warm-front type. Thus, St. Louis and Cairo had 48% and 41%, respectively, of this type, whereas Shreveport and Vicksburg had only 2 and 7 per cent. This was to be expected, considering the pressure distribution already noted; but whatever the type, it is obvious that the excessive rains were due to the large importation of vapor from tropical waters.

Conclusion.—The April contribution to the Mississippi flood was not a single paroxysmal rainstorm, such as produced the New England flood in November, 1927, but a number of heavy rains at frequent intervals over substantially the same region. The vapor for these rains came day after day in a great flow of air from Southern waters. Suffering little depletion on the coast, this air converged in the central portion of the Lower Mississippi Basin and was there also forced to rise not only over the mountains of Arkansas, but also over great barriers of denser air pouring out of the northeast, north, and northwest. Furthermore, as the frequent thunderstorms bear witness, so great were the temperature contrasts in short distances, both vertically and horizontally, that the warm humid air was forced violently to great heights. These several causes of ascent and, therefore, cooling and drying of enormous masses of humid air acted over practically the same regions for days at a time, and, in consequence, produced the tremendous rainfalls that were chiefly responsible for the great flood.*

William Gerig,† M. Am. Soc. C. E. (by letter).—Major Godfrey has presented an excellent paper on the subject of the improvement of navigation and flood control, and has correctly described the characteristics of the Lower Mississippi River, particularly during the low-water stages when navigation improvements are necessary.

A channel 9 ft. deep has been maintained during the past thirty years (since about 1890) by dredging between Cairo, Ill., and the mouth of the Red River. This channel is temporary and is dredged, on some of the bars or crossings, during each low-water period. The depreciation of the channel is caused primarily by material deposited on the bars from caving banks immediately above the troublesome crossing. If, therefore, the banks of the river are stabil-

* For a full discussion of the Mississippi flood see *Monthly Weather Review*, Supplement 29, by H. C. Frankenfield and others, summarized in *Monthly Weather Review* for October, 1927, pp. 437–452, 10 diagrams and photographs, and very briefly in *Science*, January 5, 1928, pp. 15–16.

† Senior Engr., Office of Chf. of Engrs., U. S. Army, Washington, D. C.

ized, the channels in the crossings will unquestionably become more fixed as the quantity of material carried by the river is considerably reduced. The river will then cease, to some extent at least, its "restlessness".

The low-water channel in certain localities, even after the banks are stabilized, will require some dredging or regulation in order to hold it in a definite location. The regulation can probably be done, to some extent, by contraction works of proper design. The writer believes that considerable experimental work should be done in order to develop, at a reasonable cost, an effective type of contraction works for the lower river.

Since 1883 many types of contraction works have been tried on the Mississippi River below Cairo. They consisted of permeable pile and brush dikes, abattis dikes, massive rock-filled brush dikes, sand dams, etc., all of which were either total failures or have proved to be only temporary. These types were successful on the Upper Mississippi and other rivers. However, if the banks are stabilized well in advance of the construction of contraction works, a proper low-water type will no doubt be developed.

It has been computed that the Mississippi River expends at the rate of 60 000 000 h. p. of energy or heat during great floods in its course from Cairo, to the Gulf of Mexico. Some of this energy is, of course, expended in the erosion of the river banks and in the transportation of material in suspension. If bank erosion is curtailed, the energy saved will possibly be utilized to deepen the channel. The writer, however, does not believe that such an improved low-water channel will have any marked effect on flood heights, except that they may be slightly reduced in floods where the conditions are similar to those of 1927. During that year the Mississippi River was at or above flood stage for many months prior to the great rainfall in the lower valley during March and April, and at no time did the river fall sufficiently to permit erosion of the bar channels that had been filled. Erosion of sand-bar obstructions in the channel begins soon after the stream has precipitated some of the material in suspension. Precipitation starts when the peak of the flood is reached and continues as the river falls, and as the river is relieved of the work of transportation, it applies this energy to providing a channel across the bar obstructions between the pools. The Mississippi River has one characteristic that is common to almost all streams whether large or small, that is, it is composed of a series of pools separated by shoals and rapids. This condition (high bars across the channel) has decreased the slope of the river to some extent, and at Cairo, and other points, has caused somewhat higher stages for a given discharge, than would have occurred under normal conditions or with stabilized banks.

Again, when the banks are stabilized, the depreciation of the channel below a crevasse will be decreased, for the reason that the river is not transporting such large quantities of material in suspension, its source of supply has been considerably curtailed, and, hence, there will be little difference between the effect on the low-water channel of a controlled spillway or weir and that of the uncontrolled spillway.

The writer agrees with Major Godfrey that some minor straightening of the low-water channel, as long as the general regimen of the river is not affected, may be advantageous in some localities. Careful study, however, should be given such proposals before they are undertaken, or otherwise the high-water slopes may be affected.

C. H. EIFFERT,* M. AM. SOC. C. E. (by letter).—Mr. McCarthy states the weight of dry forest litter at the Wooster, Ohio, Station to be from 1 827 to 17 545 lb. per acre and that it will absorb 1½ to 2½ times its dry weight in water. The weights were obtained in the fall before the leaves had fallen. The annual deposit of litter is estimated to be about 2 tons, dry weight. The average weight of dry litter per acre would be about 5 tons. Add to this the annual crop of dry leaves and there would be about 7 tons of litter per acre to absorb water during the following flood season. Assume the absorptive capacity of this litter to be two times its dry weight, or 14 tons per acre. This would amount to 450 cu. ft. of water, or 0.12 in. of rainfall. The Ohio Basin is estimated to be one-third forested. (The area that might be reforested, although it amounts to considerable in acres, will affect this proportion very little.) If 0.12 in. were absorbed by the forested area, it would amount to 0.04 in. over the entire Ohio Basin. The absorptive capacity of the litter when dry is assumed to be 14 tons per acre. It will never be dry during February, March, or April, when the great flood-producing rains occur. Assuming the quantities of litter stated to be the average, the net effect of the forest litter on run-off may be considerably less than 0.04 in. in the Ohio Basin in a great flood.

In the quotation from "The Relation of Forests and Water" by Zon, it is stated that forests retard the melting of snow in the mountains. Whether or not this retarding action helps to reduce floods is questionable. The forest in this case acts as an uncontrolled reservoir and may release its storage at the wrong moment.

It is very difficult to take the results of experiments such as those being made at Wagon Wheel Gap, Colo., in the White Mountains, or in Switzerland, and try to deduce therefrom possible results in the Mississippi drainage basin. These are small areas. Their geology, climatic conditions, altitudes, and geographical locations differ greatly from the parts of the Mississippi Valley contributing most of the flood run-off. The Swiss experiments were referred to in order to show the difference in run-off between forested and deforested areas during a violent summer storm. These experiments seem to be the most thorough and complete that have been made along this line, and the results for a period of thirteen years have been reported by Dr. A. Engler. Some of the conclusions reached are as follows:†

"The run-off due to heavy rainfalls of short duration as thunderstorms or cloudbursts is much less from the forested than from the deforested area, peak discharges from the forested area being from one-third to one-half of those from the deforested tract and the total run-off for this class of storms from the former is usually about one-half that from the latter.

* Chf. Engr., The Miami Conservancy Dist., Dayton, Ohio.

† The writer's translation.

"The run-off due to long continued rainfall is greatly affected by the water content of the ground prior to such rainfall. In case this water content is considerable the forest will have no effect, the run-off being the same from forested as from deforested areas.

"Over the entire period of 13 years the run-off factors for the two areas are practically identical, being 60.0% for the forested and 60.4% for the deforested area."

The writer wishes to emphasize the matter of the water content of the soil or its absorptive capacity by an illustration from the Miami Valley. This valley may be considered as deforested. During the storm of September 12 and 13, 1925, the average rainfall north of Dayton, Ohio, over an area of 2 525 sq. miles, was 3.20 in. The run-off was 0.04 in., or 1.25% of the rainfall. During the storm of March 19 to 21, 1927, the rainfall was 3.44 in. and the run-off resulting from it was 2.31 in., or 67% of the rainfall. The first-mentioned storm was of shorter duration and other factors being equal, would have given the greater run-off. The maximum stage reached at Dayton during the first-named storm was 2.9 ft. while during the latter it was 12.8 ft.

Unquestionably the difference in run-off between these storms was due to the difference in soil conditions. The storm of September, 1925, came at the end of the growing season and following a dry period during which the transpiration and evaporation had been abnormally great. At the beginning of this period there had been a deficiency in rainfall of about 5 in. since the first of the year. These factors combined to give the soil a tremendous storage capacity.

Preceding the storm of March, 1927, there had been little evaporation, and there was no growing vegetation to consume moisture. To November 1, 1926, there had been an excess of 5.79 in. in precipitation since the beginning of the year.

It seems to the writer that while the absorptive, retentive, and retarding effects of the forests have been greatly emphasized by those who advocate reforestation as a means of assisting in flood control, the same factors in regard to pastures, growing crops, or well cultivated fields, have been generally neglected or entirely disregarded. The comparisons made are too often between forests and denuded or barren hill and mountain sides. That part of the Mississippi Basin east of the 100th Meridian yields more than 95% of the Mississippi flood water. The part of this area which is not forested, consists principally, not of barren hillsides, but of well tilled farm lands which have a considerable capacity for retaining moisture.

While there may be a small surplus of farm land at the present time, no one would advocate returning good agricultural land to forest conditions. On the other hand, there can be no valid objections to reforesting the denuded hills, not for flood-control purposes, but for the products of the forest. Let forestry stand on its own merits. Even if it could be shown that forests might have an important influence on great Mississippi River floods, the areas which might be available for reforestation would not be great enough to alter materially present conditions.

The forest will undoubtedly prevent, to a large extent, the washing away of the soil from the hillsides, but this is not necessarily an argument in favor of reforestation for flood control. The Missouri experiments, mentioned by Mr. McCarthy, seem to show that it will require 437 years to erode the 7-in. surface layer from land planted with a rotation of corn, wheat, and clover, and 3 547 years to erode 7 in. from land in blue-grass sod. One may see gullies and other signs of erosion even in the forest. Will it take longer than 3 547 years to take 7 in. of soil from forested land?

Referring to Colonel Kelly's paper, the writer desires to call further attention to the possible effect of the Miami River flood-control works on floods in the Ohio River.

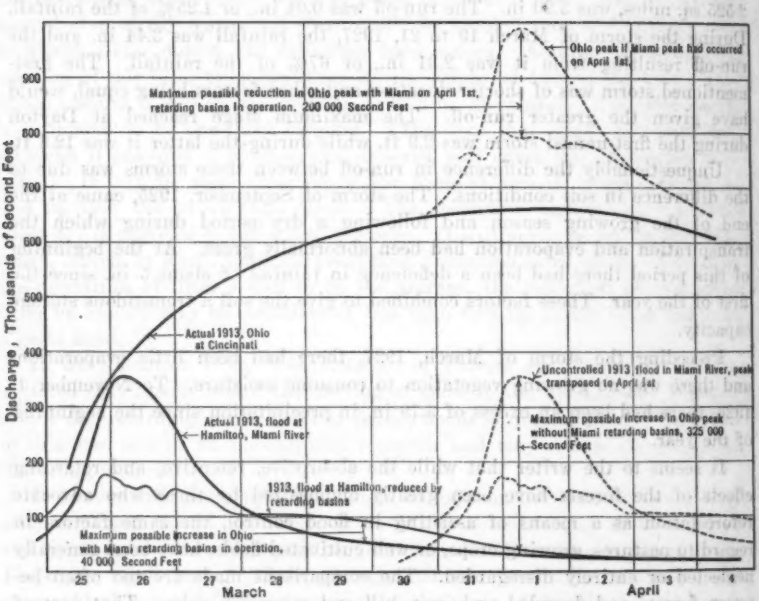

FIG. 46.—HYDROGRAPHS OF THE 1913 FLOOD.

In Fig. 46 are shown hydrographs of the actual 1913 flood in the Ohio, at Cincinnati, the 1913 flood in the Miami River, at Hamilton, a controlled 1913 flood, at Hamilton, and a 1913 flood in the Ohio with the peak in the Miami, occurring on April 1 instead of March 26. The actual figures at the mouth of the Miami River would exceed those shown herein. Information for completing hydrographs for both streams at the mouth of the Miami was not available; however, the curves shown answer the purpose of illustrating the point it is desired to emphasize. Comparing the curves for the actual and the controlled 1913 flood, at Hamilton, it is seen that the maximum excess of the controlled flood over the actual is 40 000 sec-ft. and occurs on March 29. The maximum possible increase in the Ohio, therefore, would be 40 000 sec-ft.

for such a flood and would occur if this stage of the Miami flood occurred simultaneously with the maximum stage in the Ohio. Under any other conditions the increase would be less than 40 000 sec-ft. Suppose, however, that the peak in the Miami, instead of coming on March 26, should synchronize with the Ohio peak occurring on April 1. The uncontrolled Miami River flood would then increase the Ohio peak by 325 000 sec-ft., but controlled as at present this increased peak would be reduced 200 000 sec-ft. In other words, in a flood like that of 1913 controlled by the retarding basins, the maximum possible increase in the Ohio River would be 40 000 sec-ft., while the maximum possible reduction might be as much as 200 000 sec-ft.

It cannot be safely argued that because there is no record of this combination, it cannot occur. There are no definite previous records of floods as great as that of 1913 on the Miami, or like that of 1927 on the Mississippi. Before they occurred, they were thought by many to be impossible. Yet certain combinations made them possible.

The writer does not wish this to be understood as an argument in favor of reservoirs on the head-waters of Mississippi tributaries. He simply desires to state a possibility which has not heretofore been emphasized.

SHERMAN M. WOODWARD,* M. AM. SOC. C. E. (by letter).—The paper by Colonel Kelly serves as an admirable illustration of the urgent necessity for the creation of a fact-finding commission, authorized to use ample time and money, to whatever extent may be necessary, in order to investigate and determine the best solution of the Mississippi River flood problem.

If engineers had accurate maps of actual important reservoir sites with data showing storage capacity at various depths; if they had detailed estimates of quantities and costs covering the dam, spillway, control gates, and flowage rights, all accompanied by complete flood hydrographs of the stream bearing the reservoir site and other information needed to show the time relation of the storage to the flood flow in other tributaries, and to the regions to be protected; if they had such actual information, it would be possible to discuss, much more satisfactorily, the methods used for determining the cost of reservoir control, the comparative value and merit of such control, and the reliability of the conclusions reached.

As it is, it may be profitable to consider briefly some methods used in such studies. The approximate studies already made seem to indicate that complete protection might be secured by levees alone at a cost of approximately $1 000 000 000, and that an equal degree of protection could be secured by reservoirs at a cost somewhat greater. The wisest and most economical protection would then undoubtedly be some combined plan using the most advantageous features of both methods. To work out the best combined plan requires careful detailed consideration of each feature and each reservoir separately. In such a study, to lump the effect of a number of reservoirs or to average them, would vitiate the results. The last or top foot of such a system of levees might cost $100 000 000. If a group of reservoirs were found, the construction of which would contribute to the flood protection at a more

* Prof. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

advantageous or cheaper rate, this group should be included in the combined plan, and the expenditure on levees should be reduced accordingly. Even if only a single reservoir were considered advantageous, its effect being considered equivalent to 0.1 ft. on the height of the levees, the levee should be lowered that much, thereby reducing the expenditure for levees by perhaps $10 000 000 and using the needful amount for the cost of the reservoir. This should be the method of balancing to be used, notwithstanding the fact that perhaps the ultimate fixing of the levee grade remains finally a somewhat arbitrary matter, being placed empirically at some foot or half-foot mark. The point is that the comparative advantages and disadvantages of different features can be and should be determined with more precision than may be claimed for the finally adopted dimensions.

The estimates so far published (1928) for the construction of floodways are vague and uncertain. When these estimates are satisfactorily settled, the same plan of comparison may be equally well applied to them.

It would be highly desirable to build at least one large reservoir or one group of reservoirs conveniently situated, for flood protection on the Lower Mississippi, if merely as a demonstration or experiment and for the purpose of testing the operation of the reservoir during flood times. This is a field in which there is very little experience as a guide.

What Colonel Kelly calls dependable operation of flood-control reservoirs, is storage at a uniform rate for a period of 90 days, entirely irrespective of flood conditions on other tributaries, or any other existing condition. This is perhaps the least efficient system of operation that can be imagined and still be called a system of rational control. It seems probable that reservoirs close to the region to be protected can be operated three times as efficiently. Colonel Kelly bases most of his estimates of comparative value on averages of large groups of reservoirs. To determine the most economical combined system, the comparison should begin with the least expensive single reservoir measured in units of flood protection, and then should proceed regularly toward the more expensive. Taking all these items into consideration, it appears probable from Colonel Kelly's figures that a considerable number of reservoirs will be desirable and economical in a combined system for flood protection. It is impossible to determine this point satisfactorily or conclusively until more detailed and accurate data are available.

The other point to be considered is the question of the advantage of close proximity of the reservoir to the area to be protected. It is a great advantage to have some of the reservoir storage near the protected area, but it should be understood that it is not necessary or particularly beneficial to have all the reservoirs close together. This can most easily be made clear by a simple example. Assume two equal reservoirs on the same or different tributaries with adequate flow, Reservoir A being close to the protected area and Reservoir B, two weeks distant. It can be shown that, under rational control, they can in general be operated as efficiently as if both of them were as close to the protected area as Reservoir A. Assume that on a certain date conditions make it desirable for the flow below Reservoir A to be reduced by a constant amount, such that when stored in Reservoirs A and B it would just

fill both of them in the eight weeks. Let x = one-eighth of the capacity of Reservoir A. Then, to effect the desired protection below Reservoir A, $2x$ is the quantity of water per week by which the flow below it is to be reduced. The operation of the controlled reservoirs would be as follows.

On the given date, begin storing water in Reservoir A at the rate of $2x$ per week. This would reduce the flow below Reservoir A by the desired amount. On the same date begin storing water in Reservoir B at the rate of $\frac{4}{3}x$ per week. At the end of 2 weeks the reduced flow below Reservoir B would reach that of Reservoir A. At this time change the rate of storage in Reservoir A to $\frac{2}{3}x$ per week. This rate of storage combined with the reduced rate of flow from Reservoir B would maintain the desired reduced flow below Reservoir A. At the end of 6 weeks from the beginning, Reservoir B would be full, and the entire stream flow would be allowed to pass, but this flow would not reach Reservoir A until 2 weeks later, that is, at the final end of the 8-weeks period. At this final date Reservoir A would also be completely filled, having stored at the rate of $2x$ for the first 2 weeks and at the rate of $\frac{2}{3}x$ for the next 6 weeks, making a total final storage of $8x$ in each reservoir.

This simple example is only to illustrate the general method. Whatever the sizes and locations of the various reservoirs in a system, they can be similarly operated in co-ordination with each other with perfect elasticity to the capacity of the stream supplying each reservoir.

W. J. Schlick,* M. Am. Soc. C. E. (by letter).—The careful study made by Professors Woodward and Nagler, furnishes valuable evidence on the much debated question of the effect of drainage development on flood flows. Although the available data are not extensive, the definiteness of the indicated conclusions warrants their general acceptance. It is doubtful if the effect of drainage will be more pronounced on any of the streams in the Mississippi water-shed, so there seems to be no question of the accuracy of the conclusions in the paper as applied to floods of that great river, particularly since only a small portion of any major flood flow can come from an area which is drained, or in which any extensive drainage development is economically probable.

It seems that, if there are any inaccuracies in the conclusion, these are the results of insufficient data and apply to smaller water-sheds in which lateral under-drainage is, or may become, more nearly complete. The water-shed of the Des Moines River above Fort Dodge, Iowa, is of such character that a very large proportion of it probably will be underdrained eventually. The resulting effects of this drainage development on flood flows, and particularly on maximum flood flows, are problematical but are worthy of consideration.

In 1920 the Iowa Engineering Experiment Station instituted a study of the discharges from several of the larger drainage districts of the State. In two of these districts (with drainage areas of approximately 25 and 35 sq.

* Drainage Engr., Eng. Experiment Station, Iowa State Coll., Ames, Iowa.

miles, respectively), the outlet drains were just being completed. The fact that the rainfall during the spring and summer months has not been excessive, and that there has been an economic depression in the agricultural States, has so retarded the installation of farm under-drainage systems that the flow records obtained to date (1928) represent very largely the surface run-off admitted to the open ditches directly and through inlets in the district tile lines. The curves of "surface flow", Fig. 47, are for one of these districts and a lateral area of it.

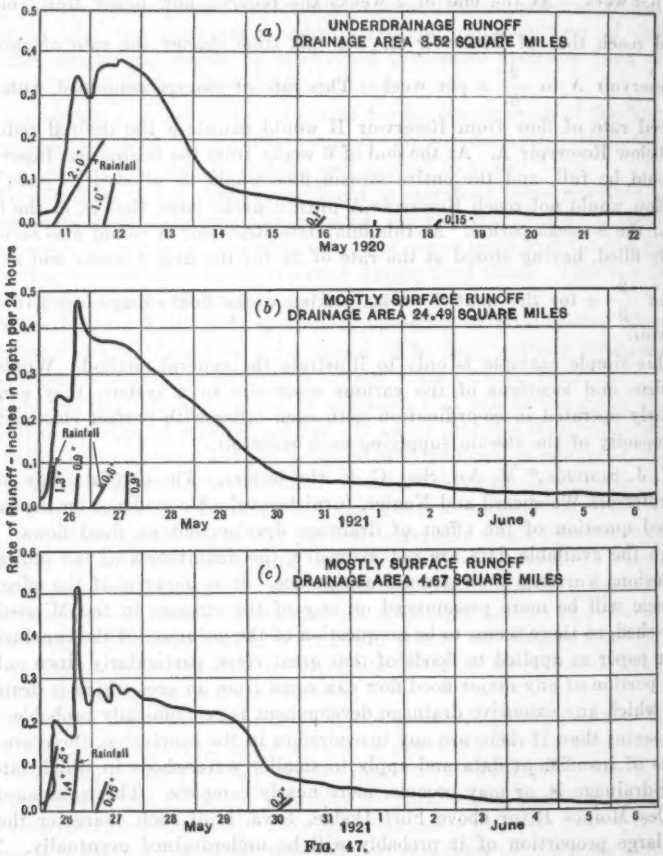

FIG. 47.

Another of the districts studied was rather completely underdrained, with no provisions for admitting surface run-off. The discharge from this system is entirely under-drainage flow, except for the surface run-off of a small area immediately adjacent to the outlet.

The shapes of the rate-of-run-off curves shown on Fig. 47 are illustrative of those obtained during this study. They present some interesting possibili-

ties in connection with the study of the effects of drainage on flood flows. The curves for the "under-drainage" area are always flatter and the peaks less sharp, than those for the "surface run-off" areas. Neither of the curves represents the run-off from the maximum storms that reasonably may be expected, although the maximum rates shown are as high as any during the period from 1920 to 1927, inclusive. Only one of these areas is in the water-shed of either of the streams studied by Professors Woodward and Nagler, but they are typical, in a general way, of the flatter areas of both those water-sheds.

The available data do not warrant any definite conclusion as to what effect the extensions of under-drainage may have on the correctness of the conclusions of Professors Woodward and Nagler. The percentage of the water-shed of the Des Moines River that probably will be underdrained is unknown, but it is doubtful if it will exceed 75% of the water-shed above Fort Dodge, 50% of that above Des Moines, and 25 to 33% of that above Keosauqua. Since the present drainage development has had no determinable effect on flood flows, it seems reasonable to expect that the effect of future under-drainage development on the flood flow at Des Moines and Keosauqua will not be material. However, the shapes of the curves do indicate the possibility of such an effect, especially on the medium high floods from the smaller water-sheds.

The present-day limits of the economical maximum intensity of under-drainage are such that the storms producing the maximum flood flows usually cause some surface run-off from underdrained areas. Also, the tile lines of nearly all drainage-district systems are now provided with inlets to hasten the removal of surface water. These two facts will tend to minimize any effect under-drainage may have on flood flows, particularly maximum flood flows.

S. L. Moyer,* Esq. (by letter).—The wide divergence in run-off behaviors under the current conceptions of the relation of run-off to rainfall, is most effectively disclosed by an examination of the diagrams presented in connection with the paper by Messrs. Woodward and Nagler. This fact seems to indicate a very real need for a rational evaluation of the accidental influences which give rise to such a haphazard showing. This apparent need affords a timely opportunity to present an entirely different conception of the nature of the problem in hand.

The method of attack herein outlined assumes that there is some general law governing the accidental occurrence of storms, and that the chance for such events arises out of basic causes in combination, after the fashion of the "hit-or-miss" fall of the dice or cards.

As distinguished from the current theory of probabilities, this development does not assume that rainfall magnitudes are the result solely of causes in summation; but, on the contrary, it is conceived that these events may also be influenced by factors (dice of destiny) combining by multiplication, rather than summation, of values.

In common with other probability methods, time and count are herein assumed to be one and the same thing; and time in its totality or eternity is taken as unity, or 100 per cent. The extent of time, or count, is measured

* Civ. Engr., Montevideo, Minn.

in relation to the opportunity offered for the occurrence of magnitudes, without regard to the sequence of events; and the procession of time is viewed as to its content in event magnitudes, instead of in the ordinary terms of the chronological order of occurrence.

The words, expectancy and probability, are perhaps unfortunate in that they seem to suggest an element of uncertainty; but an expectancy examination of data, in its recognition of the accidental elements and in its attempt to assay the chance, elects to face a situation which other methods ignore. Once the fate factors are given proper weight, a surprising uniformity of results may be achieved.

An expectancy analysis was made, based on the data given for monthly rainfalls and run-offs for April, May, and June, during the two periods before and after drainage, covering the basins of the Des Moines River above Keosauqua, and of the Iowa River above Iowa City, Iowa. This single showing cannot be said to prove conclusively the validity of the approach to the problem in question. However, the apparent harmony of the results obtained from this analysis does seem to tend to prove that, on the expectancy average: (1) run-off is a proportion of rainfall after deducting a constant loss factor; (2) the constant loss factor is little, if at all, affected by agricultural drainage; and (3) as applying to the area actually subjected to drainage improvements, agricultural drains of the Iowa type have apparently effected a reduction in the run-off proportion to the extent that the value after drainage is about 40 to 45% of the original value before drainage.

An ordinary rain-gauge has a catchment area of (roughly) one hundred-millionth part of a square mile. In the case of the Des Moines and Iowa River basins, on which Weather Stations are fairly numerous, there seems to be about one significant rainfall record to a section of 300 sq. miles, or the gauge sample of the rainfall is about one thirty-billionth part of the section it presumes to represent. The gross inadequacy of such representation as evidence of what happens in a given storm on the 300-sq. mile section, may perhaps best be seen by comparison with a car of wheat.

An ordinary freight car transports about 1 500 bushels, or 90 000 lb. of wheat (1 440 000 oz.). An ounce of wheat contains somewhat less than 2 000 kernels; so a carload of wheat is made up of a scant 3 000 000 000 kernels. Assuming a sample of the wheat in proportion to the rainfalls in question, 1 kernel must be taken as a fair sample of 10 or 12 carloads, if the rainfall samples are fair, and the absurdity of the representation becomes self-evident.

On the other hand, it is a matter of common observation that different storms travel in different ways, so that during the course of a few years, the rainfall record at the gauge will include practically all the variations in intensity that fall to the lot of the whole section which the gauge represents. Therefore, the gauge record does fairly represent the trend of magnitudes for the whole section, and since expectancy has to do with the trend of magnitudes, the sample is fair for expectancy purposes.

It is obvious that run-off records fairly represent the whole of the events, either for a given storm or for the trend of storm magnitudes. The limita-

tions of mathematics demand that the association of values in any given operation be confined to subjects and predicates displaying uniformity in logical kind or type. This restriction, which is the result of extensive mathematical experience, therefore, suggests that the only fair basis for the relation of run-off to rainfall, is found in that aspect under which rainfall samples appear to be fair, or in the expectancy viewpoint.

In its essence, expectancy or probability is an assay of time as to its content in magnitudes. The writer conceives time to be the opportunity for the occurrence of events. An event may be said to be a manifestation of activity, a behavior in the material, or a phase of transition, which occurs, happens, befalls, takes place, or comes to pass in a series, a parade, or procession of incidents.

The monthly rainfalls and run-offs for the Des Moines and Iowa River basins above Keosauqua and Iowa City, given in Table 31, under the expectancy conception, may be regarded as events of the same kind or type with respect to the time lapse in which the magnitudes have accumulated. Some of the phenomena, however, are subject to widely different types of seasonal influence, and, therefore, may be said to be unfair in association. For this reason, all the magnitudes in Table 31 have been discarded, except those covering the months of April, May, and June in each of the years listed.

While these three months are not exactly of uniform seasonal kind or type, any difference is progressive and may be fairly regarded as reducible to expectancy. The inclusion of more than one month for each year of the record is not valid as to expectancy over a period of years, but this sort of representation is believed to result in assemblies of rainfall and run-off data which are logically comparable.

Even by this means of expanding the expectancy series by inclusion of several months in a given year, the remainder of the data given by the authors is entirely too scant for analysis by this method, so it must also be disregarded. Maximum 24-hour magnitudes for each of these months might be compared, but the writer prefers to have these data compiled by one who is a stranger to this system of analysis, in order to avoid any suspicion of "colored" statistics.

With fair samples on hand, observations to be used for expectancy purposes may next be graded, as sizes are screened and sorted in sand and gravel analyses. The accidental occurrence of the sizes in a gravel deposit, as to arrangement in place, is important in so far as it affects the picking of a fair sample, but after such sample has been secured, the original order of deposit has no particular significance. Similarly, the sequence of magnitudes in the time parade is of no consequence, after the expectancy samples have been selected, and the grading of the samples is effected simply by arrangement of the observations in the order of their sizes.

For the expectancy assay of events, no division into arbitrary classes, as in gravel analyses, is necessary because the analysis of the magnitude content of time is accomplished through the ratio of the count of observations,

found above and below any given stage, or by the odds of the number of items of data exceeding and short of the position in question.

Every line of attack on the probability problem, including even the classic Gaussian law of error, attempts to evaluate the content of time in its eternity; and as this can never be known exactly, each such effort to solve the mystery must of necessity be merely an empirical approximation of magnitude trends. It is the writer's belief that the method herein presented, represents a definitely practical step in advance, affording a broader insight into the various aspects of the subject than any hitherto proposed. The broad field to which the idea may be applied, if it proves sound, warrants searching and critical study.

As the mathematical mechanism is an empirical development, the practical operation will be shown before attempting to state the logical reasoning that may be said to support the writer's analytical expectancy charts (Figs. 48 to 52).

Notation.—

Let F = the frequency, or the average interval in the count of events between magnitudes exceeding any given stage.

P = the probability, or proportion of the count of events exceeding any given stage of magnitude.

N = the numerical designation of an observation when the expectancy series is arranged and observations are numbered in the order of magnitude, beginning with the least.

T = the total number of observations in the expectancy series.

d = any position on an arithmetical base scale covering a range from zero to unity, or covering time in its totality.

v and z = two arbitrary variables influencing the form and position of the scale of F (Fig. 48) in reference to the basic and fixed scale of d, and by means of which data trends may be reduced to an approximate straight line for one-half or more of the range of the trend in a given approximation.

e = the tangent of slope for any straight line on a chart (Fig. 48) having the d scale as a horizontal base and magnitudes as vertical arithmetical ordinates; or the difference in magnitude on the straight line between the two limits of the d scale.

c = the ratio of the magnitude on the straight line at the upper limit to e; or that position on the d scale where the straight line intersects zero magnitude or would intersect zero magnitude if the d scale were extended.

Q = the magnitude for any point on the straight line.

A = the proportion of catchment area unaffected by drainage improvements.

B = the run-off proportion for the area, A, after deducting constant loss factor.

C = the proportion of catchment area affected by drainage.

D = the run-off proportion for the area, C, after constant loss deduction.

E = the run-off proportion for entire area after drainage, the constant loss factor being first deducted.

For the purpose of assigning logical frequency values to the various observations in an expectancy series of data, as a guide to the plotting of the magnitudes on the writer's analytical expectancy chart, it can be demon-

strated that Equation (1) produces values that are consistent, on the average, for both long and short series:

$$F = \frac{T + 2\left(\frac{T-1}{T+5}\right) - 1}{T + \left(\frac{T-1}{T+5}\right) - N} \quad \ldots\ldots(1)$$

Expressing the numerator of Equation (1) by a, and assuming,

$$b = T + \frac{T-1}{T+5} \quad \ldots\ldots(2)$$

Equation (1) may then be written,

$$F = \frac{a}{b - N} \quad \ldots\ldots(3)$$

or, since P is the inverse of F,

$$P = \frac{b - N}{a} \quad \ldots\ldots(4)$$

Equation (4) is not essential to the distribution of data in this analysis, but it is introduced in order that a clear conception may be had of the relation to the ordinary, current conceptions of probabilities.

As a general equation by means of which the law of chance curvature for occurrences of a given kind or type may be asserted, the following empirical expression is offered:

$$d = \frac{v}{F} + \frac{(1 - v)\ (1 + z)}{F + z} \quad \ldots\ldots(5)$$

The form of Equation (5) is such that when $F = 1$, $d = 1$, and when $F = \infty$, $d = 0$. The limits of the d scale, therefore, always include infinite time or eternity. Writing Equation (5) in a form expressing the trend of rainfall and its consequences as to magnitudes expected,

$$d = \frac{3}{10\,F} + \frac{35}{F + 49} \quad \ldots\ldots(6)$$

Equation (6) also approximates the curve form for four chance elements falling in accidental combination and influencing event magnitudes by multiplication of cause values.

The magnitude for any point on the straight line shown in Fig. 48 is determined by the formula,

$$Q = (c - d)\ e \quad \ldots\ldots(7)$$

The writer's expectancy charts for rainfall and run-off (Figs. 48 to 52) are designed under and portray the law of chance expressed by Equation (6). By means of Equation (3), a series of observations of phenomena which are truly representative of the chance, may be assigned a logical frequency on the diagram against the F scale and plotted in proper frequency position. The graphic representation of the magnitudes may then be approximated by a straight line, and an equation of the expectancy representing the straight-line reconcilement of the data, may be derived under the principles of Equation (7).

In Table 39, the rainfall and run-off magnitudes listed in Table 31 and covering the Des Moines River above Keosauqua and the Iowa River above Iowa City during the months of April, May, and June, for which both rainfall and run-off magnitudes are listed, are arranged in the order of their respective sizes. These magnitudes have then been numbered in the same order and the frequency, F, has been computed as shown by the F values in Table 39, utilizing the principles of Equation (3).

14	21.	June, 1919	7.05	June, 1919	1.67	14	21.	May, 1918	8.32	June, 1918	3.90

Based on the magnitudes and frequency values of Table 39, graphic distribution and representation of the data have been accomplished as shown in Figs. 48 to 51, inclusive.

Referring to Fig. 48, after plotting the data in accordance with the computations of frequency, these magnitudes have been approximated by a straight line for both the rainfall and run-off data. From the scales of this diagram,

values of the factors in Equation (7) have been derived as shown in Column (2) of Table 40. This process has been repeated for Figs. 49, 50, and 51, and the values have been derived as shown in the other columns of Table 40.

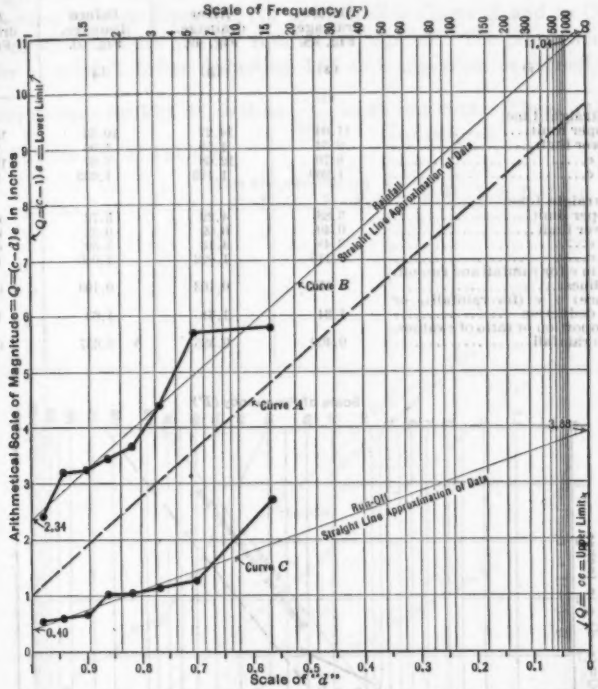

FIG. 48.—DES MOINES RIVER, KEOSAUQUA, IOWA, BEFORE DRAINAGE.

The approximation of the observed magnitude by a straight line in each of these cases is somewhat a matter of judgment, but from the very nature of the data arrangement, erratic magnitudes must tend to fall in the main in the upper or lower portions of the series. The magnitudes in the middle section are thus seen to be entitled to the greatest weight in such graphic reconcilement. In all eight of the series thus reconciled, no adjustments whatever have been made subsequent to the final computation of results.

In Table 40 (Column (2)), beside the item "Constant Deduction", appears the value, 1.34. In Fig. 48, a broken straight line (Curve *A*) is drawn parallel to and at a magnitude of 1.34 below the straight line for rainfall (Curve *B*). The value 1.34 is such that Curve *A* will intersect the straight line for run-off (Curve *C*), when both are extended, at the zero position on the scale of magnitudes. From this, it will be seen that after the deduction of 1.34 in. from rainfall, on the expectancy average, the remainder is related to run-off by proportion.

TABLE 40.

(1)	Des Moines River. Before drainage, Fig. 48. (2)	Des Moines River. After drainage, Fig. 49. (3)	Iowa River. Before drainage, Fig. 50. (4)	Iowa River. After drainage, Fig. 51. (5)
Rainfall, Straight Line:				
Q for upper limit	11.04	14.27	10.33	15.74
Q for lower limit	2.34	1.59	1.96	1.94
Value of e	8.70	12.68	8.37	13.80
Value of c	1.269	1.125	1.233	1.141
Run-off, Straight Line:				
Q for upper limit	3.88	4.22	5.72	6.71
Q for lower limit	0.40	0.09	0.22	0.12
Value of e	3.48	4.13	5.50	6.59
Value of c	1.115	1.022	1.040	1.019
Difference in c for rainfall and run-off, straight lines	0.154	0.103	0.193	0.122
c (difference) $\times$ e (for rainfall), or constant deduction	1.34	1.31	1.62	1.68
Run-off proportion or ratio of e values, run-off to rainfall	0.400	0.326	0.657	0.477

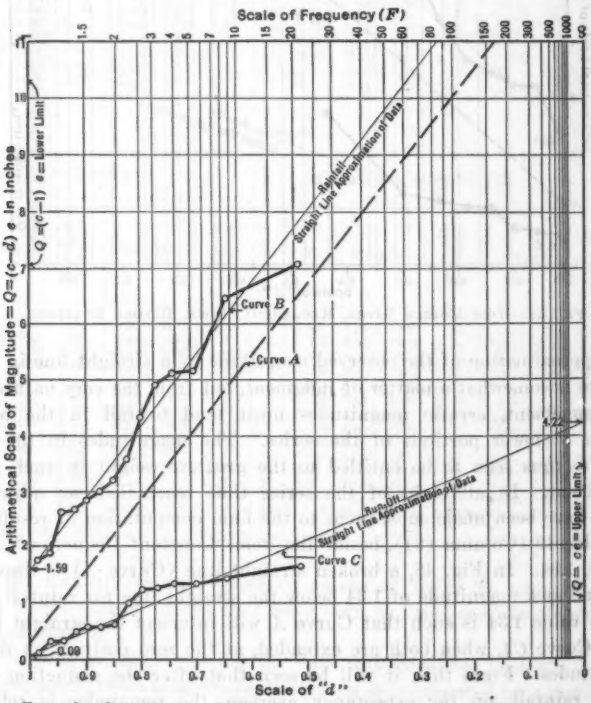

FIG. 49.—DES MOINES RIVER, KEOSAUQUA, IOWA, AFTER DRAINAGE.

Since Curve A is parallel to Curve B (Fig. 48), both curves have the same slope or the same e value in Equation (7). Since the broken straight line, A, intersects zero magnitude at the same position on the d scale as the straight line for run-off, C, both these curves have the same c value. The only difference between Equation (7) as applied to Curve A and to Curve C, is in the respective values of e for rainfall and run-off. The proportion of the remainder of rainfall (after deducting 1.34 in.) appearing as run-off, on the expectancy average for Fig. 48, is then $\frac{3.48}{8.70} = 40$ per cent. These values are given in Column (2) of Table 40.

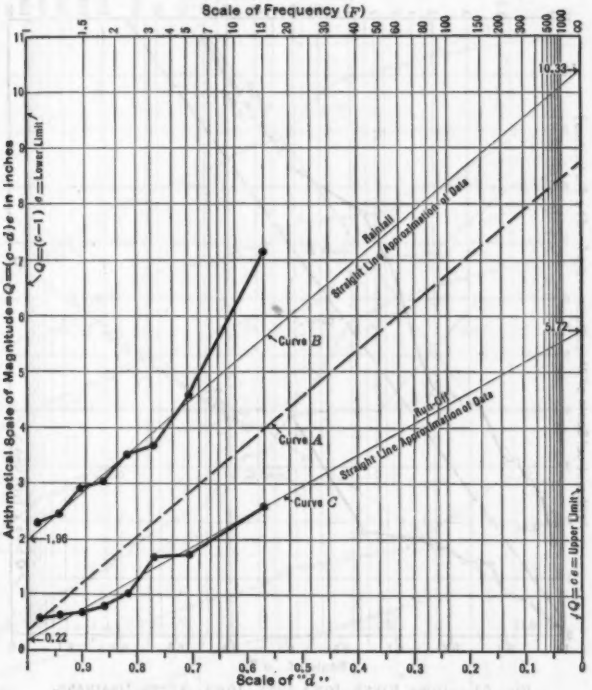

FIG. 50.—IOWA RIVER, IOWA CITY, IOWA, BEFORE DRAINAGE.

A similar process determines the values for the other columns in Table 40, and from these the following relations may be stated:

Des Moines River, Keosauqua, Iowa, Area = 13 900 sq. miles:

Before drainage, the run-off = 40.0% of (rainfall — 1.34 in.)
After drainage, the run-off = 32.6% of (rainfall — 1.31 in.)

Iowa River, Iowa City, Iowa, Area = 3 140 sq. miles:

Before drainage, the run-off = 65.7% of (rainfall — 1.62 in.)
After drainage, the run-off = 47.7% of (rainfall — 1.68 in.)

Assuming that the run-off proportion for the whole area before drainage truly represents the run-off proportion for the undrained area after drainage, then the run-off proportion for the area affected by drainage, on the Des Moines River, is equal to:

$$D = \frac{E - A\,B}{C} = \frac{0.326 - 0.673 \times 0.400}{0.327} = 0.174$$

For the Iowa River the same run-off proportion is equal to,

$$D = \frac{0.477 - 0.535 \times 0.657}{0.465} = 0.271$$

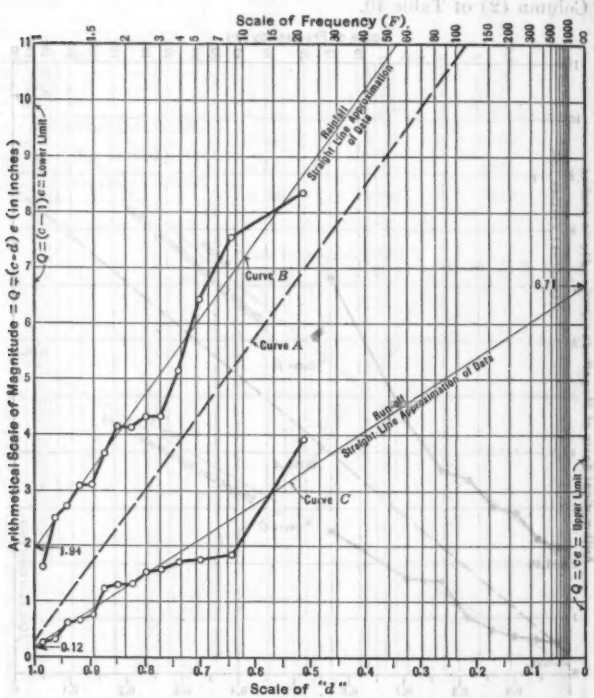

FIG. 51.—IOWA RIVER, IOWA CITY, IOWA, AFTER DRAINAGE.

After the constant deduction, the proportion of run-off from the drained areas on the Des Moines River is reduced from 0.400 to 0.174, or 43.5% of the original proportion. Likewise, the corresponding proportion for the Iowa River is reduced from 0.657 to 0.271, or 41.2% of the original proportion.

Since drainage, for agricultural purposes, is generally installed only in sections having flatter topography and slower rates of flow concentration, the assumption stated as a premise to these final computations is not exactly sound. However, the error thus introduced must be small as compared with the marked effect of drainage which the computations tend to prove.

In the very nature of the regions subjected to drainage improvements, also lies an explanation of the fact that these works show no appreciable effect on the rate of flow depletion after the conclusion of a storm. This rate would seem to be essentially a function of the more flashy portions of the catchment area, and while the writer is compelled to admire the ingenuity of the authors' attack along this line, it is difficult to conceive how drainage works on the slower areas, can be expected to show appreciable effect on this index.

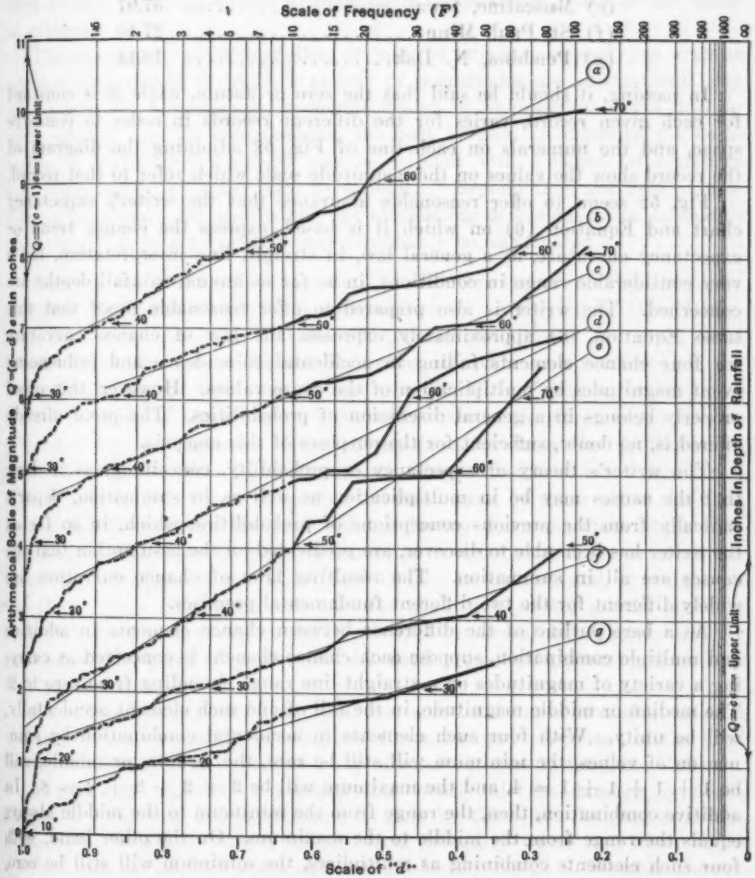

FIG. 52.—ANNUAL RAINFALL DEPTHS.

In Fig. 52, seven of the longer rainfall records of the United States are portrayed on the same chart design used in this analysis. The distribution of the data for each diagram has been effected under the principles of Equation (3), and the straight line approximating the data, in each case, has been

marked by a letter within a circle, for identification. These letters refer to the records published by the U. S. Weather Bureau, listed as follows:

Total annual rainfalls for:	Inches (mean).
(*a*) Boston, Mass.	43.57
(*b*) Philadelphia, Pa.	42.70
(*c*) Marietta, Ohio	41.22
(*d*) St. Louis, Mo.	39.77
(*e*) Muscatine, Iowa	37.07
(*f*) St. Paul, Minn.	27.40
(*g*) Pembina, N. Dak.	18.14

In passing, it should be said that the zero or datum, while it is constant for each given record, varies for the different records in order to conserve space, and the numerals on each line of Fig. 52 adjoining the diagram of the record show the values on the magnitude scale which refer to that record.

Fig. 52 seems to offer reasonable assurance that the writer's expectancy chart and Equation (6) on which it is based, express the chance trend or expectancy curvature, as a general law, in straight line interpretation, for a very considerable range in conditions, in so far as annual rainfall depths are concerned. The writer is also prepared to offer reasonable proof that this same Equation (6) approximately expresses the law of chance curvature for four chance elements falling in accidental coincidence and influencing event magnitudes by multiplication of the cause values. However, this proof properly belongs in a general discussion of probabilities. The proof already offered is, no doubt, sufficient for the purposes of this analysis.

The writer's theory of expectancy or probability, conceiving, as it does, that the causes may be in multiplication as well as in summation, departs radically from the previous conceptions of probabilities, which, in so far as the writer has been able to discover, are predicated on the assumption that the causes are all in summation. The resulting laws of chance curvature are widely different for the two different fundamental premises.

As a bare outline of the difference between chance elements in additive and multiple combination, suppose each chance element is conceived as carrying a variety of magnitudes on a straight-line range extending from zero to 2. The median or middle magnitude, in the fall of one such element accidentally, will be unity. With four such elements in accidental combination by summation of values, the minimum will still be zero, the median, or middle, will be $1 + 1 + 1 + 1 = 4$, and the maximum will be $2 + 2 + 2 + 2 = 8$. In additive combination, then, the range from the minimum to the middle always equals the range from the middle to the maximum. On the other hand, with four such elements combining as multipliers, the minimum will still be zero, the median, or middle, will be $1 \times 1 \times 1 \times 1 = 1$, and the maximum will be $2 \times 2 \times 2 \times 2 = 16$. With four chance elements in multiple combination, it is then evident that the range from median to maximum is fifteen times the range from minimum to median. This may serve to illustrate the radical difference in the curvature under the two conceptions.

It is common knowledge that in the mathematical interpretation of natural phenomena, the known cause elements, especially when rates or velocities enter into the determination, are generally factors in multiplication, instead of items in summation, and it is this fact that tends to support the writer's theory.

The writer hopes that this outlook on the problem under consideration may prove of interest. The subject outlined is endless, and the effort has been to call attention merely to some of the outstanding links in the chain of evidence.

The expectancy method applies, or may be adjusted to apply, to a great number of problems in which a variety of magnitudes are encountered. By this means, for instance, the economic design of engineering works dealing with rainfall and its consequences, the best bargain in capacity for combating or utilizing the run-off may be selected with a degree of certainty that other methods cannot hope to approach. Beyond this, the field of usefulness is perhaps still speculative, but astonishing developments in extending the scope of human knowledge may reasonably be anticipated.

WILLIAM M. HALL,* M. AM. SOC. C. E. (by letter).—This discussion describes the formation of floods and flood crests on the Upper Ohio River, their movement, duration, and relation to the great floods and great flood crests on the Mississippi River. It invites attention to a condition of the movement of storms from west to east over the Ohio Valley which makes it appear probable, if not apparent, that in the case of the Ohio, better service will result by locating some if not all the detention reservoirs on the tributaries entering the Ohio above Cincinnati, Ohio, rather than below Louisville, Ky. It also undertakes to show that the crest wave, or water above the flood line, is the only part of the great volume flowing down the Ohio which it is advisable or necessary to catch in detention reservoirs in order to abate the great flood damage on the Ohio; that it may be caught, and, if caught on the Upper Ohio tributaries and held for about two weeks, it will probably reduce the height of floods on the Mississippi by several feet, thereby greatly increasing the factor of safety for the flood protection project proposed by General Jadwin.

From this Symposium it appears that some additional available data on the subject afford control, showing the formation and movement of the flood crests may be useful in a further study of reservoir sites in the Ohio Valley.

Presumably engineers are aware that nearly all the damage by floods along the Ohio and the Mississippi is done by that part designated as the crest wave, which is formed mainly from tributary water and flows above the flood line or the flood stage plane established by the U. S. Weather Bureau and shown on its daily reports for the gauges at the principal cities and towns along the rivers from Pittsburgh, Pa., to New Orleans, La. To eliminate the damage caused by a flood it is only necessary to reduce or eliminate the crest wave sufficiently; or, in other words, temporarily to detain

* Parkersburg, W. Va.

in reservoirs that volume of water which would flow above the flood stage, as designated by the Weather Bureau.

In general, the floods in the Ohio Valley are produced by storms which approach the Ohio water-shed from the southwest, travel across it from its southerly or westerly boundary to its easterly or northeasterly boundary, a distance of 600 to 800 miles. This meteorologic condition is so uniform it seems safe to assume that, of the great floods, 90% or more occurred from storms which passed from the southwesterly edge of the drainage area to the easterly or northeasterly boundary, occasionally being augmented by a storm from the west or northwest joining the one from the southwest in the area north of the Ohio. Such a condition caused the great flood of 1913. This movement of storms from west to east usually consumes a period of 2 to 4 days from the Mississippi River to the easterly boundary of the Ohio water-shed.

The assembly of a part of the available data on the actual formation and movement of the greatest floods in the Ohio Valley since 1884 appears to explain the formation and movement of flood crests. It may be useful in coming to a final conclusion as to the location of reservoirs in the Ohio Valley for reducing flood crests in the Mississippi, which reservoirs will greatly relieve the Ohio of its present greatest unconquered menace and affliction without undue cost to the Mississippi project.

The writer appreciates the great accomplishment of the authors of the Symposium; also the great amount of work involved in the formulation of a complete report and estimate of cost of the flood control of the Mississippi River in its alluvial valley in so short a time for its presentation to Congress by General Jadwin. Therefore, it would be most surprising if some details of the many elements which affect the problem may not at first have been given too little value. Moreover, as has been well said, it is perfectly sound engineering to consider first the repairs to the levee system, to provide spill-ways or other adequate ways for the release and quick discharge of all the water which may converge from every source in the Lower Mississippi, and thereafter to treat, as an additional factor of safety, the location and building of reservoirs or other aids for the reduction of the floods at Cairo, Ill., and thereby throughout the alluvial valley. In this connection it is well to remember that the flood record of 75 years is very brief for estimating what may occur in the coming 500 to 1 000 years; therefore, it appears that the factor should be made adequate. The writer's work of twenty years on the improvement of the Ohio has involved a familiarity with the formation, movement, and character of its floods and their intimate relation with the Mississippi floods. The additional data here presented may be useful in making the best and possibly the most economical solution of the problem.

In Table 41, the movement from day to day of the crests of thirteen of the largest floods from 1884 to date is shown for nineteen gauge stations, from Pittsburgh to New Orleans. The gauge readings are taken from the records of the U. S. Weather Bureau reports, and from the Mississippi River Commission reports of "highest and lowest annual stages".

The same information is shown graphically in Fig. 53. It also shows the water surface on March 29, 1913, the day of greatest flood stage at Marietta, Ohio, and Parkersburg, W. Va., from which is more easily visualized the effect on that flood of catching the water for five days or more which passed above the flood line from March 27 to April 2 at Catlettsburg, Ky.

An inspection of Table 41 and Fig. 53 in connection with Colonel Kutz' Tables 13 and 14, with a map (Fig. 54) makes it obvious that all or nearly all the great floods in the Mississippi River and the Lower Ohio River have their beginning in the Upper Ohio water-shed. By a comparison of the data it is observed that most of them are not only formed in the Upper Ohio River above the mouth of the Scioto, at Portsmouth, Ohio, but from that locality to Helena, Ark., above the mouth of Arkansas River, the movement down stream is very uniform from all the floods except those of 1897, 1916, and 1920, the movements of which were somewhat checked.

In the flood of 1897 the time of crest at Evansville, Ind.—7 days from Pittsburgh—was prolonged to 28 days in reaching its peak at Cairo, because the very large flood from the Tennessee was unusually slow in arrival at the Ohio. In 1920, the slow movement of 17 days to Cairo appears to be due to a slow and large discharge of several tributaries. In 1916, the 21 days' difference in time of crests at Pittsburgh and Cairo was because the large discharge from the Mississippi (about 41% as large as from the Ohio) was slow in arrival at Cairo. Of the floods tabulated, those of 1916 and 1927 appear to be the only ones in which the Mississippi affected the time of the arrival of the Ohio crest at Cairo, or caused any delay in its movement down stream. The delay was nearly 2 weeks in 1916 and about 2 days in 1927. The quick arrival of the Ohio crest at Cairo in 1907 and 1904 was due to the formation of crests at Pittsburgh on or about the same dates as at Portsmouth, 338 miles farther down stream, which, in turn, was due to unusually large discharges by the tributaries from the Big Sandy to the Kanawhas.

From Table 41, for the thirteen floods the average difference in time of the flood crests at Pittsburgh and Cairo (978 miles) is 13.9 days; omitting the three slow movements in 1920, 1916, and 1897, the average time of passage of crests from Pittsburgh to Cairo is 11.4 days, a minimum of 8 days and a maximum of 16 days. This gives an average velocity of 86 miles per day for the crest movement. From Cincinnati to Cairo, 510 miles, the average difference of time for the thirteen floods is 10 days, or 51 miles per day. From Parkersburg, as far down the Mississippi River as Helena, the movement is fairly uniform, the average time for the 1 285 miles being 23 days, or 47.8 miles per day, the fastest movement being 16 days for the 1907 and 1927 floods, and the slowest, 38 days in 1897. From Helena to New Orleans, 657 miles, the average difference in time of passage of the flood crests given as 21 days is obtained without including the 1927 flood, when an early crest was produced by crevasses and an artificial by-pass which effectually stopped the rise at New Orleans 2 days before the head rise reached Helena.

From these data, personal observation, and study of flood movement, the writer believes that in great rivers like the Ohio, between banks from $\frac{1}{4}$

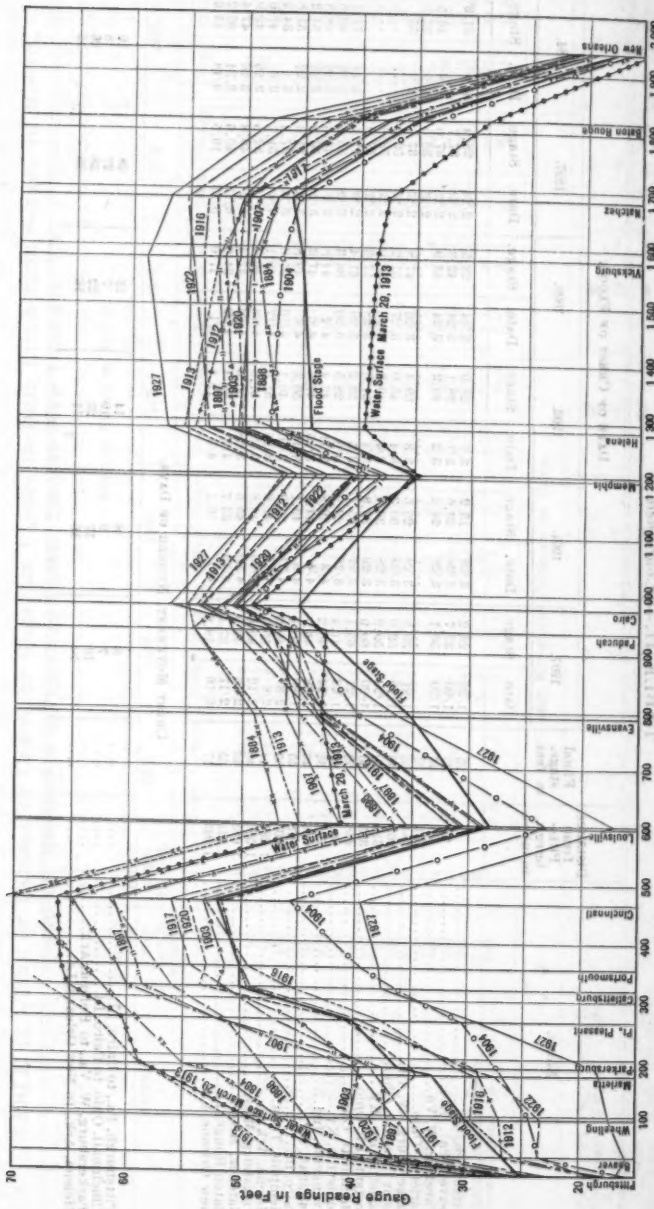

FIG. 53.—FLOOD STAGES OF THE OHIO AND MISSISSIPPI RIVERS.

mile wide at Parkersburg to 1 mile wide near Cairo, and the Mississippi, from ½ to 1½ miles wide between Cairo and the mouth, the great mass of water, flowing 20 ft. or more above the bed of the river and 300 ft. or more from the shores, is so little affected by the friction of bed and banks that the velocity is nearly uniform throughout any section, except where it is more or less disturbed by the inflow from large tributaries and by going over the 26-ft. fall at Louisville.

As may be observed from Fig. 54, between the Scioto, at Portsmouth (above which the governing crest peak is usually formed) and Cairo, 610 miles, there are only seven tributaries large enough to cause much disturbance in the crest wave; or, including the Falls, only one dislocation of relative position of the particles of water in the crest wave for each 75 miles of river. It is believed, therefore, that in any great flood crest passing Portsmouth, if the particles of water in any section of the crest, 100, 200, or 300 miles long, could be located and their relative position determined, when passing Cairo, it would be found that in the corresponding section nearly all the water in crest near Portsmouth would be found near Cairo, of course, augmented by the intermingling of the increments of inflow from tributaries.

In a discussion of this subject* the late James A. Seddon, M. Am. Soc. C. E., designated such condition as "perfect flow". The crest wave of approximately so-called perfect flow is probably about 1 000 ft. wide in the section of river from Catlettsburg, at the mouth of the Big Sandy, to Cincinnati, and about 2 200 ft. wide below Paducah, at the mouth of the Tennessee. Due to this increase of width and also to an increase of several miles in width of back-water into side streams and overflowed bottom-land from Paducah to Cairo and down the Mississippi, the effect of catching any definite part of the crest-wave water in the upper section of the river cannot be estimated with accuracy at Cairo.

Although topographical maps of the area up to the high-water plane are not available, it is known that the flood-plane broadens out to a width of several miles over which this crest wave must spread at stages above 45 to 50 ft.; and at its entrance to the Mississippi, it must flow in between levees about 1¼ miles apart. With such approximate data, the water surface area for that 100 miles of river, or the acre-feet of water per foot of depth, is estimated to be approximately 136 000. It appears, therefore, that should the daily discharge of the crest wave from above Cincinnati be reduced by 300 000 to 400 000 acre-ft. (or 150 000 to 200 000 cu. ft. per sec.) for a period of from 3 to 10 days, while the peak of the crest is passing Cairo and entering the Mississippi, the crest height would certainly be reduced by 2½ to 4 or 5 ft., the exact amount depending upon local conditions, such as the stage of the crest peak, the discharge of the Mississippi River above the Ohio, the impounding effect of the levees, etc. Therefore, observations of flow and comparisons of discharge at respective localities appear to be the best guide, until more exact information is obtained as to areas flooded at high stages. The reader may more readily visualize the effect simply by inspecting Fig. 53 and imagin-

ing all the water withheld from Beaver, Pa., to Louisville enclosed by the flood-stage line and the various crest lines.

A study of the greatest floods which passed Cincinnati, 468 miles below Pittsburgh, from 1870 to 1921 (Fig. 55), shows that there were thirty-eight up to or above the flood line (52 ft.) and that their duration above that line was from 1 day to 18 days; that six of them were from 1 day to 10 days above the 62-ft. stage (10 ft. above flood stage), the total being only 30 days in 51 years. At Cincinnati, the fluctuation between high and low water is the greatest on the Ohio, and the duration of floods is probably as great or greater than at any other locality above Paducah at the mouth of the Tennessee.

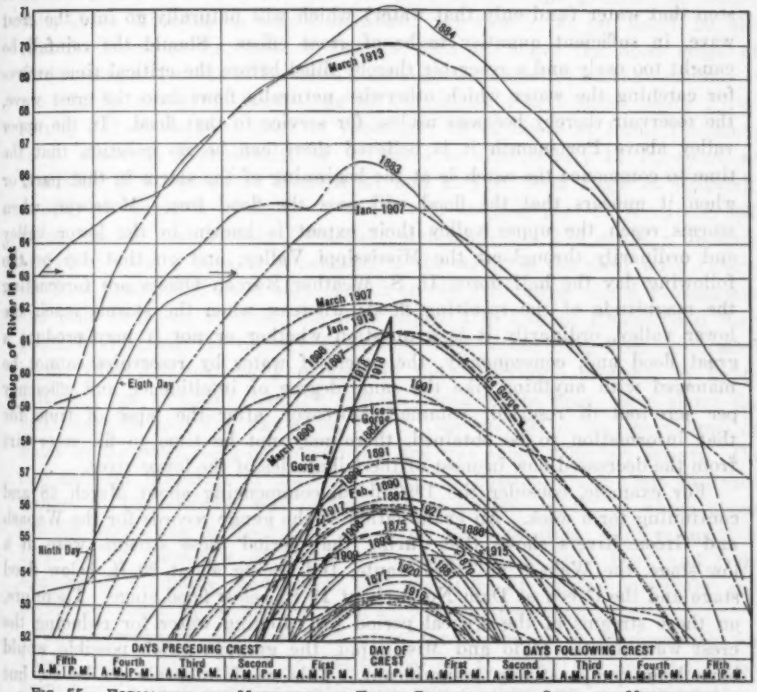

FIG. 55.—FORMATION AND MOVEMENT OF FLOOD CRESTS IN THE OHIO AND MISSISSIPPI RIVERS, SHOWN BY HYDROGRAPHS AT CINCINNATI, OHIO.

Thus, the crest waves, which do practically all the damage along the Ohio, are generally of short duration. As compared with the great volume of water which goes down the river, it is evident that only a small fraction of 1% needs to be caught in order to eliminate the damage; and with one exception in 58 years it has passed in the four months, January to April, inclusive. By a similar study, the passage of the largest floods by Cairo is found to range with one or two exceptions from 12 to 31 days. Therefore, it

is probable that the water which passes Cairo before the stage has reached the flood line, that is, prior to 5 to 10 days before the passage of the peak of the crest, ordinarily does no damage. It certainly does no damage unless it happens to meet a discharge from one or more of the largest tributaries down stream sufficient to produce a flood stage in the lower river; or, unless bottled up by insufficient outlets, a condition which will be relieved by General Jadwin's plan.

Due to this formation and movement of flood crests from the upper river and the condition of ordinarily having rain storms in the Lower Ohio Valley several days prior to those in the upper valley, reservoirs built in the lower valley will probably be found more difficult to fill at just the right time to stop that water (and only that water) which will naturally go into the crest wave, in sufficient quantity to be of great effect. Should the rainfall be caught too early and a reservoir thereby filled before the critical time arrives for catching the water which otherwise naturally flows into the crest wave, the reservoir thereby becomes useless for service to that flood. In the upper valley above Portsmouth it is believed there can be no question that the time to commence the catch is at the beginning of the storm in that part, or when it appears that the flood will pass the flood line. Moreover, when storms reach the upper valley their extent is known in the lower valley and ordinarily throughout the Mississippi Valley, and on that day or the following day the half dozen U. S. Weather Bureau Offices are forecasting the magnitude of the resulting flood; whereas, when the storms reach the lower valley, ordinarily it is a question whether or not it may produce a great flood and, consequently, the catch of water by reservoirs cannot be managed with anything like the same degree of intelligence and efficiency per acre-foot of reservoir volume. Moreover, after the lapse of time for that information to be obtained, there may not be time to fill reservoirs from the decreased flow in most of the tributaries of the lower river.

For example, consider the 1920 flood, commencing about March 28 and continuing for a week. An examination of the gauge records for the Wabash and Green Rivers shows that during that period these streams were at a low stage, the Wabash at Terre Haute, Ind., being about 20 ft. below flood stage and the Green at Dam No. 4 about 18 ft. below flood stage. Therefore, on those streams at the critical period for catching water for reducing the crest wave in the Ohio and Mississippi, the greatest catch possible would have been comparatively insignificant. This would not always be so, but it appears that it would frequently be so. The data on those streams for the earlier floods are not available. It is not claimed that a reservoir on the Wabash or on the Cumberland or on the Tennessee would not be desirable or effectual for some floods or be inadvisable to build, but it is believed the condition named will result in more difficulty in their efficient operation, or in less efficiency than for those in the upper river. Regularity of the movement of the crests from Pittsburgh or above Portsmouth to Cairo largely reduces the objection to the greater distance from Cairo of detention reservoirs on the upper tributaries between the Scioto and the Beaver.

Moreover, should it be determined to operate reservoirs on the lower river solely for the benefit of the Mississippi, that is, to let the crest wave in the tributary run out without restraint regardless of its local damage, and thereafter catch the water which would naturally go into the Ohio and Mississippi River crest wave, a serious conflict of interest might result. It is for this reason that it has been concluded that the Miami River Conservancy cannot be operated for the protection of the Miami Valley and at the same time for the protection of the Mississippi River.

Data for accurately determining the quantity of water in the crest wave are not available, therefore, only an approximate estimate is possible.

The greatest flood of record at Pittsburgh was in 1907 and the greatest on the Mississippi, in 1927, and the 1913 flood is the greatest of record from above Wheeling to near Cincinnati. At 6:00 P. M., on March 29, the 1913 flood was at its crest of 58.3 ft., 22.3 ft. above the flood stage at Parkersburg and about 25 ft. above flood stage at Marietta; on the same day it was slightly below the flood stage at Coraopolis, Pa., 9 miles below Pittsburgh; 7 ft. above flood stage at Wheeling; 20 ft. above at Point Pleasant; 16 ft. above at Portsmouth; 14 ft. above at Cincinnati; 13 ft. above at Louisville; 8 ft. above at Evansville; and at just flood stage at Paducah, possibly the greatest quantity of water ever in that part of the river, 925 miles. In the part between Coraopolis and Louisville, 593 miles, a distance of flow of about 5 days, it is believed, if the water in the crest wave (above the flood line) could have been caught on the tributaries above Portsmouth and held for 15 or 20 days, the time required to flow to Helena, and then gradually released, the damage from that flood would have been eliminated in the Ohio and materially reduced in the Mississippi, probably by 2½ to 4 ft. in stage at Cairo. As the average depth of the crest wave above the flood stage on that day was about 12½ ft., for the 593 miles, the volume of water in the crest wave or above flood line was about 2 000 000 acre-ft. On that date the discharge of the Ohio under the Baltimore and Ohio Railroad Bridge, at Parkersburg, was probably about 700 000 sec-ft., of which about 300 000 sec-ft. was in the crest wave above the flood line. This estimate is based on an inspection of the river, by traversing it in a boat, and from memory of discharge observations and velocities at various low-water and high-water stages up to 45 ft. at Dam 18, 5 miles up stream.

An independent measurement* gives the discharge at Parkersburg for 7 days, March 26 to 31, as 323 654 400 000 cu. ft. (7 450 000 acre-ft.) which harmonizes with the writer's estimated rate of discharge. Applying those rates for the 5 days the river was above the flood stage at Parkersburg and Marietta, it is found that about 1 490 000 acre-ft. passed that locality flowing above the flood-plane and 5 960 000 acre-ft. flowing below the flood-plane; or, if 1 500 000 acre-ft. of that water had been caught at the proper time from the Little Kanawha, Muskingum, Beaver, or other tributaries, and held for 10 days or more before releasing, there would have been no flood damage in that part of the Ohio; and, thereby, a corresponding reduc-

* *Bulletin Z*, U. S. Weather Bureau, 1913.

tion would have occurred in the crest height to the mouth of the Ohio and in the Mississippi until the crest reached the water impounded by the action of the levees. The discharge of the same flood wave at Cincinnati (Mile 470) above the flood-plane, was a little more than double the corresponding discharge at Parkersburg, that is, somewhat in excess of 3 000 000 acre-ft. It was 11 days in passing, and its peak was 17.9 ft. above the flood line. Had that 3 000 000 acre-ft. been caught and held for 15 to 20 days, it would at least have eliminated most of the damage above Paducah and beyond reasonable doubt would have reduced the crest by several feet from Cairo to Helena, Ark., or farther down, if it had not become impounded by levees.

Should a great flood in the Mississippi be mainly produced from other tributaries as occurred in the exceptional case of the 1927 flood, a detention reservoir system in the Upper Ohio Valley could be made effective in reducing stages in the Mississippi by closing the detention dams when that condition was observed from the rainfall or from gauge readings of its other tributaries. It would be entirely practicable to fill the reservoirs, provided the flow in the Ohio was not reduced to a stage below a 10-ft. navigable stage, a very improbable condition. For example, when the flood of 1927 was forming, it was known 10 days before the crest peak passed Cairo that a great flood was approaching, and 5 days before, it was remarked in the Engineer Office at Louisville that the previous record at Cairo would probably be broken.

As the Upper Ohio Valley along the banks of the Ohio River is much more thickly populated than either the part below Louisville, or the Mississippi Valley, and as above Parkersburg the greater part of its banks are densely occupied by industrial plants, the money loss by floods is probably greater per mile of river than from Louisville to New Orleans. The money damage to Dayton and the Miami Valley by the same flood has been stated to be from $30 000 000 to almost $100 000 000. By the same measure for estimating, the loss in the Ohio Valley above Cincinnati by the same flood must have been much more.

It should be realized that on the way down these two great rivers, 1 942 miles from Pittsburgh to New Orleans, it is the same crest water that passes Pittsburgh, Marietta, Parkersburg, Cincinnati, Louisville, and Cairo, doing such vast damage in its passage; and it is a large factor, usually the principal factor, in the formation of the crest wave at Cairo (its contribution in the thirteen floods tabulated being from 51 to 87% of the water passing Cairo at crest stages), which proceeds on down the Mississippi to New Orleans, producing many more millions of damage and untold human suffering. Now seems to be the time for the National Government to join with the Ohio Valley States in eliminating this great menace to property, life, and happiness, by managing it as a part of the larger Mississippi River project.

To those familiar with the construction and operation of a series of locks and movable dams for navigation, such as that on the Ohio, the problem of a system of detention reservoirs appears little or no more difficult; certainly not so difficult as the proposed Ohio System appeared twenty-five years ago. No one can read the Weather Bureau meteorologic report of the rainfall which produced the 1913 flood without concluding that

a greater flood is a possibility if not a probability. That condition, combined with the fact that population and property values are continually and rapidly increasing, makes it appear that the construction of detention reservoirs is only a matter of time. If so, it is possible that land values required for the reservoir sites may increase more rapidly than the interest on the money required for construction.

An estimate of cost of catching 2 000 000 or 3 000 000 acre-ft. of water from any one of the major floods noted is an engineering problem of no greater difficulty than many others which have been successfully solved by many engineers employed by the Government and by many other members of the Society. Of course, such provision for future floods is more difficult, but from a study of the records of all recent great floods over the entire valley, it appears that a system of reservoirs may be devised that will completely or materially reduce the destructive part of every crest wave, and reduce its height at Cairo by several feet; provided the reservoirs are operated so as to be filled from the water which would otherwise go into the crest wave.

It is a customary practice to forecast for the dams under construction on the Ohio, the probable rise from an up-river crest 100 to 500 or 600 miles distant. In the accuracy of such forecast is frequently involved the flooding of coffer-dams, the suspension of construction, and the lay-off from work of hundreds of workmen. From the charts used for such forecast prepared from the record of actual floods the following data are abstracted: Storms producing a flood crest at Catlettsburg, Mile 319, of 31.4 ft., on September 9, 1926, produced rises, as follows:

At Dam 46, Mile 757, about 4½ days later, 8 ft. to a stage of 21 ft.
At Dam 52, Mile 939, about 7 days later, 7 ft. to a stage of 22.5 ft.
At Dam 53, Mile 963, about 7½ days later, 7 ft. to a stage of 29 ft.

Data from this and similar floods were plotted for use as guides in forecasting because the conditions of discharge from tributaries during the periods of their flow appeared to be near the normal. It is realized that the rises indicated are not entirely due to the rise at Catlettsburg, but evidently they are largely due to it. Hence, if all the water which produced the rises at Catlettsburg had been caught and held for a period of 5 to 8 days and then gradually released, no rise therefrom could have occurred at Dam 53, 16 miles above Cairo, where gauge readings fluctuate nearly alike by changes in discharge from above Cairo on either river.

There are no data for determining with exactness the reduction in rise at Cairo from such a catch above Catlettsburg, because no two floods on the Ohio are exactly alike, and because of tributaries the discharge from each of which is a factor in the problem. Notwithstanding, it is customary practice to make such forecasts for periods of several days and distances of several hundred miles and to name within a few hours the arrival of the peak of the crest and its gauge reading within a few tenths of a foot. On the accuracy of such forecasts is based action of much moment.

A further reason for locating a part of the proposed reservoirs on the upper instead of on the lower tributaries of the Ohio is that they may also be made to serve as storage dams for filling the pools of movable dams immediately after raising them. As is well known to navigators on the Ohio, for several days after raising the movable dams there is usually a deficiency of depth of water in the upper part of pools for navigation. The defect has not yet been corrected. When all the locks and dams are finished in 1929, traffic may demand a remedy. It may then be found that to store water on some of the tributaries is the only cure for this navigation defect. As such shortage of water only occurs after the flood season, flood-control dams and navigation-control dams would readily serve the dual purpose.

As to finding possible locations for dams and reservoirs, the tributaries above the Scioto are hundreds of miles long, and in a hilly and mountainous country, the question of engineering may be found to be largely that of comparative costs between the best locations. For example, take the possibility of a choice being made of the Little Kanawha River Valley, the tributary entering at Parkersburg (Mile 185). Between points about 32 and about 102 miles above Parkersburg, there are no railways, no paved highways, a sparse population, no factories of great value, only one bridge, and with a difference in elevation of water level for the 70 miles of about 100 ft. With one or two dams in that valley it is probable that 20 or 25% of the desired storage may be provided, or a storage sufficient for catching the entire discharge for a period of 6 to 10 days. As the writer has traversed the valley he feels safe in stating it is almost beyond question that it will be possible to found such dams on rock ledge at or near the river-bed level.

In conclusion, the reason for building storage reservoirs in the upper valley of the Ohio in preference to the lower valley, thus increasing the factor of safety in the Mississippi River flood-control project, may be briefly stated as follows:

(*a*) The catch of the water in the Upper Ohio tributaries can probably be made with more precision as to efficiency in reducing the crest of Mississippi River floods than one in the lower tributaries.

(*b*) It will add 600 miles or more of river flood protection in the most thickly populated part of the entire Ohio water-shed.

(*c*) The storage dams for flood protection may be used, without detriment thereto, during the low-water season for navigation water supply, thereby improving navigation depths in the pools of the movable dams more quickly than can be done otherwise.

(*d*) Surveys in the Upper Ohio Valley may disclose as favorable and economical sites per acre-foot of storage as in the lower valley.

(*e*) As there is greater population and greater damage in the upper river, there is correspondingly greater wealth of property to be damaged, and, therefore, local co-operation may be more readily obtained and organized. It probably only needs the co-operation of the Government organizing force with

the Ohio River States to induce them to join in planning for the work of construction.

(*f*) Reservoirs in the upper valley will be of as much, or nearly as much, protection to the Lower Ohio River communities along the river as if they were on the tributaries in the lower valley; and their operation should be made as much as 90% efficient in catch of the actual discharge of flood crest water from each storm.

(*g*) Finally, the reduction of 2, 3, or 4 ft. in flood crests at Cairo and thence on down the Mississippi to New Orleans, by detention reservoirs in the Upper Ohio Valley, may be found to be the most positive, the most economical, and the most reliable way of producing such result for the 1 900 miles of river within those limits of great floods. For the welfare of the millions of people dwelling or employed along the Ohio and Mississippi Rivers, it is a question of as great importance as any which ever arose not involving their liberty. Now is the opportune time for its consideration by all those most concerned.

C. E. Ramser,* M. Am. Soc. C. E. (by letter).—The subject of the excellent paper by Professors Woodward and Nagler has long been the cause of a great difference of opinion among drainage engineers, based largely on personal observation, often local in character. The results presented in their paper are especially valuable since they are based on actual measurements of run-off made both before and after extensive drainage operations on the water-shed.

The writer's remarks will be confined solely to the rate of run-off or peak run-off. It is believed that the difference of opinion mentioned has been due chiefly to the fact that the rate of run-off is increased in some instances and reduced in others, depending on the nature of the drainage, governing conditions of the water-shed, such as soil and covering; and intensities and amounts of rainfall considered. As a general rule open-ditch drainage is regarded as increasing the rate of run-off, and tile drainage as decreasing it. This statement being true, it is readily apparent that combinations of the two types of drainage tend to complicate the problem greatly, since, with a certain combination of the two types, drainage would produce no effect on the rate of run-off.

In general, it may be said that the effect of both open-ditch and tile drainage on the rate of run-off is primarily governed by changes in the time of concentration for the water-shed and storage conditions. The maximum rate of run-off for a given rainfall intensity occurs when water from every part of the water-shed reaches the channel at the lower end. The rain that produces this maximum rate must continue as long as the time required for water to flow from the most remote point to the lower end of the water-shed, and the greater the intensity of this rain the greater will be the rate of run-off. It is a well-established fact that, in a general way, the intensity of rainfall varies inversely as the duration. From the foregoing it follows that the reduction in the time of concentration of a water-shed increases the rate of run-off. Open ditches which increase the

* Senior Drainage Engr., Bureau of Public Roads, U. S. Dept. of Agriculture, Guthrie, Okla.

velocity of the water reduce the time of concentration for the water-shed. Tile or sub-drainage tends to increase the time of concentration since a longer period is generally required for the water to move through the soil and sub-drainage channels than over the ground surface and natural channels. Where open ditches induce sub-drainage for long distances through pasty or sandy soils, the effect of sub-drainage would be to counteract the effect of open-ditch drainage on the rate of run-off.

The storage of water on a water-shed tends to reduce the rate of run-off. Open ditches which eliminate storage in swamps and old lake beds, or reduce the height and duration of overflows on adjoining lands, have the effect of increasing the rate of run-off for rains such as are ordinarily provided for in drainage improvements. It is conceivable that a rain could occur, with a duration greatly in excess of the time of concentration of the water-shed, that would produce practically the same maximum rate of run-off before and after drainage for certain water-sheds. In tile or sub-drainage the storage of water in the soil tends to reduce the rate of run-off to the point of saturation of the soil.

It appears to the writer that while the conclusions reached by Professors Woodward and Nagler are sound for water-sheds on which both tile and open-ditch drainage have been extensively practiced, it is not believed that the results are generally applicable to all water-sheds in the Mississippi Valley, such as the St. Francis and Little Rivers on which considerable open-ditch drainage, but comparatively little tile drainage, has been done.

T. KENNARD THOMSON,* M. AM. SOC. C. E. (by letter).—It has been estimated that the flood of 1927 caused a loss of $1 000 000 000, of more than 200 lives outright, and that more than 700 000 people lost their homes. In addition, the number of people whose health was shattered and whose lives were shortened from exposure and worry, must be appalling.

While the 1927 flood was the highest, those of 1912 to 1916 and many other years were also very high. Even the so-called ordinary floods, of frequent occurrence, cause enormous direct and indirect losses. Surely, therefore, a radical remedy is justifiable.

Levees which raise the water level 50 ft. above the surrounding country are a standing menace to life and property, especially as they are so easily destroyed.

The writer has read with great interest and some sorrow the various papers of the Flood Symposium. None of the very able engineers has taken the "bull by the horns" and submitted a real remedy.

The proper solution is the application of the old homely saying that, "if one horse cannot pull a load get two or more". The specific plan devised by the writer is shown in Fig. 56. He is satisfied that the Mississippi River problem can be economically solved by creating four new rivers, with non-corrodible banks and bottoms, one in the approximate location of the present river, and the other three as Rivers *A*, *B*, and *C*. For the sake of clearness

* Cons. Engr., New York, N. Y.

only a few contours are shown and the thousands of smaller rivers and streams have been omitted.

River A.—The construction of River *A* should start at the Gulf of Mexico, about 300 miles, more or less, west of the mouth of the Mississippi River; 100 miles from its mouth, it would have an elevation of 100 ft.; 300 miles, 500 ft.; and 700 miles, 700 ft. It would tap the Missouri River near Kansas City, Mo., at a cost of less than $200 000 000 per year for 20 years; but long before reaching the Missouri the profits from the construction should be realized, thus ensuring the construction of Rivers *B* and *C* and the reconstruction of the Mississippi.

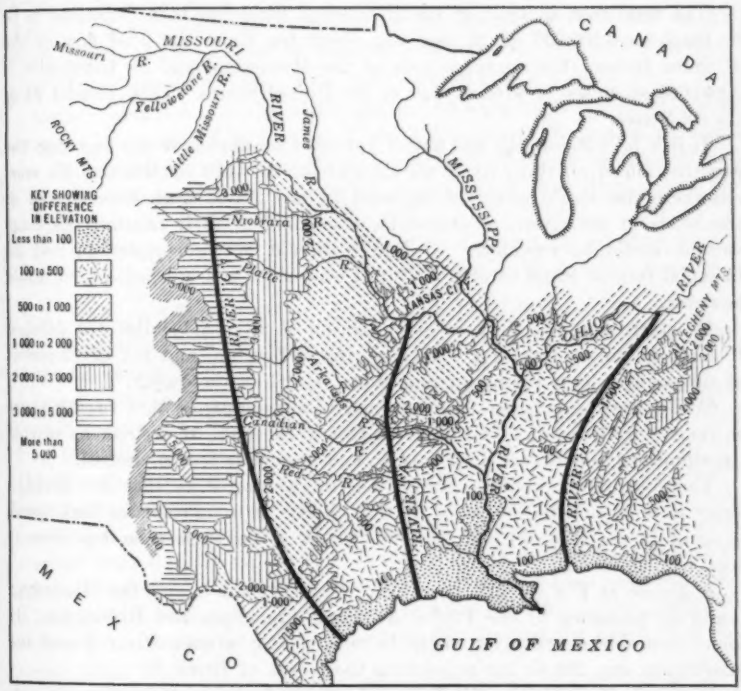

FIG. 56.—PLAN OF THE MISSISSIPPI RIVER VALLEY.

River B.—The work on River *B* should commence 100 miles, more or less, east of the mouth of the Mississippi, on the Gulf of Mexico; 100 miles from the mouth of River *B* its elevation would be 100 ft., tapping the Ohio River near Ashland, Ky., or near the Big Sandy River.

River C.—River *C* should have its mouth on the Gulf of Mexico about 500 miles west of the mouth of the Mississippi; 80 miles from its mouth its elevation would be 100 ft.; 120 miles, 500 ft.; 150 miles, 1 000 ft.; 450 miles, 2 000 ft.; 600 miles, 3 000 ft.; and 1 100 miles, 4 000 ft., where it would con-

nect with the Niobrara River. If found desirable River *C* could eventually be extended in a northwesterly direction to the Canadian border.

Engineers should control and utilize the forces of Nature instead of allowing such forces to create ruin and havoc as is usual in all cases where floods are not controlled.

To realize the potential values of such huge heads and volumes of water a comparison might be made with the Great Lakes: Lake Superior has a surface elevation of only 600 ft. above sea level (its bottom is 150 ft. below sea level), and the mean flow over Niagara Falls is about 220 000 cu. ft. per sec. When fully developed, the water power of the Niagara and St. Lawrence Rivers will be worth more than $2 000 000 per day.

The flood flow, in 1927, of the Mississippi River has been estimated to be as much as 3 500 000 cu. ft. per sec., about ten times the flood flow of the Niagara River. The drainage area of the Mississippi and its tributaries is 1 240 050 sq. miles, or 41% of that of the United States. This includes 24 of the 48 States.

It will be noticed that the writer has tried to emphasize the fact that the construction of all these rivers should start at the Gulf of Mexico. To start anywhere else would result in financial failure, for if work were started at the heads of the rivers, or elsewhere, instead of at their mouths, the excavations would be repeatedly filled up with silt before completion, and no financial returns could be obtained until each river was finished, which would be never.

By starting at the Gulf, as every section of 50 or 100 miles was finished it could be turned over for operation, for navigation, and the development of the country, thus giving an immediate return on the outlay.

While, for the purpose of estimating, it was suggested that twenty years be taken for River *A*, as a matter of fact work could, if desired, be started simultaneously on Rivers *A*, *B*, and *C*, and pushed as fast as desired.

The four rivers would naturally be interconnected so that low or high water in one could be controlled by the others. It is unusual for high water to occur in the Missouri and the Ohio Rivers at the same time, but when it does, trouble results.

A glance at Fig. 56 will show that Rivers *A* and *C* and the Mississippi would be connected by the Platte, Arkansas, Canadian, Red Rivers, etc. If found desirable a new river might be constructed between River *B* and the Mississippi, say, 200 or 300 miles from the mouth of River *B*.

Rivers *A*, *B*, and *C* should all be narrow and deep (say, 1 000 ft. wide and, at least 25 ft. deep) and should be regulated so that navigation could be carried on 365 days per year, instead of being periodically interrupted by both high and low water, as at present, to the tremendous financial loss of the country. All the rivers should have flat slopes and beds lined with concrete so as to avoid scouring of the banks, forming new channels, etc.

Silting basins should be constructed so that the millions of dollars worth of top-soil which is now lost (1 000 000 000 cu. yd. per year) can be collected and distributed where and when needed, irrigating and reclaiming waste land, etc. Two examples that follow illustrate the quantity of this silt:

First.—When building a bridge over the Ohio River near the junction of the three States of Ohio, Kentucky, and West Virginia, the latter two being separated by the Big Sandy River, the writer found low water at 6 ft. and high water at 106 ft., with no soil on top of bed-rock. A coffer-dam about 30 by 60 ft. was landed on rock, but was not sealed, before high water compelled stopping work for the winter. In the spring it was found that the coffer-dam, 25 ft. deep, was filled with silt and there was no means of telling whether it would have been filled more than once if it had been emptied as fast as filled.

Second.—In placing some pneumatic caissons for a bridge in the Missouri River, in South Dakota, the writer did not consider it feasible to dredge a channel to float the caissons from the shore to the pier sites, as the channels would fill up almost as fast as dredged; so platforms were constructed on piles from which the caissons were suspended while being built.

As the drainage area of the Mississippi and its branches is nearly 800 000 000 acres, the increased value of the land, due to navigation, irrigation, reforestation, and general development—to say nothing of the hydro-electrical possibilities—should so enhance the value of the land that these rivers would soon be fully paid for.

Furthermore, the mere undertaking of this project would tend to open up vast territories, to the benefit of the entire Continent of North America.

W. E. Elam,* M. Am. Soc. C. E. (by letter).—That section of the Mississippi River lying between Arkansas City, Ark., and Greenville, Miss., known as the Greenville Bends, is, in many respects, one of the most interesting on the river.† At this point a series of five great bends is lying so close together that 45 miles of the river are compressed into a rectangle of approximately 9 by 10 miles (see Fig. 57). Two points, 40 miles apart by river, are only 10 miles apart in a straight line. Local tradition tells of the Indian, who, having to travel from Greenville to Arkansas City, floated down stream 5 miles, cordelled (that is, pulled his boat) across Leland Neck; floated down stream 4 miles; cordelled across Tarpley Neck; floated down stream 4 miles; cordelled across Linwood Neck; floated down stream 3 miles; cordelled across Ashbrook Neck; and by this process was 30 miles up stream from his starting point without having to row up stream at all. Instead, he had floated down stream about 16 miles.

The Mississippi River Commission estimates the possible range at the upper end of the Greenville Bends to be 78.1 ft. Considerable revetment, as well as two long spurs built to prevent cut-offs, are found in this reach. Here, the greatest change in flow conditions has been caused by the construction of levees, and a large percentage of the discharge flows across necks during extreme high stages of the river. The upper section is one of the wide sections and the lower end, at Warfield, Miss., is one of the much discussed "bottlenecks" that does not entirely bear out popular ideas.

---

* Asst. Engr., Mississippi Levee Board, Greenville, Miss.

† *Engineering News-Record*, June 28, 1928, p. 996.

A detailed study of the hydraulics of this reach would do much to clarify flood control problems. It is an ideal hydraulic laboratory and a few more data on bank-full and lower waters would furnish a complete study of the slope problem that must be solved to get and maintain an adequate channel. Enough information to determine the normal slope is essential, but even this will be of little value unless high and low-water channel lengths and locations are made coincident. Then, determination of the proper length of channel to lower the high-water levels will be possible. It must be recognized that this discussion is a study using "incidental data" and the results can only be accepted as such. The maps and other data used, are taken largely from published records of the Mississippi River Commission and are known to be very accurate; but some vital data are interpolated from known data that may not be close enough for final conclusions.

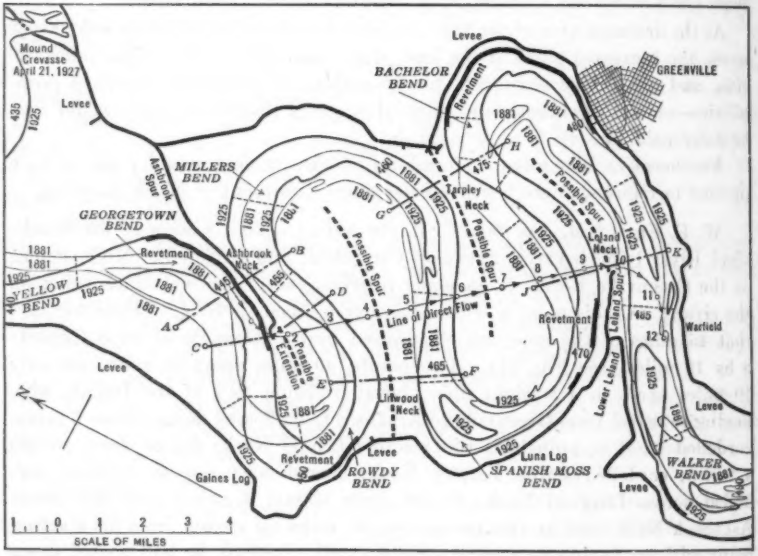

FIG. 57.—THE GREENVILLE BENDS, MISSISSIPPI RIVER.

Physical Features.—Under low and moderately high water conditions this part of the river is a simple channel, 56.74 miles long, from a point just below Arkansas City to Warfield Point about 5 miles below Greenville. When the water level gets above the natural surface of the ground at the neck sections, each neck becomes a weir, by-passing varying volumes of water to the bend below. The ends of these points are much higher than the neck sections and are constantly being built higher with deposit left by each extreme high water. On most, and probably all, of these points are small areas of land that build up almost as fast as the water rises. With a fall of less than 1 ft. from a maximum stage, land begins to appear on these points. The necks show some

tendency to build up, but owing to the depth and velocity of the water, the rate of deposit is not nearly so rapid.

The gauge relation between the Arkansas City and Greenville gauges has changed materially since 1881. Fig. 58 was constructed by plotting the differences in gauge readings for waters cresting between 10 and 30 ft. on the Arkansas City gauge. Two periods were selected, 1882 to 1887, inclusive, and 1922 to 1926, inclusive. The differences are plotted as plus quantities, using Arkansas City as a base. The Arkansas City gauge readings have probably been changing more than the Greenville readings, as there has been less change in channel length and flow conditions immediately below Greenville than between Arkansas City and Greenville. The curves could be drawn by eye through these points close enough for the purpose and show that for waters cresting in the low-water channel, and not flowing across points, the Arkansas City gauge averaged about 3¼ ft. higher between 1922 and 1926 than it did from 1882 to 1887. This is an average increase of about 1 in. per year for the period. Discharge observations are not readily available to compare the discharges over these gauge readings during these periods. Only two stations on the river, showing a maximum discharge in 1927, have been given by the Mississippi River Commission.* These are at Chester, Ill., and Carrolton (New Orleans), La., both far removed from this reach. This change of gauge relation is not in the right direction to indicate increased carrying capacity of the channel and must have some cause in the low-water channel because the writer has not considered any other water in determining the gauge relations. Two main causes that could produce this result are: (1) Lengthening of the channel; and (2) deterioration in the discharge capacity of the channel.

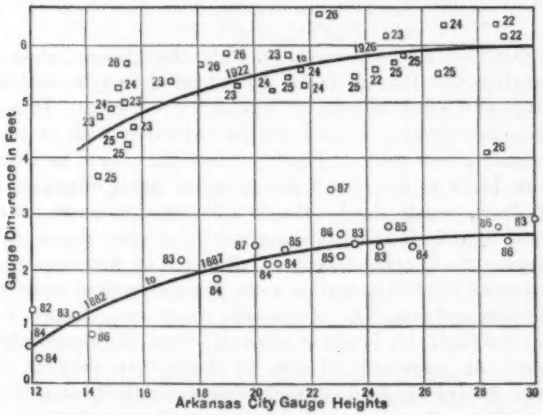

FIG. 58.—GAUGE DIFFERENCE BETWEEN ARKANSAS CITY AND GREENVILLE.

In 1881 and 1925, the length of the channel differs slightly from that given by the Commission. No very great refinement was attempted, but the distances were measured on the map as nearly along the line of the center of gravities of the sections as could be estimated by the eye. The length was

* Special Rept., Mississippi River Comm., November 28, 1927, Special Table No. 5.

estimated to be 48.34 miles in 1881 and 56.74 miles in 1925. The average slope from 1882 to 1887 was 0.218 ft. to the mile, and from 1922 to 1926, it was 0.247 ft. to the mile. This is a considerable increase of slope (in a longer channel) in view of the fact that two of these bends are practically completely revetted. This indicates that revetment alone cannot be depended on to flatten slopes and calls for an exhaustive study of the channel-way. An inspection of the profile, Fig. 59, shows that the channel is decidedly deeper in

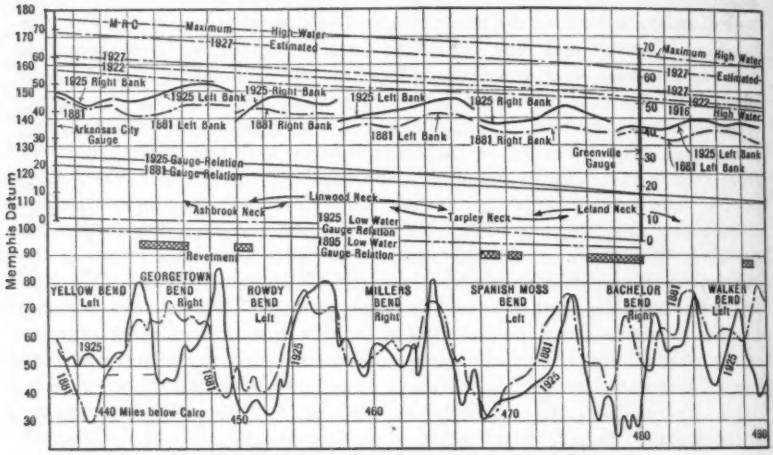

FIG. 59.—PROFILE ALONG CHANNEL, MISSISSIPPI RIVER.

those bends that have the most revetment; yet, the crossings show a tendency to be more shallow now than in 1881. This shoaling is more noticeable in the upper crossings and seems to have no relation to revetment. It is more probable that the crossings are shoaled during extremely high stages when the water is by-passing over necks. The lower crossings could be cleaned out by the draw from below as the river falls, while the upper crossings, beyond the effect of this draw, remain shoal. The area between the levees from Ashbrook Spur to Leland Spur is, in a sense, a reservoir in extreme stages with the main current following the channel except as influenced by flow across necks. The draw across Leland Neck is enough to make practically dead water in Bachelor Bend. The filling and emptying of this area create some changes from normal channel flow, although this is not so apparent from the gauge relation of the higher waters. An inspection of Fig. 60 shows that, in 1922, the average depth of water flowing across these necks was about 10 ft., and, in 1927, about 13 ft. The timber and undergrowth serve to check the velocity and maintain the slope at present. Whether this will continue at higher stages cannot be foretold. Shoaling of the channel in the bend also serves as a balancing influence and helps to maintain the slope.

The break in the slope of the low waters appears to be very much changed since 1881. At that time the upper part of this reach had a slightly steeper

grade, while now the lower section is the steeper and there is a decided hump in the slope through Miller's Bend which is behind Ashbrook Spur and is affected by the by-passing over Linwood and Tarpley Necks. This is shown on Fig. 59. The break in the slope in Bachelor Bend opposite Leland Point shows the presence of a constricted channel during high stages at this point, where it is 6 miles between levees, and also 9 miles above the "bottle-neck" at Warfield, where the levees are only 6 600 ft. apart. In extreme stages so much

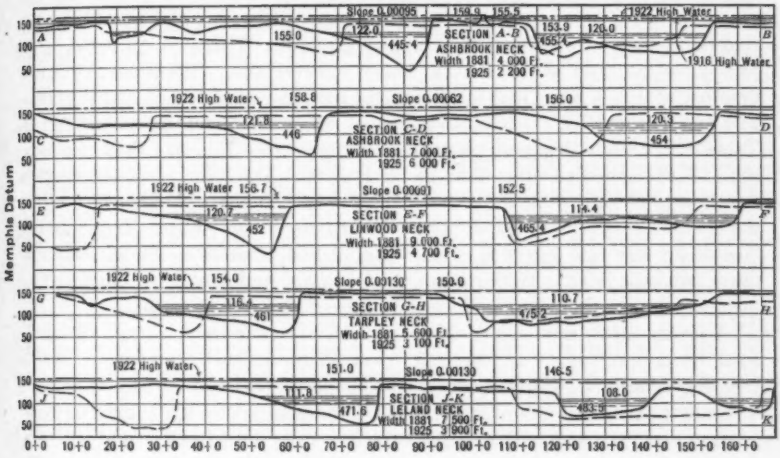

FIG. 60.—SECTION ACROSS NECKS, MISSISSIPPI RIVER.

water is passed over Leland Neck that there is practically no current in Bachelor Bend and the constricted channel is probably due to deposit dropped when the water is checked. The heavier materials would not be carried over the neck and would stay in the channel until dropped by the diminished current. It is also interesting to note that the channel is silting up at this "bottle-neck" and that the water lines show that there is no constriction at this point in either low or high water. When the water gets past Leland Neck it seems to have a free outlet. The only explanation for this is that the swift current that prevails here during high stages makes up for the lack of area, but this does not explain why the area is getting smaller. If it was known at what stages and under what conditions this deposit took place, some explanation could be given.

In order to determine the changes that have taken place in this reach, the Mississippi River Commission maps of 1881 and 1925 were reduced to a scale of 2 in. to the mile for working sheets. In the channel 10-ft. contours were drawn from soundings given on the maps. The zero contour on both maps is the estimated water surface of a crest of 20 ft. at Arkansas City passing to a crest of 17.7 ft. at Greenville, which was the gauge relation in 1881. It must be recognized that this discussion is a study of incidental data. The maps are known to be accurate, but this is a use not contemplated when they

were made; also, the exact determination of this water slope is impossible now. The data available are thought to be close and the line to be within a very few tenths of the actual slope.

Fig. 57 is a combination of the two working sheets, except that only 20-ft. contours are shown in the 1925 channel in order to give a better idea of the under-water channel conditions. The levees of 1881 can be ignored as they confined the water ineffectually and could have had little effect on channel conditions at that time. The bank lines of 1881 and 1925 are shown as the estimated water line at 20 ft. on the Arkansas City gauge and 17.7 ft. on the Greenville gauge, instead of the actual high bank. This is for a better comparison of that part of the channel under consideration. Revetment is shown practically as it is now (1928). The dotted lines show the divisions of the channels as separated for studying the changes which are given in more detail in Table 42. Lettered range lines across the necks (see Fig. 57) show the locations of the compiled cross-sections on Fig. 60. The "line of direct flow" is drawn as a straight line from the channel near the end of Ashbrook Spur to the channel just below Leland Spur. At extremely high stages water does not flow along this line where it crosses the channel; but it is the shortest distance from the inlet to the outlet of this reservoir and effects the channel flow in proportion to the volume of water by-passing over these necks.

A profile along this line is shown on Fig. 61. The lines marked "Possible Spur Extension" and "Possible Spurs" were drawn in such a way as to provide as nearly a uniform width of over-bank channel as possible and also to prevent excess by-passing of water over the necks. This would make the lengths of high-water travel very nearly the same as the low-water travel and would probably cause the channel to enlarge and perhaps scour out the shoaled crossings. To do this without reducing the length of the channel enough to compensate for the water that now by-passes over these necks, would probably raise the Arkansas City gauge to greater relative heights as compared with the Greenville gauge. Assuming that the 1881 channel was a natural channel, that length might be a very good guess. It is possible, though, that it might be less and perhaps cause more lowering of the Arkansas City gauge. This is a problem because, when the channel is enlarged, the slope may become flatter. With the by-passing and channel disturbances that now exist, it is not possible to state what the natural slope would be or even what it is now in this reach. From the profiles along the channel this appears to be a very flat section of the river when, in fact, it might be the reverse. There is also some doubt as to what the Arkansas City-Greenville gauge relation would be with a maximum or a 1927 estimated water confined between levees and greatly increasing the flow across these points and further disturbing the slope. The probability is that this break in the slope in Bachelor Bend would be accentuated and the fall across Leland Neck would be greatly increased. The Arkansas City gauge could hardly be reduced because it is just below the foot of a larger reservoir section very similar to this, except that the Arkansas and White Rivers empty into it.

Fig. 59 is based on the 1925 distances, in order to bring all possible points in common and compare changes. The depths of water, taken from sound-

ings, are the greatest in each line of soundings. At crossings, one sounding may be on one side of the river and the next sounding on the opposite side, with no regard to alignment. This method is thought to show more nearly the actual hydraulic conditions than that of following any alignment. Revetment is indicated as well as the approximate surface elevations along the neck sections immediately below each bend. High-water lines are shown as nearly as it is possible to estimate them from elevations along the levees on both sides of the river. The gauge relation in 1881 and 1925 is shown distributed. This distribution is based on only one water in each instance and then is adjusted to average gauge relations.

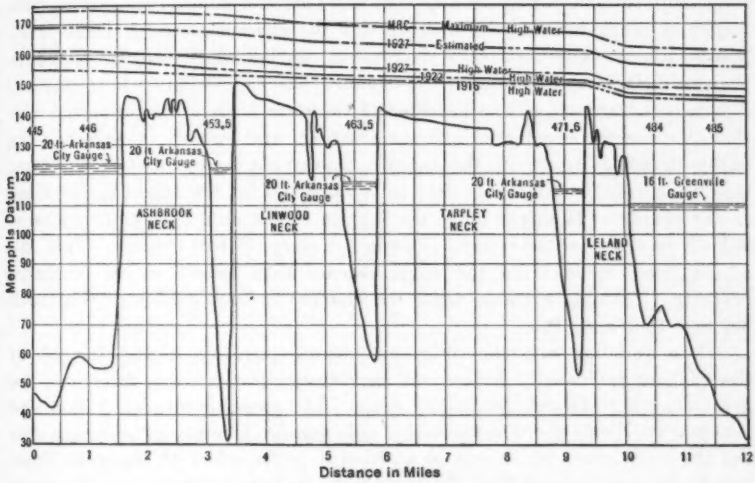

FIG. 61.—DIRECT-FLOW PROFILE.

The Ashbrook Spur was completed after the high water of 1916, and seems to have had some effect on the water lines, although not as much as the general public thinks. The 1916 water shows a depression at about Mile 450 (not shown in later waters) that is probably due to the local effect of the flow across Ashbrook Neck. The Arkansas City-Greenville gauge relation was 5.65 on that crest and 6.03 in 1922. This small increase could be attributed to the lengthened travel of the water in going around the spur instead of across the narrow neck, but lengthening of the channel is the more reasonable cause. During the 1922 high water, rapid currents were very noticeable near the outer end of Ashbrook Point both in the channel and across the point. This must have enlarged that channel to some extent. Scaling this slope on Fig. 59 shows it to have been about 0.17 ft. to the mile in 1916, 0.33 ft. in 1922, and 0.30 ft. in 1927. This is a closer agreement with anticipated results than was hoped for with the data used, and it confirms the assumption that the channel was first clogged up and then scoured out in 1922, restoring the normal slope nearer the critical point through an enlarged channel. This indi-

cates that 0.30 ft. to the mile is approximately the critical slope for this reach of the river. Using this as a basis, the 35 miles of river that existed in 1881 will give a difference of 10.5 ft. in the elevation of the water at these points, which corresponds exactly with the gauge relation curve. This was in a channel that was little affected by by-passing. The distance now is 43.5 miles and calculating the theoretical drop in the same way gives a difference of 13.05 ft. against an actual difference in 1922 of 13.86 ft. This indicates that flow across points helps little and may be a detriment. It also gives the hydrologist something to think about when he is hoping to get relief from high floods by widening the space between the levees. There is no section of the river more suitable for by-passing than this part and none where it is possible to get as much lowering by area outside the channel proper. There is no section where such short travel over necks can be substituted for such long channel distances. Shoaling of the channel must be attributed to by-passing. Navigation interests will be benefited if the river is improved in such a way that the channel is enlarged and the crossings are lowered. Compelling the entire discharge to follow the channel appears to be the first step. After this, some wide crossings may have to be narrowed for low stages by low dikes in the channel. If this is done, the 0.30 ft. to the mile may be found to be slightly in error for the critical slope in the more efficient channel. This will adjust itself by lowering the upper reaches with benefit to the discharge capacity. Table 42 gives in detail the changes in each section of this reach between 1881 and 1925.

Those familiar with the river can advance plausible reasons for any of the changes indicated. A few will be attempted where the differences are great enough to be definite in any sense. The crossing between Yellow and Georgetown Bends shows considerable enlargement (mainly by widening near the low-water line) which can be attributed to the effect of Ashbrook Spur. The Georgetown-Rowdy Bend Crossing seems to have lost area, and this might be due to material that came from above and to the fact that the force of the water was not enough to clean it out. Probably Ashbrook Spur is too short to create the current necessary to do this. Georgetown and Bachelor Bends, both almost completely revetted, show deepening and loss of total area but a gain in under-water area. This shows the good effect of revetment and the evil effect of allowing water to by-pass the channel when the current is best able to carry this material away. The Miller-Spanish Moss Crossing shows a loss of area and depth and an increase of width, probably due to island growth, aided by by-passing. In Table 42 the columns showing channel width are significant. With two exceptions (Rowdy and Miller's) the bends show a decided narrowing and deepening. The loss in area is mainly between low water and 20 ft. on the Arkansas City gauge, while on the average below the low-water line the area shows a gain. This indicates that revetment is mainly effective during low water. It is a little too much to expect to get this effect in high water when the force of the water is expended over the necks.

The writer defines critical velocity as that at which the material forming the bed and banks of the river is on the point of being moved by the force

of the current. This velocity depends somewhat on the material and its resistance against disturbances. Critical slope is the slope or fall per mile necessary to create the critical velocity in the channel under discussion. The critical slope varies with every change of channel shape and channel material. The discharge channel, its size, and shape, depend on the critical slope. If the slope is less than the critical slope, the discharge channel will decrease in area and build up the upper reaches and the slope; if more, the channel will scour and restore the critical slope. The channel can scour either wider or deeper. If it widens, the critical slope becomes steeper; if it deepens the channel, the critical slope flattens. For this reason the river will have to be regulated to a very close margin in order ever to be able to tell exactly what results will follow these changes. While this is being determined the river can be regulated for all practical purposes and lowered gradually to obtain the required discharge channel. One problem to face when this is started will be to keep the sediment in motion, and this can probably be done by shunting most of it into old sections of the river that are to be abandoned, regulating this by a close determination of the slope. To get a channel for the Mississippi River large enough to carry a maximum flood, conditions will have to be created that will set up velocities in excess of the local critical velocities. Adjustment of length and alignment is the simplest method to get this condition. The entire flow must first be concentrated on the desired channel by properly located levees or spurs and further undesired bank caving prevented by revetment. The present concrete revetment used in the Third District, Mississippi River Commission, has about reached the stage where it can be depended on to hold almost any bank.

The Mississippi River has banks in the middle reaches that appear almost fluid at times. The hydraulic adjustments look almost hopeless when changing flow conditions create trouble at unexpected places; but the concentration of the flow along the same location for both low and high-water conditions will, no doubt, remedy this to a great extent.

The reach described is only one of many in the river from Cairo, Ill., to Baton Rouge, La. Beginning 10 miles above Arkansas City is a wide reach about 24 miles long, with an average width of 11 miles, that is even more complicated in its hydraulics. It has the Arkansas and White Rivers emptying into the upper end of it, and the back-water area of these two rivers adds complications to the problem. This area may be one of the places that cause the great range between high and low waters at both the White River and Arkansas City gauges. However, it is so disposed that, by constructing a spur about 17 miles southward from the Laconia Circle Levee, the back-water levels would be materially reduced and would give a more normal slope in the Mississippi River from White River, Ark., to Arkansas City.

All these considerations, then, support the following conclusions:

1.—Changes in gauge relations are due primarily to changes in channel length.

2.—Flow across points, or outside the channel proper, has little effect on slope, unless cut-off is imminent; then the slope in bend is flattened locally, thereby hastening channel deterioration and the cut-off.

3.—Flow across points tends to steepen the general channel slope and raises the upper gauges by checking the water in the bend and causing deposit which diminishes the channel efficiency.

4.—Channel elevations can be controlled to some extent by regulating the distance to tide-water.

5.—Channel capacity can be increased by making high and low-water channels coincident.

6.—Cut-offs require several high-water periods to develop and are seldom, if ever, accomplished suddenly.

7.—A study of channel changes throughout all the cycles of an actual cut-off is essential. Then, knowledge of facts will take the place of opinions.

R. W. DAVENPORT,* M. AM. SOC. C. E. (by letter).—The studies of Messrs. Woodward and Nagler show that apparently there has been no appreciable change in the flood run-off from the Des Moines and Iowa Rivers, caused by extensive development affecting one-third or more of the parts of the drainage areas considered. The authors conclude that agricultural drainage has had a negligible effect on the magnitude of either the total flow or the maximum discharge of the floods of the Mississippi River, since less than 5% of the water-shed has witnessed agricultural drainage operations.

Agricultural drainage undertakes to facilitate the escape of storm waters from agricultural lands and, consequently, when established on a large scale the possibility is suggested that its influence will be reflected by some modification in the regimen of stream flow from that existing in a state of Nature. The conclusion must be accepted, apparently, that particles of water falling on a drained area will pass through a cycle of behavior different from that which would have occurred before drainage. The determination by inductive processes of the net effect of the modified behavior on the resulting stream flow seems quite complex. Moreover, the characteristics of stream flow with respect to quantity and occurrence depend on numerous factors, and the effect of a change in a single factor, unless it is of predominating importance, may be obscured or practically obliterated by variations in the behavior of other factors.

If one can detect no appreciable effect of drainage works on the flood discharges of the Des Moines and Iowa Rivers, it may mean that the effect is relatively so small, in comparison with those discharges, that it is obscured by the variations of factors which are active in the production of floods. If one could determine what the net effect of drainage may be at lower stages where it can perhaps be more easily detected, it might throw some light on the nature of the effect at high stages.

A comparison of the characteristics of stream flow with respect to frequency of occurrence by use of the duration table or curve affords an excellent means of studying changes in the regimen of flow in a given stream by artificial causes. It occurred to the writer that such a comparison for the Des Moines and Iowa Rivers might be illuminating in this instance. Fig. 62 shows the results obtained for Des Moines River at Keosauqua and for Iowa River

* Hydr. Engr., U. S. Geological Survey, Washington, D. C.

at Iowa City. The comparison is made in each case between the 3-year period, June, 1903, to May, 1906, and the 6-year period, October, 1917, to September, 1923. The investigation did not include the Des Moines River at Fort Dodge and Des Moines, because the records were not continuous through these periods. It is recognized that the periods studied are not long enough to show the frequency distribution with close accuracy, but it was thought that they might show evidence of any outstanding changes.

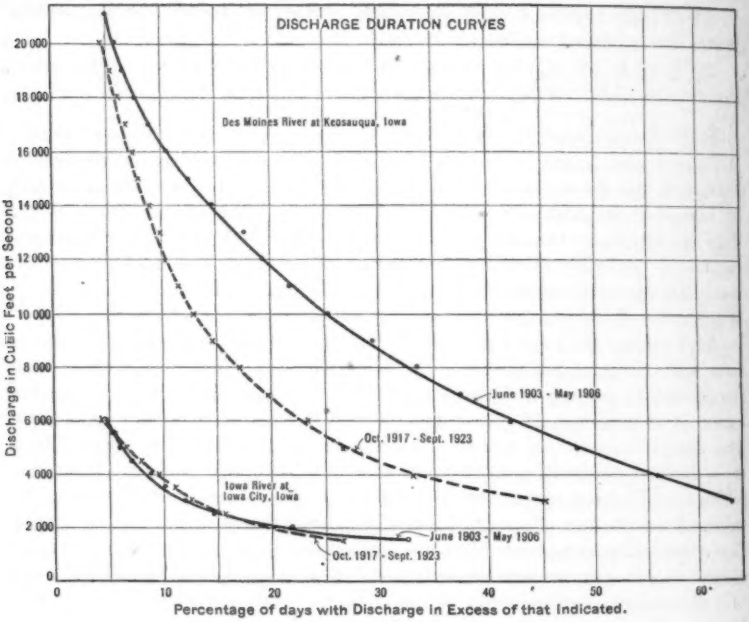

FIG. 62.

Because of inaccuracies involved in estimates of flow in times of ice cover, which, however, generally affect only the lower discharges, no attempt is made to define the duration curve below 3 000 cu. ft. per sec. for the Des Moines River, or below 1 500 cu. ft. per sec. for the Iowa River. Data are not shown for the highest discharges, 5% of the time being taken as defining the upper limit.

The curves for the Iowa River within the limits shown appear to be rather similar for the two periods. There seems to be a tendency for more frequent occurrence of lower discharges in the later period, 1 500 cu. ft. per sec. having been exceeded 33% of the time in the first period and 27% in the second. It may be that the records are not long enough to make this difference of special significance. If it is significant it is consistent with the deduction that the effect of drainage is to reduce ground-water storage, thereby taking away in part the reservoir available for maintaining low-water flow. It would,

of course, be a corollary to this that there must be a corresponding increase in the higher discharges. However, such increase need not have affected the highest discharges. In fact, it seems possible that in a flat country typical of those where drainage is practiced, a condition might exist comparable to that of a lake. If the ground and surface storage on the drainage area, like the storage on the surface of the lake, were utilized to high capacity, the escape of water from the storage on the drained area might be determined to a predominating extent by physical features largely or entirely unaffected by drainage works, in a similar way that the escape from the lake at any given stage is controlled by the characteristics of the outlet and is unaffected by artificial changes in the bed or shore of the lake at a distance from the outlet. Under the assumed condition, facilitating the escape of water from the drained area would become proportionally more effective as the stage of water fell and artificial drainage channels became relatively more influential in the discharge of water.

The results for Des Moines River show a difference in the characteristics of the occurrence of stream flow between the earlier and later periods, which is so great that it is not easy to reconcile it with the facts in an adequate way. The data indicate that the mean flow for the latter period is materially less than that for the former. It appears from superficial examination of precipitation records that there was apparently not sufficient variation between the two periods in regard to this factor to explain any material difference. This is supported by the fact that on the neighboring drainage area of the Iowa River there was no similar wide difference in quantity of run-off between the same two periods. Examination of the data on which the estimates of discharge were based, indicates no probability of any misinterpretation which could adequately account for so wide a variation. The writer's experience leads him to suspect that the apparent difference is probably greater than would be expected unless there had been a change in some important factor entering into the determination of run-off. However, he is unable to reconcile satisfactorily the extent and character of the apparent change in regimen with any probable effect of agricultural drainage.

Although failure to explain this difference may seem to make its consideration of little value to this discussion, it is presented as possibly having some bearing on the validity of conclusions based on the comparison of these records and with the hope that the authors will state from the standpoint of their intimate knowledge what they believe is the correct explanation of the matter.

E. W. Lane,* M. Am. Soc. C. E. (by letter).—Psychological conditions are often major items in flood control. Rarely, if ever, is a locality given adequate protection against floods until after a catastrophe has occurred with damages greatly exceeding the cost of suitable flood-control works. The City of New Orleans, is an extreme case of this condition. In spite of the frequently repeated example of the need of adequate protection in years past, culminating in the damage of several million dollars resulting from the artificial crevasse at Caernarvan during the 1927 flood, the danger from flood is

* Associate Engr., U. S. Engr. Office, Baltimore, Md.

as great as, or greater, in New Orleans than in any city of which the writer has knowledge. Such an obvious condition has not escaped the attention of some of the local engineers, but a frank statement of the situation is frowned upon by those who fear that it may frighten away business, or increase the apprehension of the citizens.

Some of the protection work has been excellently done. Levees with 50-ft. crown, 1 on 4 river slopes, and 1 on 10 land side slopes, inspire confidence. Even if the free-board is slight, there is ample opportunity for emergency topping which will hold stages higher than the poorer levees up stream. However, a chain is no stronger than its weakest link, and in this same main river levee are sections no larger than the old Mississippi River Commission standard, which the 1927 flood demonstrated to be inadequate even for the protection of agricultural land.

The greatest danger to New Orleans in the recent flood was not these main river levees, however, but in its second line of defense. Up stream from the city extends one of the weakest stretches of levee along the entire river. A breach there might flank the main river levees and flood a large part of the city. To guard against this contingency, a protection levee was built from the main river line to Lake Pontchartrain, connecting with the lake levees there. This is little more than a camouflage, however, for with a section of about 4-ft. crown, and 1 on 2 side slopes, with many street and railway openings to be closed with temporary bulkheads of piling or sand-bags, it is utterly inadequate protection for a city of 400 000 population against a flood of a month or more in duration. A large part, perhaps the major part, of the necessity for the Caernarvon crevasse arose from the weakness of this levee, which no one dared trust.

The construction of the Bonnet Carre Spillway, which will no doubt be finished as one of the first steps of the Mississippi flood-control project, will greatly reduce the hazard at New Orleans from Mississippi River floods, but it has no beneficial effect on what is perhaps a greater danger; that is, hurricane floods from Lake Pontchartrain. This lake lies north of the city and has an area of 600 sq. miles. It is connected to the Gulf of Mexico by two large passes. With the rapid growth now in progress, the city will soon occupy all the land between the lake and the Mississippi River. Much of this area is less than 2 ft. above Gulf level, some of it being below mean tide. To protect the city against rises in the level of this lake a levee, much of which is not more than 5 ft. high, extends along the shore. Through this levee, leading into the heart of the city, are several canals, the banks of which are only 2 or 3 ft. high. There are no gates or other protection works where the canals pass through the levee.

The Gulf coast is subject, at not infrequent intervals, to high tides due to West Indian hurricanes, which sometimes raise the levels 10 ft., or more, above the ordinary levels. New Orleans has been especially fortunate thus far in having escaped disaster from these storms. In 1915, the center of such a storm passed nearly over the city, but just enough to the proper side so that the wind blew from the city toward the lake, pushing back the water from the city. On the other side of the storm center, where the wind blew from the lake toward the

land, great damage occurred. On the main double-track line of the Illinois Central Railroad the rails were lifted bodily from a fill as high as the levee protecting New Orleans, and were thrown over into a swamp.

The situation at New Orleans is quite similar to, but even worse than, that at the towns along Lake Okeechobee, which were so badly damaged by the storm that passed over Florida in October, 1927, and which suffered so terribly in the storm of September, 1928. It is greatly to be hoped that the engineers who realize the situation will be able to secure support for adequate protection before "the horse is stolen".

C. McD. Townsend,* M. Am. Soc. C. E. (by letter).—As stated in the opening address of the Symposium, its object was to determine "in the further control of the river, to what extent shall levees, dredging, reservoirs, spillways, floodways, and other safety measures be used." The papers presented furnish many data on the subject, and elicit numerous differences of opinion.

Prior to the flood of 1927, the Mississippi River Commission attempted to solve a fairly simple problem: What was the best means of controlling the greatest flood that had then occurred in the Mississippi Valley? The Commission had a definite standard, the flood of 1882, which exceeded all those that had been recorded during a period of 142 years, and it arrived at the conclusion that a levee line of a computed grade was the cheapest method of regulating such a flood.

The flood of 1927, far exceeding that of 1882, has established a new standard; and this Symposium has not been devoted to a solution of the problem thus created, but to a determination of the best methods of controlling any flood which may occur. There is no precedent which can be used in a prediction of the greatest possible flood. Its determination depends on the mental peculiarities of the one who makes the prediction. Mathematics affords an excellent method of deducing conclusions from known premises, but when the premises are dependent on the vividness of the imagination, a mathematical analysis merely obscures the issue.

It has been clearly demonstrated that with the excessive rainfall which occurred in the lower valley during the flood of 1927, the average discharge curves determined from preceding floods, gave too great results, and that the factor of safety of 3 ft. adopted in determining levee heights was too small. It would be practicable to adjust those factors to the conditions which existed in 1927, but when it comes to substituting for the observed maximum discharge of 1 800 000 sec-ft. at Cairo, Ill., during the flood of 1927, such figures as either 2 250 000 sec-ft. or 3 000 000 sec-ft., the assumed mathematical solution becomes merely a flight of the imagination concealed under a mass of figures and mathematical symbols. The data furnished by this Symposium indicate that no standard can be established for determining what will be the characteristics of the greatest flood which can occur. Under such conditions the most logical proposition which has been advanced is to return to a grade line similar to that originally proposed by the Commission of 3 ft. above the heights

* Col., U. S. A. (*Retired*), Washington, D. C.

attained by the flood of 1927, with spillways to relieve local conditions below the mouth of Old River; and to attempt by suitable means to guide the hand of Providence whenever extreme floods occur, so that as little damage as possible will be inflicted.

H. C. FRANKENFIELD,* ESQ. (by letter).—Acknowledgment is made to Dr. Brooks for his interpretation of rainfall data. His discussion of the causes of the spring rains of 1927 is excellent, and constitutes a very valuable contribution to the meteorological history of the great flood of that year.

Attention is also invited to the remarks by Mr. Eiffert relative to the effects of forests as factors in the prevention of floods in the great rivers, and more especially to the influence of the water content of the soil or its absorptive capacity. The controlling influence of the latter cannot be doubted, and knowledge of its character has always constituted a fundamental element of river-stage forecasting.

Relative to the need of co-operation with the U. S. Weather Bureau in the matter of rainfall records it has been stated in another connection† that "at different stations in the same region, records are made at different times of the day". This statement is only partly correct. The river-stage and rainfall records that are directly used by the River and Flood Service of the Weather Bureau are made at approximately the same hour throughout the country, with the exception of the districts west of the Rocky Mountains, where they are about two hours later, although uniform as to hour. The general statement applies to about 200 regular and about 900 special stations, a rather small number it must be admitted, but the largest possible under existing conditions. Other special services with about 350 stations in all also make rainfall measurements at approximately the same morning hour, making a total of about 1 450 stations. In addition, at more than 4 000 other special stations, known as Climatological Stations, where observers receive no compensation whatever, rainfall measurements are made each day about sunset.

Regarding the criticism that the requirement that the times of beginning and ending of precipitation should be recorded is largely ignored, it may be stated that these times of beginning and ending are accurately and fully recorded at the principal Weather Bureau stations, and special observers are instructed also to do this. However, the task is a difficult one for them to fulfill. They do not consciously and deliberately ignore their duties, but perform the service expected of them to the best of their ability. These are conditions which the Weather Bureau strives to overcome and improve as completely as possible, but, nevertheless, they are incidental to the co-operative nature of the personnel, who in reality render a highly valuable service at small expense. The observers, except at the regular stations, are local citizens who are paid only a few dollars per month, and they can neither be driven nor reprimanded for their shortcomings. Attempts in these directions are followed in many

* Meteorologist in Chg. of River and Flood Div., U. S. Weather Bureau, Washington, D. C.

† Discussion of the Progress Report of the Special Committee on Flood Protection Data, by Arthur E. Morgan, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., May, 1928, Papers and Discussions, p. 1663.

instances by prompt resignations and inability to obtain successors. Moreover, in many isolated places, the mental attainments of the observers are not equal to the correct keeping of records, although almost invariably they are able to read a river gauge and measure rainfall correctly.

As to the criticism that "the Weather Bureau records are not more in accordance with engineering needs", the only answer that can be made is that the Weather Bureau has yet to receive from the Engineering Profession any intimation as to what its needs may be. It is scarcely necessary to add that any suggestions from such sources will be given most careful and sympathetic consideration, and will be adopted within the physical capacity of the Bureau.

One further thought is that most hydro-electric plants are provided with river and rain gauges as necessary adjuncts to the proper conduct of their business. Why cannot other lines of activity involving hydrological engineering in some form or other do likewise and furnish copies of their records on their own forms to the Weather Bureau for preservation and future use by those interested? The individual cost will be small and the resulting benefits mutual. Again, when a bridge is in course of construction, why cannot the builders install a river gauge with its zero set at the bed of the river, or at the bottom of flowing water, and its elevation determined by reference to a recognized bench-mark? This is sometimes done, and the gauges need not detract from the architectural effect in any way.

The problem of effective flood control is to be attacked from every possible angle, and its proper solution will demand the best constructive thought of the engineer. The preliminary work involves the gathering and assembling of a great many data relating to precipitation and river stages, many of which the Weather Bureau is now furnishing. The need for these data as a protective measure will continue during the period of active construction work, as the value of precise river forecasting will be so evident as to require no elaboration here.

In conclusion, the writer desires to emphasize the point that for the proper conduct of flood-control work as a whole more river-gauging stations and many more rainfall stations are absolutely needed, and every effort should be made to provide them.

E. F. McCarthy,* Esq. (by letter).—Mr. Eiffert has made a very fair analysis of some of the facts presented in the writer's paper. His summary as to the absorptive capacity of litter conforms closely with available records. However, the fact should be made clear again that this absorptive capacity of litter does not include the duff and humus which may be formed beneath the litter in some types of forest. Moreover, the forest floor owes its water storage capacity to the porous and loose condition of the forest soil induced by frost and biotic agencies under the protection of the forest litter. The water storage capacity of the litter itself is a minor part of the storage capacity of the forest floor.

* Director, Central States Forest Experiment Station, U. S. Forest Service, Columbus Ohio.

The place for reforestation is not on good agricultural land nor on good pasture land, and a ride through any of the hill sections of the Ohio Valley will convince the most skeptical that there are thousands of acres that are not now cultivated nor pastured where the cover of vegetation is too thin to protect the soil from washing. These acres are sources of silt which is filling the stream channels and reservoirs, creating engineering problems, while the hill land is being eroded into the waste-land class. Delay in restoring a timber cover will continue to reduce the possible returns from forest use of this land.

While a good sod cover is doubtless a suitable means for checking erosion, the fact must not be overlooked that such a cover can be maintained with difficulty on steep land and if once the soil is exposed, erosion may make the restoration of a sod cover an expensive undertaking.

WILLIAM KELLY,* M. AM. SOC. C. E. (by letter).—It was unfortunate that the studies of the Reservoir Board appointed by the Chief of Engineers, U. S. Army, and of which the writer was Chairman, could not have been completed before his paper was presented in October, 1927. However, the results of those studies were published† shortly after that date and were used by some of those discussing the paper. It appears proper, therefore, to consider them in this final discussion.

Considerable criticism has been launched against those studies, on the ground that they are inadequate and based upon incomplete data. They have also been attacked on the ground that the U. S. Corps of Engineers long ago took a stand against reservoirs and could not now be expected to reverse itself.

In regard to the first criticism, no claim for great accuracy has been made for the studies. They were no more than preliminary surveys, such as are made by most business concerns to determine whether projects offer sufficient promise to justify the expense of accurate surveys. It is claimed, however, that they were efficiently and honestly made in such a way that the probable errors would favor the reservoirs. Had they shown any reservoirs that offered even a remote chance of economical use as part of a solution of the Mississippi flood problem, accurate and complete surveys thereof would have been recommended. No claim is made that all possible reservoirs were considered, but the cheapest and most effective ones that were found, cost so much more for dependable results than the floodway plan recommended by the Chief of Engineers, that there is no reasonable hope that undiscovered reservoirs might overcome this difference in cost. There seems to be a growing element in this country that considers the United States Treasury inexhaustible and that believes the Federal Government is belittling itself or is far behind these scientific times when it proceeds along the lines that have been proved sound by years of experience not only in the Government service, but in business organizations. It is this element that is most liberal with volunteer advice. Engineering societies should be wary of permitting themselves to be led by the earnestness and eloquence of such advisers into advocating for the

* Col., Corps of Engrs., U. S. A.; Vice-Pres., Buffalo, Niagara & Eastern Power Corp., Buffalo, N. Y.

† Committee Doc. No. 2, Committee on Flood Control, 70th Congress, 1st Session.

Federal Government unwarranted expenditures, economically unsound projects, or the discard of proven organization. The writer is convinced that the preliminary surveys made are sufficient to justify the conclusion that the expense and delay necessary for more accurate surveys of reservoir possibilities for Mississippi floods are not warranted, and that conviction was finally shared by a Congressional Committee with a predisposition for reservoirs.

In regard to the second criticism, during thirty years of experience in the Corps of Engineers, the writer has never encountered a case where pride of Corps has affected the professional judgment of its members. On the other hand, such pride as the Corps has, is in its success in upbuilding its professional proficiency and integrity. The officers of the Corps are no different from other engineers. They are trained to seek facts and to form independent judgment therefrom and are never backward about expressing differences of opinion with each other. The fact that heretofore they have independently but uniformly reached a conclusion against reservoirs as a cure for Mississippi floods is a fairly good guaranty that under the conditions that have existed up to the present, reservoirs could not be economically used to relieve the Mississippi Valley.

Mr. Hall makes the statement that,

"To eliminate the damage caused by a flood it is only necessary to reduce or eliminate the crest wave, sufficiently; or, in other words, temporarily to detain in reservoirs that volume of water which would flow above the flood stage, as designated by the Weather Bureau."

Several others have made similar statements to the writer conveying the idea that, approached from this angle, the quantity of water involved is surprisingly small. It, therefore, seems pertinent to give some data on the size of the Mississippi flood waves. An inspection of the flood waves of 1922 and 1927 in the Mississippi Valley, when the flood was above the danger stage for about 45 days, should convince any reasonable person that the amount of storage to contain the water in the crest above danger stage of the possible maximum flood in the Mississippi River is very great. For illustration, the curves, Figs. 63, 64 (*a*), and 64 (*b*), might be designated "Superflood 1922 Type" at Cairo, Ill., Arkansas City, Ark., and Vicksburg, Miss., respectively. These curves are similar in shape to the 1922 hydrographs, but have the maximum discharge increased to 2 250 000 cu. ft. per sec. at Cairo, with the Arkansas and White River floods of 1927 added. The floodway plan of the Chief of Engineers will care for a flood of these dimensions.

With the present (1914) levee grades, the danger stages are: At Cairo, 58 ft.; at Arkansas City, 60.5 ft.; and at Vicksburg, 58 ft. The discharges of the river at danger stages vary considerably, but for a flood of the kind assumed they have been taken to be: Cairo, 1 810 000 cu. ft. per sec.; Arkansas City, 2 206 000 cu. ft. per sec.; and Vicksburg, 1 978 000 cu. ft. per sec.

A flood of the type shown on these curves would be above the danger stages, as follows:

At Cairo .....52 days with 32 000 000 acre-ft.
At Arkansas City.....51 days with 41 000 000 acre-ft.
At Vicksburg .....60 days with 59 000 000 acre-ft.

Nature provided the Mississippi River with a flood channel adequate for its needs. Man has found it profitable to take away from the river part of this channel. The question now to be solved is, "How much of this flood channel is it profitable to take?" Had it been possible to solve this problem when all the land belonged to the Federal Government it would have been much less complicated, because then benefits in one place would automatically offset damages in another place. Solution at that time was out of the ques-

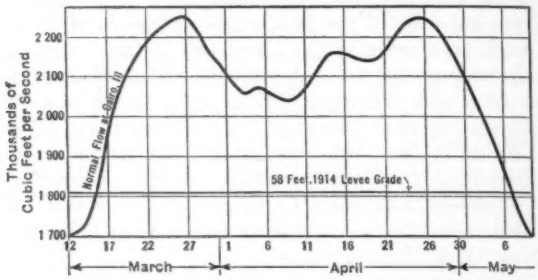

FIG. 63.—POSSIBLE MAXIMUM FLOOD (1922 TYPE) AT CAIRO, ILL.

tion and so the complications incident to ownership by different States, counties, levee districts, towns, and individuals now have to be met. Unprotected land in the valley is worth perhaps from $1 to $10 per acre. Protected land is worth from $75 to $150 per acre, and land in the towns is worth very much more. Each owner would welcome a flood plan that would promote his land to a higher value without expense to him.

The progressive confining of the river between levees has naturally been accompanied by a progressive rising of flood heights in the leveed channel. Heretofore, the funds available have never been sufficient to provide more

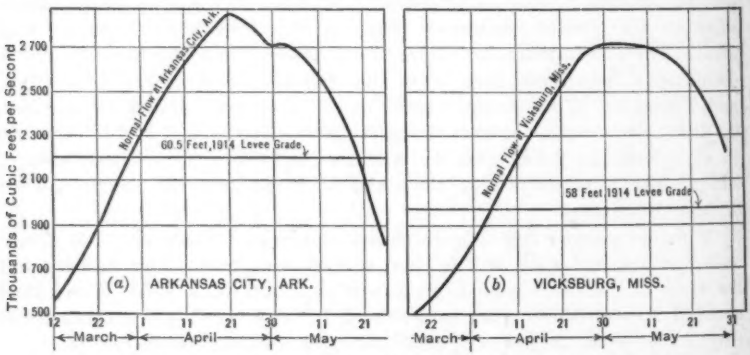

FIG. 64.—POSSIBLE MAXIMUM FLOOD (1922 TYPE) AT ARKANSAS CITY, ARK.

than the partial protection afforded by the present levee system. Property values and population have now reached a point where complete protection is demanded, and can be financed.

There seems to be general agreement that regardless of cost, the present levee heights on certain parts of the river should not be increased. On the other hand, additional channel capacity is essential unless the flood flows can be greatly reduced by reservoir storage. The studies made show conclusively that it is very much more economical to provide additional channel capacity by using a part of the natural flood channels formerly used by the river than to provide sufficient storage to make the present leveed channels adequate.

The development of such flood channels is a principal element in the plan recommended by the Chief of Engineers, and adopted by Congress. The lands within these floodways will be overflowed no more often than they have been in the past. Theoretically, therefore, their value should not be affected. On the other hand, if they could be protected from overflow, their value would be greatly enhanced. It is to be expected that the owners of land in the floodways will feel discriminated against because they are the only land owners in the valley not directly benefited; in fact, there are already indications that they will organize to protest. Whatever the equities in their case, nothing should be permitted to interfere with the development of adequate floodways, to supplement the leveed channels.

These floodways constitute the only safeguard for the remainder of the valley that can be developed within a reasonable time and, in the writer's opinion, they are the most essential part of the solution of the flood problem. If they are provided of adequate width, the flood problem can be solved promptly and economically; without them, no economical solution is possible.

It should be noted that this discussion is confined to flood control in the Mississippi Valley and does not apply to the very different problem of flood control on the tributaries of the Mississippi.

ARTHUR E. MORGAN,* M. AM. SOC. C. E. (by letter).—Probably the largest single engineering work now under construction in Europe is the reclamation of the Zuider Zee. A person examining the project is impressed with the ability and thoroughness with which every phase of this great problem is treated.

In former years there were marked differences of opinion as to proper methods, for the project is complicated, and is of the order of magnitude of the Panama Canal. To-day, however, there is substantial consensus of opinion as to the proper plans. This agreement has been reached, not through administrative discipline of divergent views, but by such a thorough working out of the problem that the essentially best solution is generally recognized and approved.

The Symposium on Mississippi flood control has brought clearly into view the fact that among representative engineers there is no general consensus as to the best solution of this great problem. The conflicts of opinion do not relate simply to details, nor are they confined to unrepresentative members of the Engineering Profession. They affect every significant phase of the problem, and they are held by engineers of every degree of standing and experience.

* Pres., Antioch Coll.; Pres., Dayton Morgan Eng. Co., Dayton, Ohio.

More than that, the orthodox and official program of protection, which was held and vigorously defended for half a century as being the only method to be considered, was suddenly abandoned as a result of the 1927 flood. Except for the spillway studies about New Orleans, La., this sudden change was caused by that flood, and did not otherwise follow any marked sudden increase of engineering understanding of the problem.

So fundamental was this change of plan that it required an absolute reversal of policy on main issues. For instance, the closing of the Tensas River Basin from the Mississippi was part of a deliberately matured policy of half a century, during which, according to the officials in charge of the Mississippi, that stream "was more thoroughly studied and understood than any other great river in the history of the world." The sudden change from this long-continued policy requires the undoing of the recently completed closure near the mouth of the Arkansas River, and the use of the Tensas Basin as the chief relief channel of the Mississippi.

There is no consensus of engineering opinion as to the proper methods to be used in controlling the Mississippi River. The present unity of policy has come by administrative discipline and not by analysis and clarification of the problem and a meeting of minds.

Where such divergent views are found concerning a great problem to which engineers have given so much attention over so long a period, the lack of unity can be explained in only two ways—either the problem is so inherently difficult that few engineers are capable of comprehending it, or else there is a lack of the essential data on which intelligent judgment can be based.

The writer believes that this latter explanation is the true one. For nearly fifty years the doctrine of "levees only" was held by the officials in charge as the only true faith, and, while a large amount of data was collected, it was with that particular plan in view, and many of the data necessary to provide an adequate criticism of that and all other plans, were not developed.

The hurried study made after the 1927 flood could not by any possibility furnish an adequate basis for the best treatment of the problem. The study of reservoirs is an example of this inadequacy. In examining the entire Mississippi water-shed in the course of three or four months with a hastily improvised staff, it was necessary to provide some general and arbitrary standards for measuring the value of reservoir sites. Colonel Kelly has described briefly what these standards are.

In the study of any particular reservoir site the use of these arbitrary standards would result in a failure to find the true possibilities of the reservoir in question. To multiply an inaccurate analysis a hundred times and to take the mean result as representative, is not dependable.

Discussing this point, Professor Woodward states,

"What Colonel Kelly calls dependable operation of flood-control reservoirs, is storage at a uniform rate for a period of 90 days, entirely irrespective of flood conditions on any other tributaries, or any other existing condition. This is perhaps the least efficient system of operation that can be imagined and still be called a system of rational control. It seems probable that reservoirs close to the region to be protected, can be operated three times as efficiently."

There is probably no one in America better equipped than Professor Woodward, both in technical training and in practical experience, for the design of flood-control reservoirs, and the writer believes that this quotation is a responsible and qualified statement of the value of the studies referred to as the basis for determining a great National policy.

The erroneous basis for calculating use is only one of the limitations of this study. The best possible sites for reservoirs, the best dam sites, and the most efficient depth of storage, can be discovered and determined only by a degree of thorough examination wholly beyond the possibilities of the limited time and personnel provided for this study.

The writer believes that an adequate study of reservoir possibilities on the main tributaries of the Mississippi still is to be made, and that to introduce into the creed of Mississippi flood control the doctrine that reservoirs are not feasible, would be premature.

Specifically, he believes that there is a strong probability that 10 000 000 to 30 000 000 acre-ft. of storage is possible on the Ohio and its lower tributaries, and that a development of even a part of this might entirely remove the need for the floodway in Missouri which is included in the present Army plan, and, in connection with the Tensas Basin spillway, or abandonment of certain Louisiana levees, might remove the necessity for any raising of the levee grade over that established before 1927. Adjustment to navigation requirements of such reservoirs on the Ohio River itself would require novel design, but the entire Mississippi problem is unprecedented, and requires unprecedented methods.

The public has often been given explanations of the levee failures in 1927 substantially in the words of Mr. Maltby,

"It is interesting to note that only one break occurred in Government levees built to standard height and cross-section based on the flood of 1912-13. It does not seem that the engineers made any very great error in designing the levee system as proposed."

As every engineer knows who has studied the situation, the Government standards referred to were totally inadequate to control the 1927 flood, even had every levee been built fully to standard. Statements like that just quoted, which were made repeatedly to members of Congress and to the public, represent a questionable type of defense.

The writer would like also to refer to the statement by Mr. Ayres,

"The writer particularly has in mind Mr. Morgan's paper. The case he makes against the Commission seems just a little bit too plausible. For example, he quotes the President of the Commission as having stated in 1912 that $73 000 000 was ample to do all the remaining necessary work on the levee system. This is no doubt a correct statement of majority opinion, but the writer happens to recall that the individual estimate of a civilian member of the Commission—C. H. West, M. Am. Soc. C. E.—at that time, was $250 000 000.

"This circumstance would seem to blunt the point of Mr. Morgan's sweeping denunciation on one score at least and leads to the belief that perhaps other scores would be similarly relieved of harshness if all the pertinent details were known. The impression of blind 'ancestor worship' so artfully created

by Mr. Morgan as the outstanding trait of the Commission personnel seems subject to discount on its face. Furthermore, it is an anachronism to state that the Commission failed to apply 1927 methods to the problems of the preceding century."

The writer made an exhaustive examination of the writings of the U. S. Army engineers and of members of the Mississippi River Commission during the past fifty years, as they appear in the *Transactions* of the Society, *Engineering News, The Engineering Record,* and *Engineering News-Record,* and the estimates in many of the Annual Reports of the Chief Engineers during that period. The figures he quoted are the representative, public statements of these officials, reported publicly and officially from year to year. No higher estimate by these officials was found in this search or omitted from the writer's original paper. What members of the Commission may have said in correspondence or conversation, the writer, of course, does not know. The estimates he quoted are those which Congress, the public, and the Engineering Profession were asked to accept as reliable on the authority of the officials in charge of this work. Such a statement as that quoted leads one to wonder whether at the present time there is the same divergence between the public and official estimates used for securing appropriations, and the private opinions of those most familiar with the problem.

Is it not remarkable, as Mr. Ayres points out, that the majority of the Mississippi River Commission—composed of Army engineers—should be more than 300% in error in their estimates, when a minority civilian member of the Commission had the basis for an estimate more than three times as large, and comparatively adequate? As to Mr. Ayres' remark about applying 1927 methods to the problem of the preceding century, is not foresight the very essence of engineering? The Mississippi River Commission made the flood of 1912 its standard to be protected against, and then announced repeatedly and unqualifiedly in its official annual reports that the completion to that standard would furnish permanent and complete protection from maximum floods. In this case was not ordinary engineering foresight lacking on a vast scale?

Mr. Ayres further remarks,

"It would seem almost self-evident that the first step in the solution of any scientific problem is the collection of adequate and indisputable facts; yet this basic phase of the Mississippi question has been undeniably neglected to a large extent, under pressure of restrictive legislation and limited funds. Lack of conclusive information doubtless explains in large measure the divergence of opinion so regrettably apparent, but for this, any indictment of the Mississippi River Commission must be leveled also at the entire profession."

Appropriations for securing the necessary information have been repeatedly introduced into Congress, and have been defeated at the specific objection of the Chief of Engineers on the grounds that adequate information is available. In 1922, the President of the Mississippi River Commission stated* that, "There is no uncertainty as to the outlay that will be necessary to make the levees safe for complete flood control * * *." That is not an excep-

* *Transactions,* Am. Soc. C. E., Vol. LXXXV (1922), p. 1479.

tional statement, but is representative of the attitude of the Commission. The fight to secure a hydraulic laboratory is another case in point. In Europe, the hydraulic laboratory has become fully accepted as an essential method for the study of hydraulic problems of every size, yet the establishment of a National hydraulic laboratory has been vigorously contested and for years definitely prevented by the Army engineers on the ground that it would be useless as an aid in solving the Mississippi flood problem. Only after continued and constantly increasing pressure has been exerted by civilian engineers in favor of a hydraulic laboratory is one now being established.

The Army engineers and the Mississippi River Commission in practice have held the purse strings, have dictated the policies, and have spent large sums in certain types of inquiries. They have definitely declined the cooperation of the profession as a whole, as tendered through the Society. A keen appreciation of the need for fundamental data on the part of those in charge of the work must, of course, precede any prospect for appropriations. In view of repeated assurances of the Mississippi River Commission and of the Army engineers that the data at hand were sufficient for the solution of the problem, the lack of adequate study cannot be attributed to the "pressure of restricted legislation and limited funds," nor can it "be leveled at the entire profession."

The writer has seen no discussion in this Symposium of the difficulties involved in constructing and maintaining the Tensas-Black River floodway from the Arkansas River to the Gulf. This area is almost everywhere densely overgrown with trees, brush, vines, and cane, no less dense than the jungles of Panama. If the area is left uncleared, its capacity for flood flow will be disappointingly small unless a very wide area is flooded, with corresponding damages.

If this floodway is cleared, leveled, and drained, so that it can be mowed with machines, that work will cost $100 000 000 to $200 000 000, and perhaps more. If it is roughly cleared and not maintained, the cost of clearing might be cut in two, but a single growing season will reproduce a young jungle with flow conditions not much better than before. To clear it by hand each year, removing the year's growth of willows and other brush, would entail an annual cost of probably more than $10 000 000 for a strip 5 miles wide and 300 miles long.

To maintain the surface of this area by pasturing, after adequate drainage works had been constructed throughout its length, would require 1 000 000 or 2 000 000 cattle. Any treatment of this floodway will be expensive far beyond any present estimate. The writer believes that the present floodway plans will gradually develop realization of difficulties that will involve the National Government in a maze of damage claims and expense that is not now foreseen.

A careful economic survey, such as should have preceded the adoption of any far-flung plan, might have proved the economy of abandoning most of the levee system on the west side of the river in Louisiana above Natchez, Miss., protecting the relatively small area in prosperous cultivation near Vicksburg, Miss., and paying damages for all other cultivated land for which protection is denied. Such a course would relieve the need for any further present levee

construction from the Arkansas River to the Gulf, and would enormously simplify the whole problem.

This step, combined with a few large dams on the Ohio River, might complete the reclamation for the next half century. The writer would be the last to advise such a program, or any final program, not based on an adequate study.

Mississippi flood control is one of the greatest hydraulic engineering problems in the world. Never was a Government better able, financially, to master such a problem. Summary and arbitrary administrative methods may be necessary to meet present emergencies, to prevent raids on the Treasury for impracticable schemes in all parts of the great water-shed, and to maintain the professional prestige of the organization long in control of policies on the Mississippi.

When those emergencies are met, however, is it not due the territory affected, the American public, and the Engineering Profession, that a thoroughgoing, inclusive, and masterly study be made of the Mississippi problem, drawing on the entire engineering resources of the country, to insure that Mississippi flood control will not be muddled through by the sheer weight of political power and public money, but shall be planned and executed so as to stand permanently as an engineering masterpiece?

MARCEL GARSAUD,* M. AM. SOC. C. E. (by letter).—The writer was deeply gratified to find the views expressed in the Symposium largely confirmed in the engineering report made to Congress by the Chief of Engineers, U. S. Army, early in December, 1927.

No engineer who has a reasonable grasp of the Mississippi River problem will question the desirability of further intensive study, or of the necessity of collecting additional hydraulic and physical data in connection therewith. The writer is firmly convinced, however, that sufficient studies have been made, and that enough data are now available, in order to determine the basic or fundamental considerations of a plan for the control of floods on the Mississippi from Cairo, Ill., to the Gulf, without further delay. It is evident that more adequate levees, compensating diversions, and bank stabilization are the three measures which constitute the most economical and most efficient method of flood protection.

While the writer advocated a spillway below New Orleans, La., he cautioned against permitting velocities greater than those obtained through New Orleans Harbor after the Caernarvon break in the spring of 1927. Since that time, enough data have been obtained indicating serious and threatening scouring at various points, due to a velocity of nearly 9 ft. per sec. This disturbance of the banks is viewed with alarm, and the writer, therefore, has completely endorsed the alternative suggested by the Chief of Engineers, namely, the diversion of 1 500 000 sec-ft. through the Atchafalaya Basin and the construction of a spillway above New Orleans at Bonnet Carre.

This plan would prevent the river from rising above the 20-ft. stage on the Carrollton gauge at New Orleans, even for a super-flood of 3 000 000 sec-ft.

* Gen. Mgr., Board of Port Commrs., New Orleans, La.

reaching the latitude of Old River, and would eliminate the objectionable velocities along the river front at New Orleans.

C. E. GRUNSKY,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—There is one matter connected with a determination of the rate of discharge at the peak of a flood which does not appear to have received sufficient attention in the past. For example, a period of about ten days intervenes between the time a flood crests at Cairo, Ill., and the time of the arrival of the peak of the flood at New Orleans, La. If a sudden rise at Cairo is taken into account, it may be nearly, if not quite, ten days before the effect of this rise begins to be felt at New Orleans. In the meantime what has become of the water which, during these ten days, has been added to the original flow of the Mississippi at the upper station?

The answer is simple. The entire discharge of water in excess of the normal flow of the river, at the end of the ten days, must be in temporary storage, either in the river channel or in the basins which receive its overflow at points between Cairo and New Orleans. It is obvious that the river at New Orleans remains high longer under the influence of an up-river flood wave than at Cairo. This must be so, because the river will remain relatively high during the time which it takes the channel above New Orleans to discharge the water temporarily stored therein. It follows, from this consideration, that channel storage is an important factor to be taken into account when the effect of a flood from a tributary or from up-river parts of the water-shed on the rate of flow at some down-stream point is to be determined. The writer has discussed this effect before† and, therefore, that analysis need not be repeated, but its application to such situations as that of the Mississippi cannot fail to show the need of large facilities for channel storage in rivers which have a long course through broad valleys of comparatively slight fall. On the Mississippi River, for example, facilities for water storage must be provided below Cairo either between river levees, in overflow basins, or in so-called by-pass channels. In the Sacramento Valley, California, by-pass areas have replaced the natural overflow basins. In other words, the temporary storage between levees must be provided in a quantity that will cut down the river peak discharge to channel capacity, that is, capacity at highest permissible water levels between levees; or as an alternative, the discharge of the river in excess of such capacity must be allowed to escape.

Much has been said in this Symposium, and in the discussions thereon, relating to the effect of reforestation and the benefits that might be derived from partial flood control by storage in reservoirs. No conclusive demonstration of any dependable favorable effect of reforestation can be hoped for, and, in consequence, it should be assumed, for the present at least, that no benefit therefrom is in prospect. In many cases, reservoirs are very effective in equalizing stream flow, thereby cutting down the peak discharge and aiding in the prevention of disastrous high river stages. It frequently happens, however, as in the case of the Mississippi River, that great floods result from heavy rainfall on a comparatively small area of the river's water-shed. In such

* Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

† *Transactions*, Am. Soc. C. E., Vol. LXI (1908), p. 332.

cases, reservoirs that may be adequate to cut down to reasonable proportions the discharge from other parts of the water-shed, may be of but little or no help in the solution of the flood-control problem. Conditions such as those on the Colorado River, where large storage far down on the stream will make possible complete control of the flow from the upper river and its upper tributaries, are rare. However, even in the case of the Colorado River—despite the contemplated regulation of discharge by storage in Boulder Reservoir—the section below Yuma, Ariz., may go to extreme flood stages on rare occasions, as it did in 1905, by reason of heavy rainfall throughout the water-shed of the Gila River, which enters the Colorado River at Yuma.

The writer refers to these matters only to emphasize the fact so well known to the river hydraulician that no general laws on the subject can find universal application. Each river system requires special study.

Very little attention has been given in the discussion of the Symposium to the economical aspects of the problems involved. A consideration of these is usually quite as important as the solution of the engineering problems. Thus, for example, attention must be given, when planning works for the reduction of a river's peak stage, to the cost of acquiring rights of way, flowage rights, etc., as against that of absolute ownership of the affected areas. The writer is of the opinion that a mistake was made in California where rights were purchased to flood at will the so-called by-pass areas. All lands required for occasional submergence, such as the submersible lands in retarding basins and in by-passes, should be owned by the public. If the inundation of such lands is periodical or only occasional they may yet be available for planting to certain crops, and can be leased for such purposes. On the other hand, if privately owned, there will always be more or less uncertainty as to the attitude of the owner, particularly if the functioning of the flood-gates, movable sections of weirs, etc., is not absolutely automatic and unchangeable. Where human judgment must determine the period during which water should be allowed to escape from a river, for example, into a by-pass or into a retarding basin, the possibility of a land owner claiming damages by reason of error in judgment should be forestalled. This can be done only by eliminating private ownership.

SHERMAN M. WOODWARD* AND FLOYD A. NAGLER,† MEMBERS, AM. SOC. C. E. (by letter).—The various discussions of the writers' paper have contained numerous interesting and useful suggestions. The writers tried to deduce in an unprejudiced and impartial manner the most complete and reliable conclusions that could be drawn from the data that were available to them, but it is evident that the subject is not exhausted. It is to be hoped that the accumulation of future data will enable still more complete and convincing studies to be made.

Mr. Moyer's discussion of forecasting future frequencies of phenomena like rainfall and run-off shows the possibilities of mathematical analysis in this direction, but his empirical methods are too intricate to be followed readily by most readers, so that some further discussion of fundamental elementary principles seems warranted.

* Prof., Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.
† Prof. of Hydr. Eng., State Univ. of Iowa, Iowa City, Iowa.

Frequency or Probability of Recurrence of a Phenomenon.—Using annual rainfall records for the purpose of illustration, suppose records for 12 consecutive years are available. If these are arranged in order of size and are numbered—the smallest, 1, the next, 2, etc.—the last and largest will be 12.

No. 12 having occurred once in 12 years may be said, according to this record, to have a probability of recurring once in 12 years, or to have a frequency of 12 years.

Similarly, it might be said that No. 11 has been reached or exceeded twice in 12 years, and so has a frequency of 6 years. Likewise, No. 10 would have a frequency of 4 years; No. 9, a frequency of 3 years; and No. 7, a frequency of 2 years.

The general formula* for obtaining the frequency corresponding to any value is:

$$F = \frac{T}{T + 1 - N}; \text{ or, } N = \frac{(F - 1)\ T}{F} + 1 \quad \ldots\ldots\ldots\ldots\ldots (8)$$

Equation (8) seems fairly simple, but it deserves further consideration. While No. 7 has been reached or exceeded on the average once every 2 years, it could also be said that No. 6 has been exceeded six times in the 12 years, or on the average of once every 2 years. With this significance:

$$F = \frac{T}{T - N}; \text{ or, } N = \frac{(F - 1)\ T}{F} \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

For some uses the latter significance of frequency might be the one desired; in other cases, the former. Therefore, in the range, or band, or strip, between No. 6 and No. 7, there is a certain ambiguity or vagueness of meaning.

Suppose that the record becomes ten times as long. For each of the original single recorded values there are now ten recorded values. These will not be identical, but will be spread over the bands or strips between the original values in the 12-year record. Some of the new values will be smaller than the least of the original twelve records, and some will be larger than the greatest. If all the new values are arranged in order and it is desired to find the value of N corresponding to $F = 2$, for example, it will now lie in a choice between the sixtieth and sixty-first recorded value. The range or discrepancy now will be only one-tenth of what it was before. It is evident that as the length of record increases the discrepancy approaches zero. This suggests the question: Can a corresponding value for this final frequency be obtained from the original brief record?

If it be assumed that the original recorded values are so well distributed that each truly represents the middle value corresponding to its possible range, and probably this assumption is as reasonable as any, then it is easily seen that the formula for frequency becomes,

$$F = \frac{T}{T - N + \frac{1}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Using, again, the original illustration of a 12-year record, Equation (10) gives, for the sixth record, $F = 1.85$, and for the seventh record, $F = 2.18$.

* For notation, see p. 910.

The fact that Equations (8), (9), and (10) are all different mathematically, is due in part to differences in definition of the meaning of the word, frequency, and in part to differences in assumptions as to the occurrence of natural phenomena. Each of these equations may be satisfactory for use in some circumstances. Which one should be chosen in any particular case is largely a matter of individual preference or judgment. The writers prefer Equation (10) for ordinary use. Mr. Moyer has evolved still another slightly different form of equation, (Equation (1)). All these different equations give practically the same result for F for small values of N. As N approaches T, however, the different values obtained for F may vary by a considerable amount. For example, in Table 39, the values for F, obtained from Equation (10), differ less than 1% from Mr. Moyer's values, except for the last two or three lines in each part of the table. For Line 8 of the first part of Table 39, Equation (10) gives a value of 16 for F instead of the value, 15; for Line 14 of the second part of the table, Equation (10) gives 28 instead of the 21 in the table. It is just the last values in the table which are known to be most uncertain of interpretation. It is evident that there is no limit to the variations in form that might be assumed for the empirical equation for F, and in the present state of engineering knowledge there is no method of demonstrating conclusively which is the best form.

The next important step in Mr. Moyer's method is the preparation of the graph paper for plotting values of Q and F so that the line obtained will approximate a straight line. The value of F is to vary from unity to infinity, and it is fairly evident that, if uniform scales for F and Q were used in Fig. 48, the resulting curve would be convex upward. In such circumstances it can always be hoped that by distorting the scale for one or both the variables it may be discovered that the curve can be transformed into an approximate straight line.

The scale for F on the upper edge of Fig. 48 evidently resembles the logarithmic scale as it appears on the ordinary slide-rule. A logarithmic scale, however, would have had the disadvantage that it would never reach infinity, although it is not apparent that this fact would be any great detriment in this case. Most investigators in such a situation would probably try plotting Q and F on logarithmic paper, or on semi-logarithmic paper, in the hope of finding a satisfactory empirical rule for distorting the F scale. Mr. Moyer adopted for his use the relationship represented by the rectangular hyperbola

With the hyperbola represented by the equation:

$$d = \frac{1}{F} \qquad (11)$$

$d = 1$ when $F = 1$, and $d = 0$ when $F =$ infinity.

By writing:

$$d = \frac{x}{x + F - 1} \qquad (12)$$

the curve has the same properties as in Equation (11) and, in addition, can be made to go through any other desired point by determining the appropriate

value of x. As may easily be found by trial, any constant value of x at about 25 will give a relationship between d and F rather close to that shown by the scales in Fig. 48, throughout much of their extent.

The equation,

$$d = \frac{1}{F^{\frac{1}{4}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

also gives nearly the same relationship between d and F as that obtained by Equations (5) and (6).

By adding two hyperbolic equations containing two constants, v and z, as Mr. Moyer does to obtain Equation (5), a curve is obtained which will go through any two desired points, in addition to the point at which d and F equal unity. It is to be regretted that he did not explain through what procedure he happened to fix upon the values of the constants, v and z, which he adopted to give Equation (6).

Mr. Moyer has displayed much ingenuity in deriving his empirical equations, but before these equations can be generally accepted it will probably be necessary to show two things: First, that these forms are better as regards simplicity, accuracy, and convenience, than any other equivalent or similar empirical equations that can be devised; and, second, that the results obtained by the equations are reliable and useful, as proved by some kind of comprehensive and conclusive test.

It is the writers' opinion that the periods selected for comparison are too short to average accidental variations in the frequency of flows of different magnitudes. Hence, while the conclusions drawn from frequency curves such as those prepared by Mr. Moyer, or duration curves such as those used by Mr. Davenport, tend to support the original findings with regard to the effect of drainage on floods, the opposite might have been a likely result from an alignment of the data covering a period of so few years.

In fact, the lines drawn on Mr. Moyer's diagrams do not appear to be determined so definitely by the few scattered points that other lines with different slopes and intercepts might not have been drawn fitting the data equally well. In one trial, the writers eliminated from the frequency data, all values of rainfall and run-off for the month of June, which originally had been selected by design, and not by chance, in using only those June months which had appreciable flood run-off. Better alignment of the curves was obtained in most cases, but different slopes and intercepts were secured, that indicated no positive effect of drainage. This is no criticism of the device used by Mr. Moyer or by Mr. Davenport, which might be applied in comparing two very much longer periods of record; but many factors which affect run-off may not have been averaged in the two periods or they may have been averaged alike in the two basins, as indicated by the duration curves prepared by Mr. Davenport.

In this connection certain comparisons of general hydrologic data are offered (Table 43) as being of significance in interpreting the results shown by the duration curves of stream flow prepared by Mr. Davenport.

The fact that the Iowa River water-shed received 2.27 in. more rainfall in the post-drainage period, while the Des Moines River water-shed received 1.51

in. less rainfall, might account for the difference in the comparative duration curves observed by Mr. Davenport. A comparison of the rainfall received during April to November, inclusive, excluding the winter period in the manner followed by Mr. Davenport, shows approximately the same difference in the relative quantities received by the basins in the two periods. In basins such as those of the Iowa and Des Moines Rivers, where the average annual run-off is only 20% of the precipitation, an additional inch of rainfall may have considerable effect on the run-off, especially if it is received in a concentrated unit in the spring or fall.

TABLE 43.

Item.	Average Values for Period:			
	June, 1903, to May, 1906.		October, 1917, to September, 1923.	
	Des Moines Basin above Keosauqua, Iowa.	Iowa Basin above Iowa City, Iowa.	Des Moines Basin above Keosauqua, Iowa.	Iowa Basin above Iowa City, Iowa.
Average annual precipitation, in inches	32.81	30.87	31.30	33.14
Average annual run-off, in inches	6.69	7.54	4.88	6.78
Average annual water losses, in inches	26.12	23.33	26.42	26.36

Average Temperatures in Iowa, in Degrees:

Month.	June, 1903, to May, 1906.	October, 1917, to September, 1923.
January	16.6	21.2
February	17.1	24.4
March	31.1	38.2
April	48.0	47.7
May	59.6	61.5
June	67.2	71.0
July	71.4	74.8
August	70.8	72.2
September	63.5	65.2
October	51.5	52.8
November	37.9	37.6
December	23.3	23.5
Year	46.6	49.2

The fact that average annual temperatures (and almost every monthly average temperature) were considerably higher in the post-drainage period probably accounts for the increased water losses in the latter period; but the periods are so short that other factors, such as storm magnitude, distribution, and location, might have quite obliterated any effect of drainage as shown by the duration curves. In the year, October, 1917, to September, 1918, the Iowa River Basin received 8.40 in. more rainfall than the Des Moines River watershed, and the Des Moines River Basin received 6.13 in. more rainfall than the Iowa River Basin in the year, October, 1903, to September, 1904. There were

more rainy days on the Iowa River Basin in the post-drainage period and fewer rainy days on the Des Moines River Basin. During the summer following the notable flood of June, 1903, the Lower Des Moines Basin received heavy rainfall which maintained high stages on the Des Moines River throughout the summer, while the undrained areas in the Upper Des Moines Basin and the Iowa River Basin received no abnormal amounts of rainfall and the Iowa River had relatively lower stages during the remainder of the year. It was the complexity of the effect of the many factors which influence run-off in general that led the writers to test the effect of drainage by the analysis of the individual floods.

The test applied to the rate of depletion was carried to flows as low as the average flow of the stream, which was not reached in some cases until twenty days after the flood crest. The water-sheds are so small that run-off from the flat areas involved in drainage would have been measured for several days at all the gauging stations. The Fort Dodge Station on the Des Moines River is so located within this area that run-off from drainage lands would certainly have been measured at or immediately following the crest of the flood. Hence, the writers found it difficult to agree with Mr. Moyer that drainage would have no appreciable effect on this index.

In regard to the question raised by Mr. Davenport as to the effect of drainage on the low-water stream flow, the writers feel that this would be fully as difficult to determine as the relations which they undertook to study. It is an interesting and important matter, but quite foreign to the subject of the paper. So many unsupported statements of opinion regarding the effect of drainage on stream flow have been made, with little basis of facts, by opponents and advocates of agricultural reclamation, that the writers hesitate to express mere opinions; but it may be worth while to point out that it is entirely conceivable that drainage may reduce low-water stream flow without any corresponding increase in high-water flow.

Paper No. 1710

THE CONOWINGO HYDRO-ELECTRIC DEVELOPMENT ON THE SUSQUEHANNA RIVER*

By Alexander Wilson,† 3d, Esq.

With Discussion by Messrs. William C. L. Eglin, J. V. Hogan, A. W. Clark, H. A. Hageman, and Alexander Wilson, 3d.

For more than forty years the possibilities of power development in the lower course of the Susquehanna River have engaged the attention of engineers and capitalists. The first evidence of contemplated power development in this river is found in the Act of the Legislature of the State of Maryland which was passed in 1884, authorizing The Susquehanna Water Power and Paper Company of Hartford County to acquire, by condemnation, certain property necessary for the proper extension and development of its existing dam or any dam it might locate or build near that site.

This water-power development consisted of a small wing-dam in the bed of the river, an intake channel, head-gate, power plant, and tail-race. Part of this work is still in existence and comprises what might be termed the first water-power development of the Susquehanna River.

Until, however, the growth of the steam-generated electric systems in near-by cities had developed a market capable of absorbing a large part of the energy in the flow of this river, its power development was not economically feasible. In 1910, the Pennsylvania Water and Power Company completed a dam and power house at Holtwood, Pa., which has an installed capacity of 150 000 h.p.

Early in March, 1926, The Philadelphia Electric Company, through its subsidiary, Philadelphia Electric Power Company, and the latter's Maryland subsidiary, The Susquehanna Power Company, under Federal license approved February 20, 1926, started the construction of the Conowingo Dam and Power

* Presented at the meeting of the Power Division, Philadelphia, Pa., October 6, 1926.
† Asst. Chf. Engr., The Philadelphia Electric Co., Philadelphia, Pa.

House, with an initial wheel capacity of 378 000 h.p. (594 000 h.p. ultimate capacity), situated about 2 miles below the highway bridge at Conowingo, Md. The energy generated in this plant will be transmitted to Philadelphia, Pa., at 220 000 volts to be utilized in The Philadelphia Electric Company's System.

As stated, the dam and power house are in Maryland, but the upper half of the reservoir and the greater part of the transmission lines will be in Pennsylvania. This required joint action by the Public Service Commissions of the two States. Also, as the War Department has ruled that the Susquehanna is a navigable river, a license from the Federal Power Commission was required.

Corporate Structure

As The Philadelphia Electric Company will use practically the entire output of the Conowingo development, it was necessary that it should control the operation of the plant. It was also essential, in order to make the securities of the project attractive to the investing public, that The Philadelphia Electric Company should guarantee its completion and be responsible for the payments on which the securities depend for support. As The Philadelphia Electric Company is not allowed by its charter to do business in Maryland, these requirements were met by arranging to have three subsidiary corporations, as follows:

The Susquehanna Power Company, incorporated in Maryland, will own all the physical property of the project in that State, comprising the dam, power house, and tail-race, and parts of the reservoir and transmission lines.

Philadelphia Electric Power Company, incorporated in Pennsylvania, will own all the physical property in Pennsylvania, this being principally lands for the reservoir, and also the greater part of the transmission lines. This Company also owns all the stock of The Susquehanna Power Company. All the voting stock of Philadelphia Electric Power Company is owned by The Philadelphia Electric Company, which also leases the transmission lines owned by Philadelphia Electric Power Company.

The Susquehanna Electric Company, which was formed for the purpose of leasing, for the term of the license, the properties of The Susquehanna Power Company in Maryland, under contract with The Philadelphia Electric Company, will operate the plant and will sell all energy generated to The Philadelphia Electric Company.

As set up, therefore, the Conowingo hydro-electric development is being made by and for The Philadelphia Electric Company, and when completed will be operated as a part of that Company's System. The construction of the development is in charge of the Engineering Department of The Philadelphia Electric Company.*

Construction Organization

The contract for the design and construction of the dam and power house has been awarded to Stone and Webster, Incorporated, which has sub-con-

* This paper was presented and published before the construction work was completed. The final status of the project is outlined in the closing discussion.

tracted the construction of the greater part of the dam to The Arundel Corporation of Baltimore, Md. This Corporation has also been awarded the contract for the relocation of the tracks of the Columbia and Port Deposit Branch of The Pennsylvania Railroad. The contracts for the design and construction of the transmission lines, and for the switching station on the roof of the power house has been awarded to Day and Zimmerman, Incorporated. Construction progress schedules have been carefully worked out, and it is expected that the initial installation will be completed so that power from Conowingo will be available to help carry the peak load of The Philadelphia Electric System in December, 1928.

Precipitation and Run-Off

With the exception of the St. Lawrence, the Susquehanna River Basin is the largest and most important on the Atlantic Coast, and embraces a total area of 27 400 sq. miles, which comprises 47% of the area of the State of Pennsylvania, 13% of the area of the State of New York, and 2% of the area of the State of Maryland.

The annual precipitation over this area, according to the records of the U. S. Weather Bureau, varies from 31.4 to 44.3 in., with a mean of 39.4 in. The run-off which eventually finds its way to the sea through the Susquehanna River, varies from 16.6 to 29.1 in. and averages 55% of the rainfall. The run-off is a minimum in August, September, and October, during which months it ranges from 5 to 30% of the rainfall and averages about 15 per cent. Like all other Pennsylvania streams, the Susquehanna River has a natural run-off which is extremely variable, both from day to day, or week to week, and from season to season.

High water frequently occurs in January from melted snow. Floods accompanied by ice gorges come usually in March and result in a high-water level, although with a lesser volume of flow than at times of clear-water floods caused by heavy rainfalls, occurring over the whole or a part of the watershed as late as June. In the late summer or fall, periods of low water are frequently noted.

During the past century there have been several great floods in this river, the most notable of which was that of June, 1889, which was coincident with, although not caused by, the Johnstown Flood, and which probably exceeded any flood that ever occurred in this stream. It is estimated that during this flood the flow reached a maximum of 730 000 cu. ft. per sec. Reliable official records on the flow of the Susquehanna River taken for the last 31 years at Harrisburg, Pa., show that the lowest minimum discharge there was 2 200 cu. ft. per sec. This occurred in 1909.

The head-waters of this river system are on the elevated plateau which separates the waters which flow south and east into the Atlantic streams from those flowing north and west into the Mississippi, St. Lawrence, and the Great Lakes.

From Northumberland, Pa., situated at the junction of its North and West Branches, the river has generally a fairly uniform grade of 2½ ft. per mile, except for local rapids between the Muncy Dam and Conewago Falls,

near York Haven. Below, or in the lower 40 miles of its course, the slope increases to an average of 5 ft. per mile to tide-water and the width of the river becomes contracted, narrowing into a gorge which, in places, is reduced to a width of 0.2 to 0.5 mile. In the last 27 miles the river drops from an elevation of 225 ft., with an average slope of 5.6 ft. per mile, causing a swift current which has worn a low-water channel of great depth in many places.

Along this lower section, the river has cut its way through a range of table-land, and its bed is walled by steep rocky bluffs on both sides, affording excellent foundation conditions for water-power developments. A part of the fall in this section, as noted previously, has been developed by the Pennsylvania Water and Power Company's Dam at Holtwood. The Conowingo Dam will develop the head from the Holtwood tail-race to within 4 miles of tide-water.

Maximum Elevation of Pool

By agreement with the Pennsylvania Water and Power Company, a pool elevation for the Conowingo Dam, 108.5 ft. above mean sea level, has been adopted. At this elevation the water will be backed up over a part of the tail-race of the Holtwood Plant, which has not yet been excavated, but which, when excavated, will result in the development of increased head and power at the Holtwood Plant. It was mutually agreed that this additional head could be developed more economically at Conowingo, and it was arranged therefore, subject to approval of commissions having jurisdiction, that the Conowingo Pool shall be maintained at Elevation 108.5, the Holtwood Company to share in the Conowingo Plant's gain accruing from the increased head.

Selection of Dam Site

With the pool elevation decided upon, it was desirable, in order to develop the maximum head, to locate the dam as close to tide-water as possible. Here, however, the relocation of the tracks of the Columbia and Port Deposit Branch of the Pennsylvania Railroad Company, on the east bank of the river, imposed a limitation, in that it was necessary to provide a satisfactory grade from the present roadbed at the north end of Port Deposit to the elevation of the relocated tracks above the Conowingo Dam. A grade of 0.35% was finally accepted by the Railroad Company.

Five possible sites for the Conowingo Dam were examined and an exhaustive study was made of the head and power available and the total cost of development at each. The site as finally adopted is approximately 2 miles below the Village of Conowingo, and is far enough north of Port Deposit, Md., to permit the use of the accepted maximum run-off grade on the railroad. A reservoir having an area of approximately 14 sq. miles will be formed. The hills on either side of the river at this location form natural abutments, that on the Cecil County, or east, side rising to an elevation of 250 ft. above sea level, and that on the Hartford County, or west, side rising to an elevation of 155 ft.

The river bed and the banks, to a height well above pond level, are of granitic formation. During the autumn of 1924 twenty-six core borings were

made along the line of the up-stream face of the dam between the two abutments. These were drilled to depths varying from 5 to 30 ft. below the rock ledge, the average depth being about 15 ft. All these cores showed firm hard granite or gabbro. In addition, four borings were made to a depth of 100 ft. below the rock ledge, and these also showed hard rock for their entire length. This rock, when crushed to suitable sizes, is excellent material for concrete. On the east bank there is ample space for the erection of the construction camp and plant and for the storage of materials. Transportation facilities are supplied by the Columbia and Port Deposit Railroad.

The main channel of the river at this site is along the west bank. The power house, therefore, is being built at this end of the dam. Space for the construction plant on this side of the river is somewhat limited, but an old canal which formerly operated on this bank has been partly filled to provide space. To supply transportation facilities for the power-house construction, it was necessary to build approximately 10 miles of railroad to connect with the Pennsylvania Railroad System at Havre de Grace, Md. The tow-path of the old Tidewater Canal afforded an excellent roadbed, requiring very little grading, and within three months of the start of construction work this railroad was in operation.

Dam and Power House

The west abutment of the dam is in a projecting hill of rock, into which the retaining wall section, extending 140 ft. from the power house to the abutment, will be built to form an adequate seal for the impounded waters. The headworks for the power house, providing for eleven main units and two station service units, then extend 950 ft. to the beginning of the spillway section, which is 2 385 ft. long. From the east end of the spillway the retaining wall section continues 1 200 ft. to the east abutment, which also serves as the abutment for the highway bridge over the relocated tracks of the Columbia and Port Deposit Railroad. The seal at this point will be made by a core-wall extending up stream into a heavy embankment at the side of the railroad. As a further protection to the railroad, a core-wall will also be extended from rock to the underside of the ties, between the abutment and the east bridge pier.

The dam is solid masonry construction of the gravity type, founded on rock, at an average elevation 15 ft. above sea level. The roadway of the highway bridge on the dam, will be at Elevation + 114, with parapet walls 5 ft. high on each side. The width at the bottom of the retaining wall section is 67 ft., and at the spillway section, 85 ft. The spillway section, designed to take care of floods up to 880 000 cu. ft. per sec., will have a fixed crest at Elevation + 86, on which will be mounted, for the purpose of regulating the level of the storage reservoir, fifty movable crest gates. These gates will be constructed of structural steel and will be equipped with two roller trains on each gate and with sealing provisions along the vertical edges and bottom. They will be 22½ ft. high by 40 ft. long, and will weigh about 42 tons each. There will also be three regulating gates, 10 by 40 ft., of similar construction, adjacent to the power house. The operation of these gates will be effected by means of three electrically operated, traveling gantry cranes, runway for which has been provided

on the top of the dam and power house. Each of these cranes has been designed for a capacity of 60 tons. Each crane will be equipped with two main hoists of 30 tons each, mounted on a single trolley and operated by the same motor. The hoisting speed will be 10 ft. per min. and the gantry travel speed, 300 ft. per min. A generator driven by a gasoline engine will be installed on one crane for emergency use.

To insure water-tightness of the foundation, grout holes are being provided on 10-ft. centers on the up-stream face. Contraction joints in the dam will be sealed with copper sheets bent Z-shaped, the top and bottom of the Z being built into the abutting sections of the dam.

At the bottom of both the retaining wall and spillway sections, a continuous drain, 10½ ft. from the up-stream face, is to be installed with transverse drains leading to the down-stream face every 45 ft. Piers for the support of the highway bridge and crest gates will be constructed on 45-ft. centers and will be 7 ft. wide.

The power house, as noted, is adjacent to the west shore of the river. The head-works provide intakes for eleven main units and two station service units. By locating the top of the intake openings 40 ft. below the pool level, protection from floating ice has been secured without the expense of constructing the usual rock-fill and skimmer arch to protect the forebay. Structural steel trash racks, in sections, 14½ by 24 ft., will be provided for all units, including the station service units. Sectional head-gates, 14½ by 25 ft., complete with bronze sealing strips, will be provided back of the trash racks for use in case it is desired to unwater the intake passages. The sectional head-gates and trash racks will be handled by the gantry traveler on the dam.

The deepest excavation for the power house will be to Elevation — 20, as required for the construction of the draft-tubes for the Allis-Chalmers water-wheels. The superstructure will be of concrete, with a structural steel frame. The high-tension switching station will be on the roof.

Power-House Equipment

Seven main water-wheel units will be installed, four to be supplied by the Allis-Chalmers Manufacturing Company and three by the William Cramp and Sons Ship and Engine Building Company. Each unit will be designed to have a capacity of 54 000 h.p. at full gate, at 89 ft. normal net head, and 81.8 rev. per min., and will have a capacity of 50 000 h.p. at the point of best efficiency. They will be of the vertical-shaft, single-runner, Francis, reaction type, with plate-steel scroll case and governors of the actuator type, and will be the largest units, in physical dimensions, built to date (1926). The runners will be of cast steel, cast in not more than four parts. Each unit will have a structural steel pit liner or generator support capable of carrying the weight of a 40 000-kv-a. generator.

The governors will have gear-driven flyballs and will be operated by oil pressure. There will be one oil-pressure system for each pair of units. An oil storage and purification system will be provided for all the governors and bearing oil for the seven main units and two station service units.

Two station service water-wheel units, supplied by the S. Morgan Smith Company, will be provided, of 1 900 h.p. each, operating at 89-ft. normal net head and 360 rev. per min. The runners will be of the single, Francis, reaction type, equipped with vertical shafts, plate-steel scroll cases, governors, oil-pressure systems, and appurtenances.

With each main water-wheel unit, a vertical-shaft, butterfly valve, 27 ft. in diameter, complete with operating equipment, oil-pressure system, and accessories, and capable of operating under an 84.5-ft. head on the center line of the valve, is to be installed in the water passages to the runners. Each valve will have a cast-steel housing and a wicket of cast steel, a forged steel shaft, and a plate-steel penstock liner extending 12 ft. up stream. These valves will be operated by oil pressure from a central oil-pressure system.

Two butterfly valves, 6 ft. in diameter, will be provided for the station service units. They will have horizontal, forged steel shafts, cast-steel wickets, cast-iron housings, and plate-steel penstocks connecting the butterfly valves to the scroll cases of the units. A motor-driven operating mechanism will be provided, capable of operating each valve under a normal and maximum head at the center of the valve of 88.5 ft. The butterfly valves will be furnished by the same manufacturers as the respective water-wheel units.

Seven main generators and two station service generators will be installed; four main generators to be provided by the General Electric Company and three main generators and the station service generators by the Westinghouse Electric and Manufacturing Company. Each main generator will have a capacity of 40 000 kv-a., generating at 13 800 volts, 3 phase, 60 cycle, and 81.8 rev. per min., will be direct-connected to a main water-wheel unit, and will be provided with a direct-connected, 715-kv-a., auxiliary, alternating-current generator and a small direct-connected exciter for the auxiliary generator. A separate motor generator set will supply the excitation current for the main generator.

The weight of the rotating elements, together with the hydraulic thrust, will be carried by thrust-bearings on top of the generators. In the generators provided by the General Electric Company a thrust-bearing of the spring type will be used, while the Westinghouse generators will have Kingsbury thrust-bearings. The guaranteed efficiency of these main generators will be in excess of 97.0% at rated capacity.

Each station service generator will have a capacity of 1 600 kv-a., generating at 460 volts, 3 phase, 60 cycles, and 360 rev. per min., will be direct-connected to one of the station service water-wheel units, and will be provided with a direct-connected, direct-current exciter and Kingsbury thrust-bearing.

Stationary power transformers will consist of four banks of three transformers, each having the following rating: 26 667-kv-a. rated capacity, 29 333-kv-a. overload rating, single-phase, water-cooled, 13 800 low-tension voltage, and 127 000/220 000 volts Y at the high-voltage terminals. The guaranteed efficiency at rated capacity is in excess of 99 per cent.

Two power station cranes will be installed in the generator room. They will be of the 4-motor, electric traveling type, each equipped with a 150-ton main hoist and a 25-ton auxiliary hoist. Both the main and the auxiliary

hoists will be installed on a single trolley. The hoisting speed will be 6 ft. per min. and 30 ft. per min., respectively. These hoists will be equipped with alternating-current motors, operating at 440 volts, 3 phase, and 60 cycles.

Two 50-ton transformer traveling cranes will be installed for separate or combined operation. They will be of the 3-motor type, having a hoisting speed of 10 ft. per min. The motors will use alternating-current power at 440 volts, 3 phase, and 60 cycles.

One 15-ton machine-shop traveling crane of the 3-motor type, equipped for control from the floor, will be installed. The electrical characteristics of the motors will be similar to those of the other cranes. A small gantry crane will be installed on a runway over the stop-log slots on the down-stream side of the station, to be used for handling the stop-logs.

The tail-race for the seven main units and the two station service units of the initial development, will require the excavation of approximately 400 000 cu. yd. of rock, of which it is expected a considerable part will be crushed and used as concrete aggregate.

Progress Schedule

The progress schedule contemplates the completion of the initial project in two low-water seasons. Construction camps have been established on each side of the river, that of the The Arundel Corporation, which is constructing the greater part of the dam, being on the east side, and that of Stone and Webster on the west side.

During the low-water season of 1926, a coffer-dam, enclosing the power house and west branch of the tail-race, was constructed, to a height such that it will not be topped by any flood of less volume than 400 000 cu. ft. per sec., so that work on the heavy excavation within the enclosed area can be continued through the spring floods of 1927; also, a coffer-dam has been constructed from the east bank of the river out to within approximately 700 ft. of the power-house coffer-dam. The schedule requires that the dam foundations within the area enclosed by this coffer-dam be poured up to Elevation 22 with alternate sections of spillway up to Elevation 30, or higher, by January 1, 1927. The latter coffer-dam has been built with stop-logs alternating with the rock-filled cribs, so that as soon as the alternate sections are poured to Elevation 40, the stop-logs can be removed, to allow additional passage for the spring floods.

During the low-water season of 1927, the coffer-dam from the east bank will be continued over to the power house, the river flow being taken care of through the stop-log openings in the 1926 coffer-dam and the alternate sections of spillway at Elevation 22. As soon as the foundation of the dam can be poured in this coffer-dam, with alternate sections to Elevation 40, the stop-logs in the coffer will likewise be removed.

As the piers for the highway bridge will be included in the alternate sections of the spillway, which are to be carried up ahead of the closure sections, these must be pushed to completion so that the highway bridge on the dam can be opened to traffic, and thus permit the removal of the existing highway bridge at Conowingo.

By the close of the low-water season of 1927, the head-works of the power house should be completed. The relocation of the tracks of the Columbia and Port Deposit Railroad must also be completed and in operation by this date. In the fall of 1927, closure of the spillway sections will be commenced and is scheduled to be completed before the spring floods of 1928. During final closure of the spillway, it is planned to pass the river flow through light 10 by 18-ft. sluices built through the dam. These will be closed finally by means of specially designed gates.

Construction work was started on March 8, 1926, and excellent progress has been made on the work on both sides of the river. The work of relocating the tracks of the Columbia and Port Deposit Branch, was commenced on May 25, 1926, and is also making very satisfactory progress.

The construction of the dam and power house will require approximately 650 000 cu. yd. of concrete, of which, 400 000 cu. yd. will go into the dam. For the construction of the dam, a steel construction bridge with a deck at Elevation 60, is being built on the toe of the apron. On this bridge are three self-propelled, electrically-operated, gantry travelers, each equipped with a 15-ton derrick and a concrete hoist tower. There are also three standard-gauge railroad tracks on the bridge, and the gantry cranes are constructed so that cars on all three tracks can pass under them. The concrete-mixing plant on this side of the river is designed so that the concrete is discharged from the mixers directly into cars at the bridge elevation. Gasoline locomotives are being used to transport the concrete. Practically no rock excavation for the dam foundation has been required, it having been found necessary only to clean off the over-burden, remove the loose rock, and clean out the joints in the ledge rock.

For the construction of the power house and tail-race, the excavation of approximately 360 000 cu. yd. of rock is necessary, part of which will be crushed and used as concrete aggregate. A suitable crushing plant has been installed, with facilities for storing the crushed rock. In the placing of concrete for the power house, it is planned to use six steel towers, 250 ft. high, with 16-in. chutes.

A total force of approximately 3 000 men is now engaged on this work. It is expected that the first unit will be ready for operation about the middle of 1928, and that several additional units will be ready to help carry the peak load in Philadelphia that year.

DISCUSSION

WILLIAM C. L. EGLIN,* ESQ.—Any one who has never been intimately connected with a project of this nature, cannot appreciate the amount of preliminary work that must be done before actual construction can be commenced. If the preparatory work is not done carefully and thoroughly, disaster may overtake the project before it is completed.

In this project there was an enormous amount of preliminary engineering investigation and study required. Many problems of legal procedure and authorization, involving the Federal Power Commission, the Public Service Commissions of both Maryland and Pennsylvania, State Highway Commissions, County Commissions, Water Boards, Sanitary Boards, and numerous others, had to be satisfactorily disposed of before the project could be launched.

Formerly, an Act of Congress was required before such a development could be made, but with the enactment of the Federal Water Power Act in 1920 a Federal Power Commission was created, having jurisdiction over all hydro-electric developments in navigable streams. It has always been contended that the lower course of the Susquehanna River was not a navigable stream but, as the Judge Advocate of the War Department decided that it was, it was necessary to secure a Federal license.

It has been pointed out that the dam and power house (the greater part of the investment) is located in Maryland, but that the pool extends into Pennsylvania. This made it necessary to secure the joint approval of the Public Service Commissions of both States. Under the Federal Act the Power Commission takes jurisdiction in all matters upon which the State Commissions are not empowered to rule. In the Conowingo Project, neither of the State Commissions could approve the issuance of securities, and it devolved, therefore, on the Federal Power Commission to make its first official finding in this connection.

When The Philadelphia Electric Company became interested, the first work was to examine all the reports that had previously been made on the development of the power resources of the Susquehanna River. The most capable engineers of the country did some real heroic work in earlier days studying this problem. The late Alfred Noble, Past-President, Am. Soc. C. E., prepared one of the most exhaustive reports on the possibilities of the hydro-electric development on the river. In fact, that report was used as a basis for the final investigations. In the preliminary work, five dam sites, pointed out by Mr. Noble were reconsidered. The final site is not the one recommended in his or in any of the earlier reports. It is known as Site 4A, that is, it is a new site, south of Mr. Noble's Site No. 4.

The rapid advance that has taken place, not only in hydro-electric development and hydro-electric machinery, but in the demand for power, changes all

* Vice-Pres. and Chf. Engr., The Philadelphia Electric Co., Philadelphia, Pa. Dr. Eglin died on February 7, 1928.

the conclusions of the earlier reports, and those that are even a year or two years old are practically out of date to-day (1926). The first one that was made for The Philadelphia Electric Company, contains approximately 230 pages and 50 or 60 plates.

It includes a study of: The water-shed, precipitation, run-off, and the Susquehanna River area flood; ice formation; the quantity of water available for water power development (from official records 1901 to 1927) and the effective head of water that can be secured; the investigation of various sites and locations for hydro-electric plants; the comparison of cost of hydro-electric development at each site; recommendations as to the selection of the most desirable site and a plan for the ultimate development of the total head available; a final analysis and review of the various alternatives possible for the development of Site No. 1 from the economical standpoint, utilizing a maximum of 50 000 cu. ft. per sec. of river discharge; a selection of sites, comparison of costs and possible development; transmission lines and sub-stations, comparing cost of the price of line, line losses, and operating costs; the estimated gross and net output and power deliverable from the hydro-electric plant (operating under probable average conditions) to the sub-station at the end of the transmission line; a complete detail of the operating expenses of the hydro-electric development at each site; a general summary of the project, its operation and operating expenses, utilization, number of units, distribution of loads between the hydro-electric and the steam plant for 1925 to 1928; total capital requirements for the development, including working capital and miscellaneous expenses; forecast of earnings and expenses for the first year of operation and estimates of increase in net earnings from year to year during the first three years of operation; a brief history of the Susquehanna Power Company and other corporations, consolidated with or related to this project; opinions from counsel regarding the status of the development; and the approximate requirements of market within reasonable transmission distance.

After this report was digested the next step was to apply for preliminary permits from the Federal Power Commission and when that application was made, all the material was discussed with the Federal Power authorities, then with the Maryland Public Service Commission, and, finally, with the State of Pennsylvania. As stated, innumerable hearings before public bodies were held. In one report, made to one commission, there were 125 pages of typewritten matter and 9 blue-prints, together with exhibits containing 150 pages and many blue-prints, there being more than 20 blue-prints and about 300 pages of typewritten reports prepared for one commission alone. This illustrates the tremendous amount of preliminary work that was necessary before construction could begin. Many of the engineering conferences started at 9:00 A. M. and ended at 11:00 P. M. The Federal Commission and the Public Service Commissions of both Maryland and Pennsylvania gave their fullest co-operation. It was a long drawn out investigation, but the immensity and importance of the problem made it thoroughly justifiable.

J. V. HOGAN,* ASSOC. M. AM. SOC. C. E.—The work of The Arundel Corporation on the Conowingo Hydro-Electric Project is divided into two contracts. The first is for the construction of the dam from its east end to a point about 50 ft. east of the power house, a length of 3 600 ft. The second contract is for the relocation of the tracks of the Columbia and Port Deposit Branch of the Pennsylvania Railroad, which will be flooded by the construction of the dam. The railroad is to be changed from Port Deposit, Md., to Fishing Creek, Pa., a distance of 16 miles.

Under the Arundel contract 1 200 ft. of the dam comprises the east retaining wall section, and the remaining 2 400 ft. is the spillway section, of which, 1 450 ft. is in the river and must be built in a coffer-dam. The Pennsylvania Railroad tracks parallel the river about 1 100 ft. from the east bank, and the level area on the down-stream side of the dam, between the railroad and the river, affords space for railroad sidings, storage yards, shops, and construction plant. The camp and office buildings are on a narrower level strip between the railroad and the hillside.

Work was started on the dam on March 8, 1926, and the erection of quarters for workmen was begun immediately. The camp has bunk houses, each 20 by 64 ft., built in pairs, connected by a room with showers, lavatories, and flush toilets. Each pair of houses accommodates 56 men in single-deck bunks. The office men are housed in a two-story dormitory containing thirty-six single rooms, each with lavatory and running water. The mess hall has a seating capacity of 600 men. A refrigerating plant, laundry, fumigating house, hospital, and general store serve the camp. The administration building is a two-story frame structure with hollow-tile vault.

A fully equipped machine-shop and a blacksmith shop, for handling heavy forging, have been provided; also a carpenter shop with a platform adjoining it for laying out large form panels. Standard-gauge yard tracks run through all shops. The general storeroom is 50 by 100 ft. Of the standard-gauge railroad tracks 5.8 miles have been laid in the yard, including 1 mile of tracks on elevated trestles.

The water supply is pumped from Octoraro Creek, a distance of 4 000 ft., to a 100 000-gal. storage tank on the hill behind the camp. The water for domestic purposes is filtered and chlorinated, while that for industrial use and for concrete is taken directly from the raw-water storage tank. Hydrants for fire protection are placed on the raw-water mains. Sanitary sewers drain from the camp buildings to two septic tanks. The effluent from the tanks is treated with chlorine before it is discharged into the river.

For the dam it is necessary to remove 170 000 cu. yd. of earth overlying, for a depth of 20 ft., the rock on which the dam is to be founded. This is being done by a 2½-yd., railroad type, steam shovel, with 6-yd., standard-gauge cars and 40-ton steam locomotives. The rock when exposed was seamy and badly disintegrated on top. However, as it was desired to prevent shattering of the foundation, very little blasting could be done, except at places where it was apparent that large quantities of rock would have to be removed. There-

* Secy., The Montrose Constr. Co.; Chf. Engr., The Arundel Corporation, Baltimore, Md.

fore, the rock is being loosened by barring and wedging and by the use of air drills and breakers. Locomotive cranes handle the rock in skips to dump cars, from which it is dumped into the coffer-dam cribs. In places, 30 ft. of faulty rock have been removed. Three motor-driven air compressors, with a total capacity of 2 600 cu. ft. per min., furnish air for this work. Five 25-ton steam locomotive cranes and two gasoline crawler cranes are being used in cleaning up the bottom.

The first coffer-dam was started on April 10, 1926, and was pumped out on July 10. This coffer is 170 ft. wide inside and 1 100 ft. long. The rock-filled cribs are 16 ft. wide, with a 10-ft. opening between them spanned by stop-logs. The water side of the cribs and stop-logs is sheathed with a double layer of 2-in. plank, outside which earth from the excavation is banked. Fig. 1 is a view of the site, and the coffer-dams. The up-stream cribs are carried to Elevation 32.5 and are 30 ft. long, and the down-stream cribs, which are 24 ft. long, to Elevation 28.5. The coffer-dam was built on the rock bottom of the river, which is at an average elevation of +15, by locomotive cranes working ahead on the finished cribs. The opening between this coffer-dam and that on the west side of the river passed a flood of 120 000 sec-ft. without overtopping the cribs. The second coffer-dam was 850 ft. long and extended from the first to connect with the coffer-dam constructed for the power house, and covered all the necessary foundation work to complete this phase of the construction in the second season. The second-year coffer-dam was constructed with alternate crib and stop-log sections similar to the first-year coffer, with the exception that the up-stream coffer-dam cribs were carried to Elevation 42.5, and the down-stream cribs to Elevation 28.5. Up stream the cribs are 20 by 40 ft., and down stream, 16 by 24 ft.

For purposes of stream control during construction, the spillway was concreted in alternate sections above Elevation 20. A section, 52 ft. long, carrying two highway bridge piers was poured, and the adjoining section, 38 ft. long, the clear space between piers, was left open. After these alternate sections were built above high water in the first coffer, the stop-logs were removed, and the river passed through the openings while work in the second coffer-dam was being done. When all the 52-ft. sections have been built to full height, and the highway bridge is completed across the dam, the open sections will be concreted in approximately 5-ft. lifts, the river flow at that time being passed as far as possible through eight 10 by 18-ft. temporary sluiceways constructed in the dam foundation, and arranged so that when the concreting of the alternate spillway sections is completed, these can be closed by means of a drop gate and filled with concrete after the water has risen in the pool to the spillway elevation.

In this work a total of about 430 000 cu. yd. of concrete will be placed. As all the rock from the excavation is needed for weighting the cribs, gravel is being used for the coarse aggregate of the concrete. Some of the gravel is being dredged near the head of Chesapeake Bay, and the remainder shipped from plants near Baltimore, Md. The Bay gravel is towed in scows to Port Deposit, Md., the head of navigation in the Susquehanna, where a derrick

FIG. 1.—VIEW SHOWING TYPE OF CONSTRUCTION USED IN COFFER-DAM OF ALTERNATE CRIB AND STOP-LOG SECTIONS.

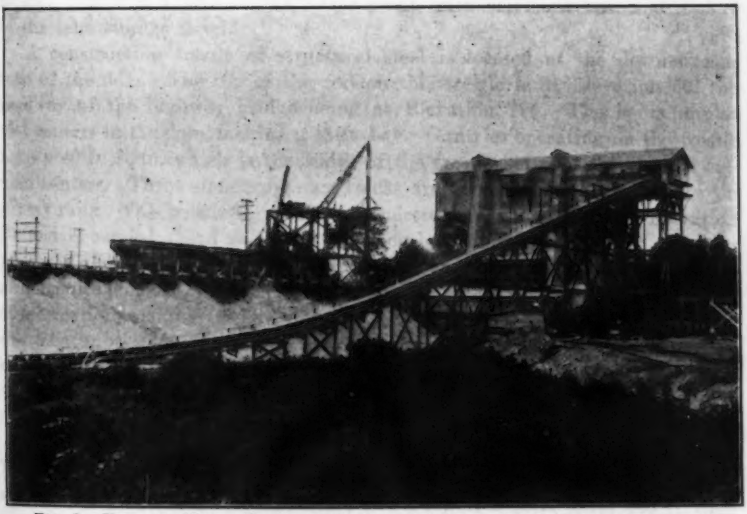

FIG. 2.—VIEW OF MIXER PLANT WITH BELT CONVEYOR, ALSO, SHOWING PART OF SAND STORAGE TRESTLE.

loads it into railroad cars, to be hauled 4 miles to the dam site. Some crushed stone has also been purchased for concrete. The sand is obtained from the same sources as the gravel.

On account of ice in the Upper Bay during the winter, which often prevents towing, a storage of 70 000 cu. yd. of sand and gravel has been provided. This material is stored under a pile bent trestle 20 ft. high, with a total trackage of 2 800 ft., through which it is dumped from 70-ton hopper cars as received from the railroad. A bin of 1 800 cu. yd. capacity, which is also under the trestle, is filled before any material is put in storage. Five 24-in. belt conveyors under this bin deliver on to a 36-in. conveyor inclined 15°, running 450 ft. per min., which feeds the mixing plant. Material from the trestle storage is reclaimed by locomotive cranes which load into cars dumping into the bin mentioned. The 36-in. conveyor delivers on to another shorter belt at the top of the mixing plant, equipped with a tripper for distributing sand and gravel in the hoppers over the mixers.

Cement is received in bulk in box cars, and is unloaded into the boots of two bucket elevators. Screw conveyors at the heads of these elevators distribute the cement into small hoppers over the mixers. When these hoppers are full they overflow into the main cement storage bin, which has a capacity of twenty carloads. This bin, in turn, feeds back to the elevator boots when cement is being taken from it. The mixing is being done by four 2-yd., motor-driven, tilting mixers. The sand and gravel are proportioned by inundators and batchers, respectively, and the cement is weighed on automatic scales. Fig. 2 is a view of the mixer plant, with belt conveyor, and a part of the sand storage trestle.

A construction trestle of structural steel is located at the down-stream face of the dam. The top of the rail on this trestle is at Elevation 60, the roadway of the highway bridge being at Elevation 114. The bents are at pier centers in the dam, making a 45-ft. bay. Gantries operating on the trestle have a 40-ft. span, which is the width of the trestle between the outside column centers. Three standard-gauge tracks are carried on the trestle between gantry rails. This trestle is erected on concrete piers with the top at Elevation 20, and is carried ahead as fast as the rock bottom can be prepared. Except the three main girders which carry the 45-ft. span, and which are riveted plate girders, all members of the trestle are standard rolled shapes with a minimum of fabrication, making for low first cost and high probable salvage. Fifty-four 45-ft. bays, or 2 430 ft. of this trestle, a total weight of 2 400 tons, will be erected west of the present Pennsylvania Railroad tracks. The concrete east of the tracks will be placed by a tower and chutes. Fig. 3 shows the construction bridge with gantry and movable tower.

Three self-propelled gantry travelers operate on the construction trestle. These are steel towers, each of which has a 15-ton stiff-leg derrick mounted with its mast at one up-stream corner, and a concrete hoist tower 100 ft. high near the other up-stream corner. The derricks are all steel, with 80-ft. booms and 2-drum, 100-h.p. electric hoists and attached swingers. The foot-blocks of the derricks are 45 ft. above the trestle floor, or at Elevation 105. These derricks are used for erecting forms and steel, and for setting castings; and,

in case cyclopean concrete should be placed, they would be used for handling plum stones. The concrete towers receive the mixed concrete from cars on the trestle, and elevate it for delivery through chutes to the higher part of the dam. Each tower has a 30-ft. boom section of chute supporting a 30-ft. counterweight chute at its outer end. The gantries have a travel speed along the bridge of 50 ft. per min.

For the lower parts of the work, two chuting outfits suspended from, and moving along, the up-stream trestle girder, are provided for receiving concrete direct from the cars without being elevated. About 25% of total yardage of concrete can be poured through these chutes.

Concrete is hauled from the mixing plant to the towers and chutes by 8-ton gasoline locomotives geared to a speed of 16 miles per hour. Four of these locomotives are now being used, each pulling a 36-ft. standard-gauge flat-car, on which are mounted four 2-yd. side-discharge hoppers. The cars are run directly under the mixers, which are placed so that two mixers may discharge into alternate hoppers on one car simultaneously. The car is then moved up far enough to take the batches from the other two mixers in the remaining hoppers. This plant was designed to mix and place an average of 1 000 cu. yd. per day, working single shift, with a maximum output of 2 500 cu. yd. It has operated very successfully, placing 56 000 cu. yd. of concrete in 1 month, the maximum daily pour to date (October, 1927) being 3 627 cu. yd. in two shifts. A batch from the mixers actually produces 2.22 cu. yd. of concrete in the dam. Wooden forms are being used, made up in large panels which are handled by the traveling derricks. A daily force of about 800 men is employed on the dam construction, including a night shift of about 200 men.

The Columbia and Port Deposit Branch of the Pennsylvania Railroad, at present a single-track road with passing sidings, is to be revised as to alignment and grade for 16 miles. The new roadbed, however, is to be graded for double track the entire length of the change. The relocation follows very closely the 118-ft. contour on the east slope of the river valley down to the dam from where it runs off, on a —0.35% compensated grade, 4 miles to Port Deposit. The hillside is in general very rugged and rocky, and in places so precipitous that the new line approaches the operating line very closely.

As an average of thirty heavy freight trains per day pass over the present road, and as this traffic cannot be interrupted until a single track on the new line is put in operation, it is necessary to shift the present tracks away from the toes of new fills at the points of proximity of the two lines, and to limit blasting to moderate shots practically over the entire line. It is estimated that 1 490 000 cu. yd. of grading will be required, of which, 880 000 has been obtained from cuts and the remainder will be borrowed. In the cuts it developed that 67% was solid rock.

In order to complete the double-track roadbed it became necessary to operate a single track on the relocated line and abandon the old line. This has been done, and under date of October 2, 1927, the first train was operated over the relocated line. This meant a total excavation and borrow of 1 109 000 cu. yd. in 15 months, the start having been made May 25, 1926. This time

FIG. 3.—CONSTRUCTION BRIDGE WITH GANTRY AND MOVABLE TOWER.

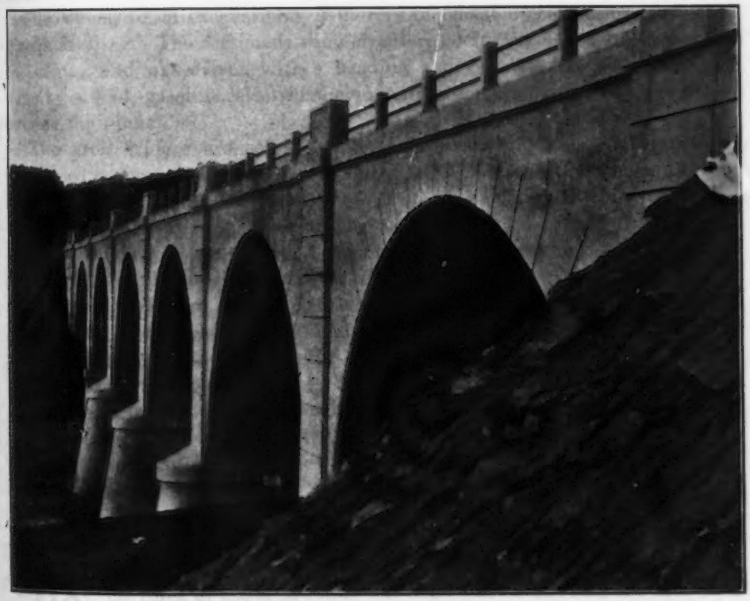

FIG. 4.—TYPE OF REINFORCED CONCRETE ARCH BRIDGE CONSTRUCTION USED ON RAILROAD RELOCATION.

limit, coupled with the difficulties mentioned, required that the grading be attacked at a comparatively large number of points. Nine steam shovels were used on the line. Four of these are standard railroad shovels with 2½-cu. yd. dippers, one is a 2½-yd. shovel mounted on caterpillars, three are full revolving caterpillar shovels with 1¾-cu. yd. dippers, and one a full revolving caterpillar with 1½-cu. yd. dipper. A small revolving shovel is being used for making fills where the present tracks are to be shifted.

Hauling from shovels to dumps is done over a 36-in. gauge track in 5-yd. dump cars. Four 14-ton and seven 8-ton gasoline locomotives and two 16-ton steam locomotives are being used. In several places, tractors and 5-yd. dump wagons made fills. Portable gasoline-driven compressors drive the jack-hammers and tripod drills on the rock work. Nineteen compressors, each of a capacity of 309 cu. ft. per min., are used. A well drill was used in some of the deeper cuts remote from the present railroad where heavy shots could be made. Some of the rock is extremely hard and seams of quartz have been encountered at places, with consequent delays to drilling.

In addition to excavation and embankment, there are three tunnels, three arch bridges, ten arch culverts, and a number of reinforced concrete pipe culverts on the railroad work. Fig. 4, a view of Octoraro Bridge, shows the type of reinforced concrete arch bridge construction on this relocation. The three tunnels are in solid rock and have a total length of 1 020 ft., representing 26 000 cu. yd. of excavation. A battery of portable compressors furnished air for drilling. The section is semi-circular, 30 ft. wide, and 24 ft. high at the center, and was driven with a heading and two benches. Mucking was done by a ¾-yd. gasoline, electric shovel, with the engine-generator set placed outside the tunnel.

The arch bridges are solid barrel, earth-filled, multi-span structures of reinforced concrete. These carry the roadbed over streams at Peach Bottom, Pa., and Conowingo and Octoraro, Md. (Fig. 4), and have three, five, and six 70-ft. spans, respectively. The bridges contain a total of 31 000 cu. yd. of concrete, which was placed with 1-yd. mixers and tower chuting plants. The construction of these bridges was scheduled so that a set of steel centers for three spans were used to complete the three bridges within schedule time. Seven 15-ft. arch culverts, one 20-ft., and one 30-ft. are required on the relocated line. All these, with the exception of the 30-ft. culvert, are now complete and were poured with ½-yd. portable mixers.

The track-laying was completed, using a maximum of four work trains with crews. This was very heavy work, the specifications requiring 130-lb. rail in general, and creosoted ties, together with about 2 miles of track laid with reinforced concrete ties. The ballast was either cinders or slag, and was spread direct from hopper cars. In general, the ties were hand-tamped, and the surfacing was done by track-jacks; but on the concrete ties a Nordberg track-shifter was used, and the track-tamping was done by air tools.

An average force of about 650 men was employed on the railroad relocation work, reaching a maximum of 1 400 during the track-laying period. The men were housed in small camps along the line of the relocation, and in camp cars which were shifted from point to point as occasion demanded.

A. W. CLARK,* ESQ.—The west side of the Susquehanna River, at the site of the Conowingo Hydro-Electric Development, is beautiful rolling farm country. The nearest railroad point, the small Town of Conowingo, is on the east side of the river, on the Columbia and Port Deposit Branch of the Pennsylvania Railroad. The river is spanned at this point by a long and very old highway bridge in poor condition, capable of sustaining a load of not more than 5 tons.

In attacking the work on the west side, it was necessary to build a railroad at the earliest possible moment for transporting materials to the site. A single-track road with an ample number of sidings was constructed from Havre de Grace, Md., on the Philadelphia, Wilmington and Baltimore Division, of the Pennsylvania Railroad, ten miles up the west side of the river, to the dam; 85-lb. rail was used throughout, and the road is ballasted with material secured from the waste bank of a stone-crushing plant, through which the railroad passes. A classification and storage yard has been built about 2 miles down stream from the work. In addition to hauling the freight necessary for construction, a few passenger trains are operated on a schedule planned to meet the working hours of employees who reside south of the dam site and in Havre de Grace. The movements of all trains are controlled by a despatcher near the works.

The first work in the field was the construction of a labor camp, started on March 9, 1926. For more than two months, until the railroad was placed in operation, it was necessary to haul all material to this site by trucks and teams.

A camp with mess halls, commissary store, and hospital has been constructed on the high ground adjacent to the west side of the river. It is capable of taking care of the needs of approximately 1 500 men. A limited number of 2-room and 5-room cottages have also been built for the use of employees with families. The camp streets and all buildings are lighted with electricity, the current for both power and lighting being supplied from the Holtwood Plant of the Pennsylvania Water and Power Company, over a transmission line built from Delta, Pa., about 12 miles distant. The water supply for the entire work is secured from the river, the domestic supply being filtered, chlorinated, and pumped to a 100 000-gal. steel tank, and from there distributed through pipe lines to the camp and the work. A sewerage system is provided with the necessary septic tank, the effluent of which is chlorinated before discharging to the river.

The camp is policed by uniformed guards who are vested with the authority of deputy sheriffs, and a barred room has been set aside as a jail for those who have imbibed too freely and insist on disturbing the peace and quietude of the community.

The area of the river covered by the power plant has been divided into two sections. The section containing the head-works, power house, and a part of the tail-race was first enclosed with a coffer-dam, and while excavation was being done in this section, the construction of the coffer-dam enclos-

* Works Mgr., Div. of Constr. and Eng., Stone & Webster, Inc., Havre de Grace, Md.

ing the remainder of the tail-race could proceed. The first section was completed and unwatered during the last week of July, 1926.

The coffer-dam consists of a double row of rock-filled timber box cribs separated by a sheathed puddle-chamber approximately 10 ft. wide. The cribs were built of commercial lengths of 10 by 12-in. Southern pine and Douglas fir and were tied together across the top of the puddle chamber with the same material, securely bolted in place. The sheathing of the clay chamber was a double course of 2 by 10-in. planking, with lapped joints.

The cribs were built up in place and carefully fitted to the bed of the river, with the bottom bearing members placed lengthwise in the direction of pressure. Caterpillar cranes, that traveled on standard-gauge tracks along the top of the completed cribs, were used to unload timbers from cars. The same tracks were also used for supplying the rock-fill and material for the clay puddle which was dumped from 6-yd. and 12-yd., two-way, dump cars.

The following quantities give an idea of the magnitude of the work necessary for completing the first section of the coffer-dam which encloses the head-works, power house, and a part of the tail-race, and comprises an area of 14.7 acres: 2 575 lin. ft. of coffer-dam; 5 600 000 board ft. of timber; 69 000 cu. yd. of rock-fill; and 32 000 cu. yd. of clay.

The second section of the coffer-dam which encloses the remainder of the area covered by the tail-race, 11.1 acres, was completed the first week in June, 1927, and contains the following quantities: 2 220 lin. ft. of coffer-dam; 2 700 000 board ft. of timber; 24 000 cu. yd. of rock-fill; and 13 200 cu. yd. of clay.

In planning the excavations for the first section, it was decided to concentrate on the head-works and power house, so that they could be constructed while the excavation for the tail-race was being done. The first-mentioned work was completed the last week in April, 1927, and consisted of the removal of approximately 100 000 cu. yd. of rock. The total quantity of rock removed for the tail-race was approximately 200 000 cu. yd.

The excavation for the head-works and power house was carried down to several different elevations, the deepest and most difficult being in the area containing the draft-tubes. This consisted in cutting a gash in the river bed approximately 550 ft. long, 80 ft. wide, and 30 ft. deep, with the up-stream side vertical, and the down-stream side sloping up in the tail-race at a rate of 1 on 6. For this particular work, a high-lift, full-revolving steam shovel on caterpillars, with a 2.5-yd. bucket, was selected. Its use minimized the number of track changes and also made it possible to remove a large quantity of material with the hauling tracks on the bed of the river or on the top of the cut. For the remainder of the work, a 3-cu. yd. steam shovel, first operated on railroad trucks and, later, mounted on caterpillar trucks, was used where the lifts were low, and two small revolving shovels on caterpillars were used for odds and ends. All this equipment was served with 6 and 12-cu. yd., two-way dump cars, hauled by steam locomotives on a standard-gauge track system. A lead connected the construction track to double-track trestle, running parallel to the down-stream leg of the coffer-dam on a 2.5% ascending grade.

Four 800-ft. compressors located on a side hill well above the possibility of flood, supplied air for the rock drills. The rock from the lower tail-race coffer-dam was dumped on an island which divides the tail-race into two channels. The dump was made from a track on a 3% grade laid on trestle and fill.

Part of the rock in the excavations was suitable for concrete and was crushed and used. A crushing plant was installed on the west bank about 1 500 ft. down stream from the dam. Stone was carried from the tertiary crushers on a belt conveyor to a 25 000-cu. yd. storage pile under which, at sufficient intervals, there were bin gates for delivering the crushed stone to a belt conveyor operating in a 6 by 6-ft. reclamation tunnel under the entire length of the pile and then up an incline to the stone bins over the concrete mixing plant. Around the bin gates were steam coils to deliver live steam to the material in winter.

Sand was delivered to the job in standard hopper bottom cars hauled over the construction railroad from Havre de Grace, and dumped from a trestle to a storage pile under which there is a 6 by 6-ft. tunnel with conveying equipment for carrying the sand to the mixing plant similar to that used on the stone.

The concrete mixing equipment consisted of two 2-cu. yd. motor-driven mixers supplied with aggregates delivered into the mixers from batchers and inundators which were filled from overhead bins. The proper proportion of cement was determined by weight. Bulk cement was stored in wood silos by means of bucket elevators operating from the track level on the ground. Wherever it was feasible, steel supports were used in the construction of the concrete plant in order to reduce the fire hazard.

Concrete was hauled from the mixing plant by 8-ton gasoline locomotives in 2-cu. yd. standard gauge, specially designed tilting cars, of the "roll-over" type. Four wooden towers, approximately 220 ft. high, supported the necessary chuting equipment.

For repairs to construction equipment a shop group was established about ½ mile down stream from the dam. A machine shop, blacksmith shop, pipe shop, and repair pits, equipped with an air hammer, lathes, grinders, drill presses, and other machine tools for the handling of such work, was built. As far as possible, equipment was purchased for these shops, that could be installed in the permanent shops.

A carpenter shop was constructed, in which the necessary wood-working machinery to facilitate the construction of forms, was installed. Space was reserved for lumber storage adjacent to the shop.

A place was also reserved in this vicinity for the storage of reinforcing steel, and, here, a power shear and power bender were installed for the fabrication of reinforcing steel. All these shops and the steel yard were served with standard-gauge tracks, which connected with the construction railroad and the track system throughout the work.

The power station is of structural steel and concrete. The work was arranged so that the concrete necessary to support the steel frame was placed as early as possible, in order that the structural steel could be erected and

traveling cranes put in operation to handle the installation of the heavy equipment.

The draft-tube concrete was the first step in this program, and concrete was completed in the elevation required for setting the draft-tube liners during the first week in June, 1927. As this work progressed, it was followed closely by concrete walls, carried to the main floor level, which allowed the erection of structural steel to start in the early part of June, and permitted the operation of the main building crane by the end of July.

By making use of the five 10-ton derricks which served the concrete operation, the erection of the water-wheel equipment was started during the latter part of April. In this way, six of the seven units were completed as far as the erection and riveting of the scroll cases and pit liners by the time the building cranes were available for the heavy lifts of the butterfly valves. As fast as the valves were in place and riveted, the concrete fill around the scroll cases was poured, and the interior of the generator room completed.

H. A. HAGEMAN,* M. AM. SOC. C. E.—Mr. Wilson has given the general features of the hydraulic design of the Conowingo Project. It is the purpose of this discussion to set forth in somewhat greater detail the design of the major parts of the structure and operating equipment.

Station Intake.—On account of the length of waterway required to accelerate the water and the width of the space necessary to house the electrical bay, the intake is in itself a stable structure. It will serve adequately as a dam and no support from the power station substructure is necessary. For the four future units, this makes necessary, at present, the construction of the intake only, and results in a minimum initial expenditure. It will also make possible the future realization of all progress in water-wheel design which may be made prior to the installation of these units.

Trash Racks.—As Mr. Wilson has explained, the entrances to the waterways of the turbines will be located near the bottom of the reservoir and a curtain-wall extending 40 ft. below the normal pond surface will be constructed up stream from them as a protection against ice. The curtain-wall is a distinct feature of the intake and is more economical than any other form of ice protection of equal efficiency. Each waterway will be divided into two parts from the entrance to a point a short distance up stream from the butterfly valve, where they will be merged into one.

The trash racks are located in each intake opening a sufficient distance behind the ice-protection wall to permit the operation of a mechanical rack rake. These racks will be made up in panels of convenient size, which will slide in guides set in the concrete. The lower panels in each opening will be equipped with flat steel bars, but the upper panels, which are located behind the curtain-wall and are, therefore, of no use in providing actual waterway area, will be faced with treated timber. The timber facing on the panels will decrease the adherence of ice to the racks at the water surface and also reduce the cost of the panels.

* Chf. Hydr. Engr., Stone & Webster, Inc., Boston, Mass.

The rack sections have been designed for an unbalanced head of 5 ft. over their entire area, under which conditions the maximum stress in the steel will not exceed 16 000 lb. per sq. in.

The guides for the emergency sectional head-gates will be located down stream from the trash racks. These gates will be of structural steel and will be used to close the waterways when it is desired to unwater them in order to inspect or repair the butterfly valves. The valves are used normally as head-gates.

A sufficient number of gate sections will be provided to close the intake of one unit. The top, or sealing section, will be arranged to seal against a casting at the top of the intake opening so that it will not be necessary to extend these gates to the water surface.

Steel stop-logs of similar design to the head-gates, but with sections of less height, will be provided to close the waterway openings for the future units until such a time as these units are installed.

Gantry Cranes.—The sectional head-gates and trash racks will be handled by the gantry cranes which travel along the intake and spillway sections of the dam. For this purpose the cranes will be equipped with a special lifting beam which will run in the guides for either the head-gates or trash racks. This lifting beam will attach automatically to a rack panel or head-gate section under water, so that each section may be hoisted out of the guides separately and transported to a suitable storage space by the cranes. When it is desired to place the head-gate, trash-rack, or stop-log sections in the intake the process will be reversed, the lifting beam automatically releasing the sections when they have reached their proper place.

The wide bellmouth provided for the waterways insures very satisfactory hydraulic conditions for the intake with the head loss at the entrance reduced to a minimum.

Velocity at Intake.—With the water-wheels discharging 5 300 cu. ft. per sec. corresponding to full generator load at 89-ft. head, the velocity through the trash racks will be about 2.6 ft. per sec. The velocity at the entrance of the waterways will be 2.8 ft. per sec. In the distance of 71 ft. from the entrance of the waterways to the center line of the butterfly valves the water will be accelerated to a velocity of about 12 ft. per sec. After passing the center line of the butterfly valve, the velocity decreases and the water enters the plate-steel scroll case of the water-wheels at about 9.3 ft. per sec.

Butterfly Valves.—The area of the entrance to the water-wheel intakes for each unit is about 1 900 sq. ft. To close this area with two or even three lift-gates of any developed type would require gates of enormous size for the pressure to be resisted, with the consequent difficulty of obtaining an adequate seal against leakage. The operating mechanism required would be expensive and the operation slow.

By placing a circular gate or butterfly valve at the entrance to the scroll case, the area to be closed is only about 570 sq. ft. as compared to the 1 900 sq. ft. for rectangular gates. Further, the perimeter to be made water-tight is only about 85 ft. for the circular gate compared to 350 ft. for the rectangular gate.

Butterfly valves, 27 ft. in diameter, of the vertical shaft, circular type, were selected as being the most practicable to suit the conditions. They will be designed to open or close in about 5 min. and may be closed with maximum flow through the turbine. In the closed position they will stand at right angles to the line of flow. Each valve will be sealed after closing by admitting water pressure to a rubber tube, 3 in. in diameter, set in the inside face of the valve housing opposite the periphery of the valve wicket. Based on tests of this sealing device, the leakage through these enormous valves will be negligible. Each valve will be operated by oil pressure in a cylinder 40 in. in diameter.

These valves will be the largest ever built, the largest now (1926) in existence being 23 ft. 6 in. in diameter, built by the Allis-Chalmers Manufacturing Company for the Niagara Falls Power Company. For the Conowingo development, three valves are being built by The Wm. Cramp and Sons Ship and Engine Building Company and four by the Allis-Chalmers Manufacturing Company, each manufacturer supplying the valves to serve as the head-gate for the water-wheels he is to furnish. The sealing device will be the same for all valves and the manufacturers have co-operated in the design of bearings, operating mechanism, and renewable parts, making them alike and interchangeable.

Water-Wheels.—The Allis-Chalmers Company and The Wm. Cramp Company are co-operating in the design of the water-wheels, with the result that only one set of principal spare parts will be required. The outward appearance of the units will also be similar. To this end, such parts as lignum vitæ guide-bearings are of the same design for all wheels and are interchangeable. The runners, while not of the same design, will have the same limiting dimensions, so that the spare runner which will be supplied by The Wm. Cramp and Sons Ship and Engine Building Company, will serve in either a Cramp or Allis-Chalmers setting with high efficiency.

It is expected that the main water-wheel units will have a maximum efficiency of at least 93% and also that, in an average year of run-off, the seven main generators will have an energy output of 1 382 000 000 kw-hr. Plate-steel scroll cases were chosen on account of their greater economy when compared to concrete which would require heavy reinforcing in the substructure and much more elaborate and expensive form work. The maximum diameter of the runner will be 17 ft. 9 in., and its weight, when completely assembled, will be about 240 000 lb. Each main shaft will be of forged steel about 36 in. in diameter, with top and bottom flanges forged integrally with it.

A structural steel pit liner and generator support will be provided for each main unit. It will be attached to the speed ring of the water-wheel and be designed to carry the weight of the generator, thrust-bearing load, and adjacent floor loads down to the speed ring, whence the load is transferred through the speed-ring vanes to the power station substructure. The support will be built of plate and structural steel instead of cast iron, as is ordinarily the case. The support is essential to the power station design as it was found that it would be very difficult to design a concrete foundation for the generator in the space available to properly transfer the enormous load to the speed ring through which it must be transmitted to the substructure foundation.

Governors.—Each water-wheel manufacturer will supply with the unit which he furnishes, actuator type, oil-pressure, relay governors of his own make, having governor flyballs mechanically driven from the main shaft of the water-wheel.

Power House.—The units and auxiliaries will be arranged in pairs. Units Nos. 1, 2, 5, and 6 will have Allis-Chalmers turbines and General Electric generators. Units Nos. 3, 4, and 7 will have Cramp turbines and Westinghouse generators.

Each pair of units will be equipped with an interconnected oil-pressure system consisting of one pressure tank and duplicate pumps and sump tanks. The governor actuators and pressure tanks will be located on the main floor of the station at Elevation 46.0 ft., but the pumps and sump tanks will be located on the station auxiliary floor at Elevation 35.0 ft.

A central oil-purification system will be provided with the necessary piping to drain any governor system and purify the oil and return it to the system.

Draft-Tubes.—The draft-tubes for each make of water-wheel will be built in accordance with the design of their respective manufacturer. The Cramp units will have tubes of the conventional Moody type with a concrete cone extending from the bottom at Elevation — 14.5 ft. to the hub of the runner. The Allis-Chalmers units will be equipped with a White Hydraucone type of draft-tube and will have its bottom at Elevation — 18.5 ft. The bottom of the outlet of the draft-tube will be at the same elevation for all units.

The substructure over the draft-tube of each unit will be supported by five cast-steel stay vanes which each water-wheel manufacturer is furnishing for the units he supplies. Down stream from the circle of stay vanes, the draft-tube will be divided into two parts by a central bearing wall.

The low setting of the water-wheels relative to the tail-water level, required for the protection of the runners against pitting, makes it necessary to provide for stop-logs at the outlet of the draft-tubes to prevent the unit from being flooded by tail-water when unwatered for inspection or repair. These stop-logs will be handled by a small gantry crane in a manner similar to the sectional head-gates and trash racks.

All waterways will be arranged with suitable connections to a drainage tunnel which will be located under the inspection tunnel, up stream from the draft-tubes. This drain will empty into a sump at the west end of the station from which the water will be pumped into the tail-race.

Spillway.—As already explained by Mr. Wilson, the head-water level at the station is to be maintained constantly at Elevation 108.5 ft. except during periods of extreme drought, at which time the draft from the reservoir will cause the head-water to fall below the normal elevation. In order to pass flood flows in excess of the requirements of the water-wheels a spillway equipped with crest gates will be provided.

The spillway is of the conventional ogee type, having a parabolic crest and a circular curved surface at the toe. The piers supporting the crest gates are 7 ft. thick and 45 ft. on centers, leaving a clear opening of 38 ft. between them. These piers also support the highway and the runway for the gantry cranes that operate the gates.

Crest Gates.—The crest gates will be of the Stoney type, 22 ft. 6 in. high by 40 ft. wide, with timber seals at the bottom and rubber-covered staunching rod seals at the sides. Fifty crest gates will be provided, having a combined discharge capacity of about 800 000 cu. ft. per sec., with the head-water level at 108.5 ft. Three smaller regulating gates, each having a capacity of about one-third that of a crest gate, will be provided for the finer adjustments of flow. Up stream from the crest gates, additional guides will be set in the piers to receive a service gate. This gate will be of the fixed roller type and will be used to close the gate-opening when it is necessary to remove one of the crest gates or regulating gates for painting or repairs.

The crest gates, regulating gates, and service gates will all be handled by the same cranes that handle the sectional head-gates. A total of three gantry cranes will be provided for handling gates on the dam and the sectional head-gates and trash racks. For handling the crest gates they are equipped with special lifting beams of different design from that used to handle the sectional head-gates and stop-logs. As this lifting beam is never submerged, it is arranged for an operator to ride on it and operate the locking device which attaches it to the gates. When the gates are raised to their open position they will be held in place by means of pawls engaging suitable stops on the ends of the gates, thus permitting the crane to move on to the next gate.

A study of the duty cycle of these cranes indicates that one crane will lift a crest gate every 9 min. As the maximum rate of rise of any flood on record has been such as to require the opening of one gate only every 30 min., ample factor of safety has been provided in these gantry cranes to insure the timely opening of these gates.

ALEXANDER WILSON, 3D,* ESQ. (by letter).—While the schedule called for operation of the first unit about July 1, 1928, construction progress was so much better that all the units were in operation by that time, the first two units having been placed in commercial operation on March 1, 1928.

In the low-water season of 1926, a coffer-dam of the puddle-chamber type was constructed, enclosing the power house and west branch of the tail-race, an area of about 14 acres. The top of this coffer-dam was built to Elevation 42, where it was estimated that it would not be topped by a flood of any volume less than 350 000 cu. ft. per sec., so that work on the heavy excavation of the power-house foundations and draft-tubes could reasonably be expected to proceed without interruption by floods in the spring of 1927.

Simultaneously with the construction of the power-house coffer-dam, another coffer-dam of the spaced crib type was built from the Cecil County shore, extending to within approximately 700 ft. of the power-house coffer-dam. About the middle of November, a flood of 350 000 sec-ft. occurred, the greatest November flood that has been recorded for the Susquehanna River. The head-water elevation was raised to within a few inches of the top of the sand-bags which had been placed on the power-house coffer-dam and, of course, topped the spaced crib coffer-dam on the other side of the river. As the foundations for the dam had been completed in this area with alternate spillway sections, each including two

* Asst. Chf. Engr., The Philadelphia Electric Co., Philadelphia, Pa.

bridge piers constructed to a height above the river level, it was not necessary again to unwater this coffer-dam after the flood had subsided.

During the winter and early spring of 1927, the pouring of the pier sections was completed up to and including the highway bridge, leaving intermediate sections 38 ft. wide at the level of the foundation (Elevation 22) to provide for the diversion of the river during the summer of 1927. Likewise, the head-works at the power station were completed during this period up to an elevation well above flood level.

As soon as the spring floods of 1927 had subsided sufficiently, the coffer-dam was extended from the last completed spillway section to the power-house head-works, and, by September, the foundations of the dam had been completed in this last coffer-dam and the alternate sections poured above the elevation of the top. With the removal of this coffer-dam, twenty 38-ft. notches in the spillway, together with eight 10 by 18-ft. sluices through the spillway, were taking care of the river flow.

The final closure of the notches was commenced early in October, 1927. The easterly ten notches were first brought up to Elevation 30, and the west ten to Elevation 35. These two groups, with a 5-ft. difference in bottom grades, were then raised alternately in 10-ft. lifts, thus providing a flow of 5 ft. through ten openings, in addition to the flow through the eight sluices. In the actual closing of the waterway at each 38-ft. opening, a steel and timber flap-gate, hinged at the top from the adjoining spillway sections, was used. The gantry cranes provided for the crest gates were used to handle these flap-gates. With the raising of the notches and the corresponding rise of the head-water level, the discharge capacity of the eight sluices increased so that finally, when the notches had been raised to about Elevation 50, the discharge from the sluices was equal to the river flow and the closing of the notches was completed without the use of flap-gates.

After the concrete in the notches had been completed to crest elevation, final closure of the eight sluices was made by lowering specially designed, reinforced concrete gates, weighing 75 tons each, and then filling the sluice-way opening with concrete.

Closure of the notches was hampered through November and December, 1927, by high water. Favorable flow conditions occurred in January, 1928, however, permitting completion to crest elevation on January 16 and, on January 17, 1928, the sluice-way gates were dropped, making the final closure of the dam.

The Columbia and Port Deposit Branch of the Pennsylvania Railroad was put in operation on the relocated line on October 10, 1927, just in time to escape a heavy flood which washed out part of the old line above the dam.

The highway bridge over the dam was opened to the public on November 15, 1927, and two weeks later the old Conowingo Bridge was destroyed by dynamiting the superstructure and dropping the spans to the bottom of the river.

Paper No. 1711

PRECISE WEIR MEASUREMENTS*

By Ernest W. Schoder,† M. Am. Soc. C. E., and the Late Kenneth B. Turner,‡ Esq.

With Discussion by Messrs. H. W. King, Floyd A. Nagler, A. Streiff, R. L. Parshall, W. S. Pardoe, R. E. Ballester, Gardner S. Williams, Th. Rehbock, Erik G. W. Lindquist, Clemens Herschel, and Ernest W. Schoder.

Synopsis

This paper presents the results of extensive new volumetric measurements of the discharge over weirs of the sharp-crested (or nearly sharp) type, occupying the full width of the channel (that is, without end contractions). In addition to experimental data by the writers, the paper includes also new experimental data by Charles L. Walker, M. Am. Soc. C. E., and Carl R. Weidner, Assoc. M. Am. Soc. C. E., William F. Martin, Francis M. Dawson, M. Am. Soc. C. E., Henry R. J. Meyer, Assoc. M. Am. Soc. C. E., and Russell A. See, M. Am. Soc. C. E., Jacob O. Jones, Assoc. M. Am. Soc. C. E., and Charles M. Weber, Assoc. M. Am. Soc. C. E.

General.—The heights of the weirs ranged from 0.5 to 7.5 ft., the heads, from 0.012 to 2.75 ft., and the widths of channel, from 0.9 to 4.2 ft. Included in the paper are the results of 2 438 separate volumetric measurements of discharge for 1 512 different heads, all made at Cornell University and now published for the first time. Of these, 1 276 measurements for 530 heads were

Note.—For Table of Contents, see p. 1109.

* Published in September, 1927, *Proceedings*.

† Prof. of Experimental Hydraulics, Cornell Univ., Ithaca, N. Y.

‡ Mr. Turner, formerly Assistant Professor of Hydraulics, School of Civil Engineering, Cornell University, died October 21, 1918. The paper is presented by Professor Schoder. The writers jointly had completed all the experimental work, had made the primary calculations, and had reached the main conclusions in a general way, although not as far as many refinements and important comparisons are concerned. Only the first of the formulas involving r_a (see p. 1038) had been suggested or tested.

* Fteley and Stearns in addition to their volumetric measurements ran 94 experiments using comparative discharges (not volumetric) with 21 heads on weirs of various heights above the bottom of the channel of approach, which were 0.5, 1.00, 1.70, 2.60, and 3.56 ft. These were without end contractions. In addition, 5 heads, 18 experiments were run on weirs with end contractions.

†In addition, Bazin Series IV to X, 228 experiments were made with comparative discharges as calculated from his standard weir which was calibrated by his Series I, II, and III.

made by the writers. The distribution of the velocities in the channel of approach was measured by current meter for 241 heads (196 by the writers), including many cases with abnormally high velocities near the surface and near the bottom. The experiments were made at various times between 1904 and 1920, with the major part between 1913 and 1916. A condensed summary of the experiments is given in Table 1.

Findings.—The main findings are:

(1) Considerable limitation should be understood as to the widespread idea that a precision in discharge estimates within 1% or 2% is obtainable merely (*a*) by careful observations of the head of water on a weir having nominally a sharp, square edge, but built without precise regard to the degree of sharpness and smoothness of the crest plate and to the velocity conditions in the channel of approach; and (*b*) by the use of the standard formulas or other estimating devices of present engineering practice.

(2) The use of the simple Francis weir formula:

$$Q = 3.33\ L\ h^{\frac{3}{2}}, \text{ or } Q = 0.623 \times \frac{2}{3}\ L\ h \sqrt{2\,g\,h}$$

as a basic formula is substantiated for cases closely approximating the ideal weir with a truly sharp, square edge, with smooth, vertical, up-stream face near the crest, and with a deep up-stream pool, or with negligible effect of velocity of approach. (For low heads, see Item (5)).

(3) This paper shows the extent and nature of the inadequacy, for general precise work, of formulas that introduce merely the mean velocity of approach; or that, as the equivalent, introduce merely the height of weir; also the inadequacy of curves and tables that merely average or approximate the data of the experiments hitherto published. This inadequacy consists chiefly in the failure of the experimenters to measure and place on record the distributions of velocities in the channel of approach. The mere statement that velocities were approximately equalized by baffles leaves the matter too uncertain except for a limited range of heads and heights.

(4) The new experimental data (by several experimenters) agree with those of Francis, Fteley and Stearns, and Rehbock, in their evidence that Bazin's coefficients and formula for sharp-crested weirs give too high discharges for low heads—by fully 2 to 3% for heads of 0.3 ft. to 1.2 ft.

(5) For low heads of less than about 0.4 ft. for weirs more than 2 ft. high: (*a*) an additive corrective expression of the Fteley and Stearns' type, but made to the simple Francis formula, $Q = 3.33\ L\ h^{\frac{3}{2}} + 0.007\ L$, is verified, although their value of 0.007 ft-sec. units is to be replaced by other values ranging from 0.004 to 0.012 in certain cases; (*b*) many data of percentage corrections for extremely low heads (less than 0.10 ft.) on a variety of crest pieces are graphically shown.

(6) The percentage increase in discharge (as compared with sharp-crested conditions) due to a slight rounding of the up-stream top corner of the crest (say, to as much as $\frac{1}{24}$-in. radius = about 1 mm., which may soon occur with exposed steel and which has been overlooked or neglected in cases intended to be "sharp-crested") is shown to be as much as 2% for heads of 0.50 ft. and 0.5% for heads of 1.35 ft. A rounding of $\frac{1}{8}$-in. radius causes

about 3%, and one of ¼-in. radius, about 5½%, increased discharge at 0.50-ft. head. Agreement is found with Fteley and Stearns' data for the larger roundings.

(7) The percentage increase in discharge due to changing the roughness of the up-stream face of the weir bulkhead from that of a polished brass plate to that of a coarse file for a distance of 12 in. below the crest is shown to range from about 2% for 0.50-ft. head to about 1% for 1.35-ft. head. This agrees with the previous findings of James Barr for V-notched weirs.

(8) The new data show no justification for a taboo on a weir with a head of water as great as, or greater than, the height of the crest above the bottom of the channel. When the use of such a weir is convenient, the new formula, involving auxiliary velocity measurements, and several simpler formulas are amply accurate. In fact, there seems to be an inherent certainty of action for the very high heads on very low weirs.

(9) While the importance of careful measurements of heads, including the precise referencing of the gauge to crest level (zero determination), and the use of appropriate instruments, are not to be minimized, yet all the writers' work substantiates the conclusions of earlier experimenters that there is no necessity for slavish imitations in the precise manner of determining the head, nor for a precise location of station up stream from the weir to agree with a particular experimenter, provided no violence is done to the general hydraulic circumstances. Hitherto, many errors have been charged to insignificant details of the head determination when the trouble has been due to lack of appreciation of other factors and to neglect in making proper arrangements or measurements.

As a general rule, rarely subject to exceptions, the head should be determined in one of two ways: (1) by a direct measurement in the channel of approach (by one of several appropriate devices); or (2) by a piezometer with a stilling-well such that no correction is necessary.

(10) For precision it is necessary to deal not (as in most formulas) with the head corresponding to the mean velocity of approach, but with the head corresponding to the velocity above the level of the weir crest. This involves auxiliary measurements by current meter, Pitot tube, or floats, etc.

Where it is possible actually to duplicate the definitely known velocity conditions prevailing for different heads and heights in the channel of approach, the use of a special formula or special coefficients fitting the particular case remains entirely proper.

The extreme difference in discharge due to altering the distribution of velocities up stream from a weir, keeping the head constant, amounted to 26 per cent. The auxiliary velocity measurements by the writers and the introduction of this new factor are, in fact, simply carrying to a logical conclusion the suggestions of J. B. Francis, Hamilton Smith, Fteley and Stearns, Bazin, and others.

(11) A tentative formula,

$$Q = 3.33\, L \left[\left(h + \frac{v_a^2}{2g} \right)^{\frac{3}{2}} + \frac{h}{3.33} \times \frac{v_b^2}{2g} \right]$$

is suggested, in which, $\frac{v_a^2}{2g}$ is the mean velocity head of approach above the

crest level, and $\frac{v_b^2}{2g}$, the mean velocity head of approach below the crest level. If the velocity conditions are unknown it is necessary to make measurements to find the distribution. This formula is tested by its application to the new experimental data and is found to fit all of them much better than the formulas of Fteley and Stearns, or of Bazin, or the curves of Lyman, or the formula, $Q = 3.33\ L\left(h + \frac{v_a^2}{2g}\right)^{\frac{3}{2}}$. In extreme cases of high heads on low weirs the corrective terms modify as much as 50% the value that would be obtained by the simple Francis formula, $Q = 3.33\ L\ h^{\frac{3}{2}}$, but, nevertheless, they fit the volumetric measurements within about 1 per cent. Other simpler formulas of limited applicability are suggested also. In particular, attention is called to Rehbock's formula, $Q = \frac{2}{3}\ \omega\ L\ h\sqrt{2\,g\,h}$, in which, $\omega = 0.605 + \frac{1}{320\ h - 3} + 0.08\ \frac{h}{d_0}$, in foot-second units ($d_0$ is the height of the weir).

(The experimental data of Francis, Fteley and Stearns, Bazin, etc., cannot be used to test the new formula because no adequate velocity measurements were made).

(12) The use of such a weir properly built, of good head measurements and good auxiliary velocity measurements in the channel of approach, should insure discharge values within 2% of the truth, and in most cases within 1% (see Fig. 18). However, this seems to be quite untrue for many weirs relied on for such a precision by the use of formulas and methods in common use.

(13) The paper in no way presumes to champion the sharp-crested weir as a measuring device superior to others.

Experimental Equipment

The Experimental Canal.—The weirs for the experimental series, A to P, inclusive, (Fig. 1) were in the Hydraulic Laboratory of Cornell University. Inside a concrete canal, 6 ft. wide, was formed a new inner wooden canal approximately 4 ft. 3 in. wide, with flared sides up stream forming an easy approach for the water; and with down-stream sides projected beyond the weir to prevent lateral spreading of the overfalling water. Aeration holes just below, and close to, the crest on the down-stream side served to admit air under the overflowing sheet of water for the low heads. For the higher heads the general construction permitted free access of air under the sheet. Other essential details of the canal are given in Fig. 1.

Water Supply.—The water supply came by gravity from Beebe Lake, a pond of 20 acres formed in Fall Creek by a concrete overfall dam, 26 ft. high, with a spillway 130 ft. wide. During the experiments the water was usually flowing over the spillway, thus insuring nearly a constant head. The watershed was 125 sq. miles. From the base of the dam the water flowed through 192 ft. of 48-in. pipe and then 52 ft. of 30-in. pipe, terminating at the side of the small canal near the up-stream end with its invert even with the bottom of the canal (Fig. 1). For regulating the flow there was a 30-in. hand-

operated gate-valve. The static head on the center of the valve with water at the crest of the dam was 17.5 ft. With water in the small canal barely flowing over the experimental weir, the back pressure in the canal reduced the difference between the head up stream and down stream from the 30-in. valve to an average of about 10 ft.

Baffles.—Instead of allowing the discharge from the valve and the 30-in. pipe to churn around unrestrictedly in the canal, and depending on the usual type of baffle-racks to quiet the flow, a deflecting hood was constructed, to serve both as an enlarging elbow and as an energy killing chamber for the first and most violent part of the commotion (Fig. 1). The water flowing out under the hood was further quieted and directed, first upward, then forward

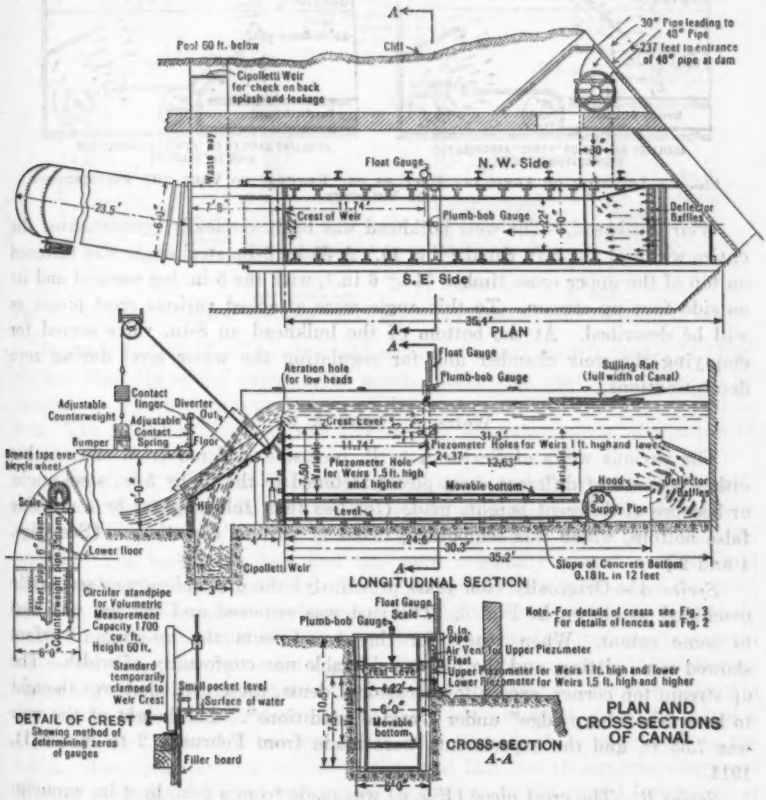

FIG. 1.—GENERAL PLAN OF CANAL, WEIR, AND APPARATUS.

over the top of the hood, by a system of open deflector baffles arranged so as to enlarge the cross-section progressively. This scheme proved remarkably effective except for some tendency to form surface waves at the very highest flows (heads above 2.0 ft. on the weir). A stilling-raft of 2-in. planks floating on top of the water above the deflectors tended to eliminate these waves.

"Fences."—In order to vary the distribution of velocities from the conditions during the so-called "regular" runs with only the permanent baffles controlling the flow, additional controls were built across the canal for some of the higher heads. These were usually in the form of inclined fences (Fig. 2) with 1 by 6-in. horizontal boards spaced by trial at such distances as to secure the desired deflection of a part of the water toward the surface or toward the bottom, as the case might be, always allowing some of it to flow through the open spaces.

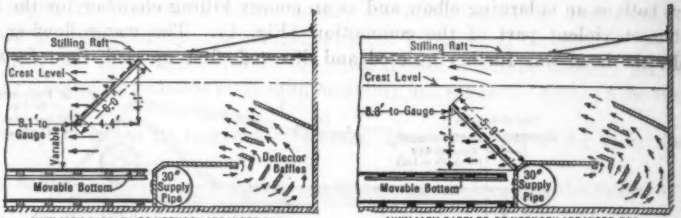

FIG. 2.—LOCATION OF AUXILIARY BAFFLES OR "FENCES" TO VARY THE DISTRIBUTION OF VELOCITY.

Weir Bulkhead.—The weir bulkhead was built vertically square across the entire width of the 6-ft. canal (Fig. 1). A 3½ by 5-in. steel angle was fastened on top of the upper cross timber (4 by 6 in.), with the 5-in. leg vertical and its outside face up stream. To this angle were attached various crest pieces as will be described. At the bottom of the bulkhead an 8-in. valve served for emptying the weir chamber and for regulating the water level during zero determinations.

Weirs of Series A to P

The various weirs of Series A to P, inclusive, differed from one another either because of different crest pieces fastened to the 3½ by 5-in. steel angle, or because of different heights made (for less than full heights) by a movable false bottom, which was temporarily fixed at various elevations. (See Figs. 1 and 2.)

Series A.—Originally (ten years previously) the crest piece was accurately machined, as shown in Fig. 3. The rust was removed and the top was filed to some extent. When ready for the experiments the up-stream surface showed some pitting, and the top, considerable non-conformity of width. The up-stream top corner, except for occasional dents, presented what was thought to be a fair "sharp edge" under "service conditions". The height of the weir was 7.53 ft. and the experiments were made from February 2 to March 11, 1911.

Series B.—The crest piece (Fig. 3) was made from a ⅜-in. by 4-in. wrought-iron plate, planed straight, square, and sharp; and was bolted to the up-stream face of the weir plate for Series A. The height of the weir was 5.51 ft. and the experiments were made from March 25 to 31, 1911.

Dawson, Series I.—The crest piece (Figs. 3 and 4) was the same as that used in Series B, but after two years' service. The up-stream face and top appeared to have suffered considerable corrosion, although the up-stream top

corner showed unevenness rather than rounding. It was more decidedly pitted than the crest piece of Series C. The height of the weir was 5.51 ft. and the experiments were made in January, 1913.

Dawson, Series II.—A $\frac{3}{8}$-in. by 4-in. wrought-iron plate was accurately planed on top and along the up-stream face. The up-stream top corner was square and sharp; the top was flat, $\frac{1}{8}$ in. wide, with its down-stream edge rounded to a $\frac{3}{8}$-in. radius. (See Fig. 3.) The experiments were made while the crest was sharp, smooth, and free from rust. The height of the weir was 5.49 ft. and the experiments were made in May, 1913.

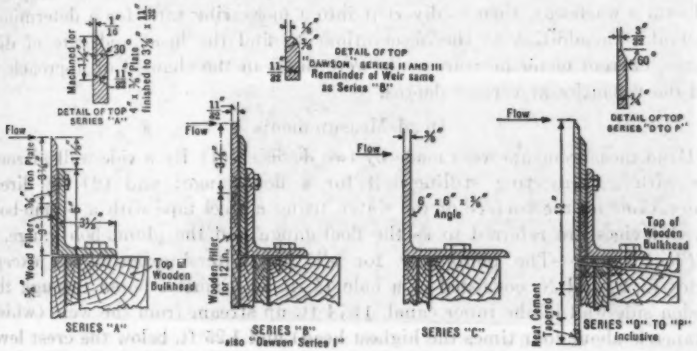

FIG. 3.—DETAILS OF CRESTS, SERIES A, B, C, AND D TO P, ALSO DAWSON SERIES, I, II, AND III.

Dawson, Series III.—The plate and setting was that used in Series II (Fig. 3), but after six weeks' exposure to water. About ten rust nodules could be detected on the up-stream top corner of the crest and slight roughness could be felt. The height of the weir was 5.49 ft. and the experiments were made in June, 1913.

Series C.—A 6 by 6-in. by $\frac{3}{8}$-in. angle (Figs. 3 and 5), a part of the crest piece from the lower 16-ft. weir in the outside experimental canal, served as a crest. This angle was used in place of the 5 by $3\frac{1}{2}$-in. angle previously described. The up-stream face and top were originally planed straight and sharp with a flat top $\frac{3}{8}$ in. wide. The experiments were made after the crest had been in service about twelve years, during which time it was frequently scrubbed and occasionally filed to keep the up-stream face and the up-stream top corner free from rust. During the Series C measurements, the crest part of the angle (see Fig. 5) was in a good state of preservation, showing extensive rusting on the up-stream face near the top, but not what would be called a pitted surface. The top had somewhat of a glaze, making it smooth to the touch. The up-stream top corner of the crest had lost its extreme sharpness so that, while for the most part square and sharp to the casual inspection, it was actually dented and felt dulled and rounded. The height of the weir was 5.34 ft. and the experiments were made from February 8 to April 12, 1914.

Series D to P.—The crest piece was of rolled brass, 12 in. wide and $\frac{1}{4}$ in. thick, and was added to the up-stream face of the crest piece, Series A. The up-stream top corner was straight, square, and sharp. The flat top was care-

fully machined to a $\frac{3}{32}$-in. width and beveled down stream 60° to the horizontal. During the experiments a true sharp corner was carefully maintained by occasional use of a fine carborundum stone. The up-stream face was kept smooth and free from organic deposits. The small shoulder at the lower edge of the plate was filled in with neat cement for a 4-in. depth and tapered to a thin edge. (See Fig. 3.)

Method of Experimentation

General Method.—The procedure was to establish a steady flow of water over the weir at approximately the desired head, permitting the discharge to fall into a wasteway, then to divert it into a measuring tank for a determined interval. In addition to the observations to find the head and rate of discharge, current-meter measurements were made in the channel of approach to find the velocities at various depths.

Head Measurements

Head measurements were made by two devices: (1) By a side-wall piezometer with a connecting stilling-well for a float-gauge; and (2) by direct observations on the surface of the water, using a steel tape with a plumb-bob. These devices are referred to as the float-gauge and the plumb-bob gauge.

Float-Gauge.—The piezometer for all the writers' experiments, except Series E, F, and N, consisted of a hole $1\frac{1}{8}$ in. in diameter bored through the wooden side-wall of the inner canal, 11.74 ft. up stream from the weir (which distance is about four times the highest head) and 1.25 ft. below the crest level (Fig. 1). For Series E, F, and N the piezometer consisted of two such holes (Fig. 1), 9 in. apart horizontally, located 0.25 ft. below the crest level, the mid-point between the holes being vertically above the single hole just described. This different piezometric arrangement was made necessary by the fact that the floor of the channel for Series E, F, and N was above the single piezometer hole. It was deemed desirable to use the same float-gauge for all series, and there was an advantage in construction in having two symmetrically placed holes, with a supposed greater accuracy of readings for these shallow channels with relatively high velocities of approach.

Into the single hole was screwed, horizontally from the outside, a 20-in. length of 1-in. standard wrought-iron pipe, but not projecting through on the inside. At its outer end an up-turned elbow connected it with a vertical, 6-in. wrought-iron pipe, 5 ft. high, serving as a stilling-well for the float-gauge proper (Section *A-A*, Fig. 1).

In the well was a cylindrical copper float, top and bottom ends dished outward so as to shed the water and not to entrap air. The float stem consisted of a $\frac{1}{4}$-in., round, brass rod passing axially entirely through the float, thus materially stiffening it.

The stem was long enough to extend above the top of the 6-in. pipe when the water level in the canal was several inches below the weir-crest level. At the top of this stem a combined index and guide (Fig. 6), traveled along the edge of a brass scale graduated to hundredths of a foot.

For Series A, B, and for 18 runs of Series C, the float was a cylinder, $5\frac{5}{8}$ in. in diameter. For all later work, a 5-in. float was used with four ver-

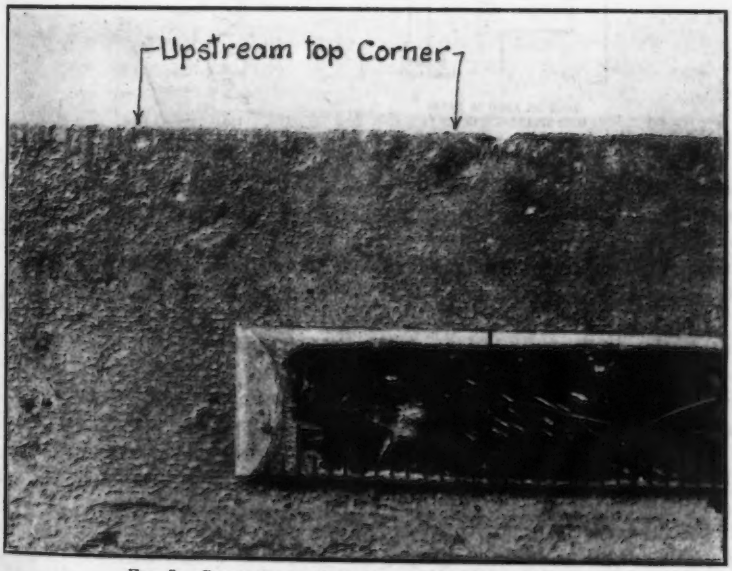

FIG. 5.—CREST PIECE, SCHODER AND TURNER SERIES C.

Upstream Top Corner

Upstream Top Corner

tical fins attached. These were rounded off so as to project ⅜ in. at the middle and ¼ in. at the top and bottom (Fig. 6), which arrangement avoided capillary lifting effects that occur when a plain cylindrical float drifts against the surrounding pipe walls curved to a radius only a little greater than that of the float. This effect has been observed to be as much as 0.003 ft.

For Series E, F, and N, a pair of horizontal 1-in. pipes led from the two piezometer holes to tees in vertical 1-in. pipes, the downward extensions of which on either side led through an elbow and a short horizontal piece to a cross in the 1-in. pipe leading out of the lower piezometer hole. The upward extensions of the vertical pipes reached above the highest water level in the canal and served as air vents. For the lower piezometer the float well itself served as an air vent. Plug cocks in the three 1-in. pipe lines enabled either the lower single-hole piezometer or the upper double-hole one to be connected to the float well.

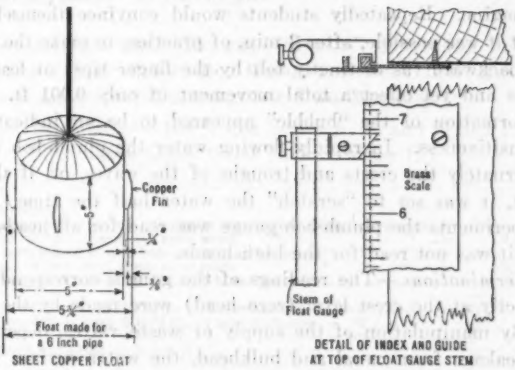

FIG. 6.—FLOAT-GAUGE DETAILS.

In use, the float-gauge has the great merit of giving continuous indications without the necessity of making settings. The degree of damping of the magnitude of waves or surges may be varied by changing the ratio of area of piezometer hole to that of the float well. To remove any mechanical friction or "sticking" of the index the observer at short intervals rapped the framework of the scale.

With high heads, or rapid flows in the channel of approach, the alternating high and low readings of the float-gauge were taken. Usually, the time interval between successive high and low indications was 15 to 40 sec. As a general rule, several readings of the float-gauge were taken just before, during, and after the discharge measurement.

*Plumb-Bob Gauge.**—This gauge (Fig. 1) consisted of a steel tape, graduated to hundredths of a foot, to the end of which was attached a brass plumb-bob. A 4 by 12-in. plank, securely bolted, across the 6-ft. canal carried the "tape block", having on its top a brass plate grooved to admit the steel tape

* The plumb-bob gauge used was substantially as designed by Gardner S. Williams, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 1261.

and marked with an index line. The tape hung over the rounded end of the block the same distance up stream from the weir as the piezometer holes of the float-gauge. In use, the plumb-bob was rapidly lowered by unreeling the tape which was then slipped into the groove where it was lightly held with the finger tips or thumb of the left hand. The right hand steadied by the back of the tape block then fed the tape down or up, as desired by manipulation between thumb and forefinger. The bob was slowly raised out of the water until the "bubble" at the point "broke" (that is, disappeared), the point then being about 0.005 ft. above the water surface. The tape was then very slowly fed out until the "bubble" formed at the point of the bob indicating contact with the surface, for which position the reading was taken. This phenomenon was of pronounced visibility, even when the observer was 10 or 15 ft. above the water surface.

The device proved to be far more sensitive than one unacquainted with it would imagine. Repeatedly students would convince themselves to their surprise that it was possible, after 3 min. of practice, to make the tape "jump" forward or backward (as distinctly felt by the finger tips) at least three successive times and yet effect a total movement of only 0.001 ft. With quiet water the formation of the "bubble" appeared to be an indicator of corresponding sensitiveness. In rapidly flowing water the plumb-bob was adjusted to show alternately the crests and troughs of the waves, or, if these were of small height, it was set to "scratch" the water half the time. For several series of experiments the plumb-bob gauge was read for all heads, but, in the later series, it was not read for the high heads.

Zero Determinations.—The readings of the gauges corresponding to water surfaces exactly at the crest level (zero head) were made by the "water-level method". By manipulation of the supply or waste valves, depending on the amount of leakage from canal and bulkhead, the water surface in the canal was held practically steady just below the level of the crest or perhaps a few thousandths of a foot above the crest.

A hook-gauge, temporarily clamped to the crest (Fig. 1), served to measure the exact difference of elevation between water surface and the crest. The point of the hook was adjusted so as to be about 1½ in. up stream from the crest. A small pocket level with a sensitive bubble was nearly balanced across the crest piece with the up-stream end resting lightly on the point of the hook. The hook-gauge was then adjusted so as to center the bubble, and the hook-gauge reading was taken. The procedure was repeated with the spirit-level reversed. Then, on signal from the hook-gauge observer, when he made contact with the water surface, the float-gauge was read. This was repeated six times and then the crest-gauge was again read for crest level.

The whole procedure was repeated for the plumb-bob gauge (there being but two observers). Such a determination was made with the hook-gauge at the middle of the crest and also at the one-sixth points out from either canal wall, so that there was an independent zero determination for each one-third of the crest length for each gauge. For some series several such complete determinations were made.

The benefits of these careful zero determinations appear in the close agreement of heads as determined by the two types of gauges. (See summary in Table 2.)

Discharge Measurements

The discharge measurements of the sheet of water flowing over the weir were obtained by diverting it for an appropriate interval of time from the wasteway into the calibrated tank.

"Diverter."—The diverter (Fig. 1) was an inclined rectangular wooden apron, 8. ft. long, fitted with sheet-iron sides, 15 in. high, so as to form a steep chute. It was hinged near its lower edge to the top of a bulkhead built at the entrance to the standpipe.

Hoisting Tackle.—This consisted of a 1-in. rope passing over a pulley, the up-stream end being attached to the apron by rod-links and the other end sustaining an adjustable counterweight.

TABLE 2.—CORRESPONDENCE BETWEEN "HEADS" MEASURED (1) BY FLOAT-GAUGE; AND (2) BY PLUMB-BOB GAUGE FOR VERY LOW HEADS, SHOWING THE CLOSE AGREEMENT BETWEEN THE TWO METHODS.

(Heads below 0.100 ft. for Series A, B, and D to P; heads below 0.200 ft. for Series C.)

Series D to P, Inclusive:		
Number of runs where plumb-bob gauge was higher than float-gauge =	70	
Average head, in feet, that these runs were " " " " =		0.0004
Number of runs where plumb-bob gauge was lower " " " " =	39	
Average head, in feet, that these runs were " " " " =		0.0004
Number of runs with the same head by both gauges =	5	
Total number of runs considered in this comparison =	114	
Number of runs with 0.0005 ft., or less variation = 92		
" " " " 0.0010 ft., " " " = 108		
Maximum variation = 0.0016 ft.		
Series A, B, C:		
1st.—Using old type float (without fins):

Average head, in feet, that these runs were " " " " =		0.0011
Number of runs where plumb-bob gauge was lower " " " " =	16	
Average head, in feet, that these runs were " " " " =		0.0008
Number of runs with the same head by both gauges =	1	
Total number of runs considered in this comparison =	26	
Number of runs with 0.0005 ft., or less variation = 11		
" " " " 0.0010 ft. " " " = 19		
Maximum variation = 0.0022 ft.		
Series C:		
2d.—Using new type float (with fins):		
Number of runs where plumb-bob gauge was higher than float-gauge =	14	
Average head, in feet, that these runs were " " " " =		0.0005
Number of runs where plumb-bob gauge was lower " " " " =	15	
Average head, in feet, that these runs were " " " " =		0.0002
Number of runs with the same head by both gauges =	2	
Total number of runs in this comparison =	31	
Number of runs with 0.0005 ft., or less variation = 24		
" " " " 0.0010 ft., " " " = 29		
Maximum variation 0.0011 ft.		

A 1-ton spur-geared chain block served to hoist the counterweight and to sustain it until after the diverter was dropped from the "up" to the "down" position. It also served as a control while adjusting the diverter contact.

To hold the diverter in the "up" position when the counterweight was hoisted, the bent end of an iron rod was "hooked" over the lip of the diverter,

the other end being hooked over an iron railing. This holding rod was called the "trigger". A small rope, tied to the trigger near the lower end, passed over the top of the extension side of the inner canal where it sustained a small counterweight. A pull on the diverter rope by one of the experimenters, bracing himself against the railing, raised the diverter slightly so that the trigger could be pulled out of the way by the small counterweight. The diverter could then be "dropped" through the sheet of water, and the large counterweight released by the chain block until it hung free. This counterweight had been adjusted previously so that the force of the sheet of water would hold the diverter down, but a slight downward pull on the counterweight would cause the diverter to rise through the sheet of water.

The diverter chute was 5.5 ft. wide, being narrow enough to have some clearance inside the 6-ft. canal and inside the entrance to the 6-ft. standpipe, and yet wide enough to project about 6 in. outside the over-head extensions of the side-walls of the inner canal. When the diverter was in the "down" position, it was supported by a "bumper" consisting of a 4 by 4-in. cross-piece resting on side posts independent of the weir bulkhead. The upper edge or lip of the diverter was about 1 in. below the down-stream edge of the small fixed sloping apron on the weir bulkhead. This arrangement caught all the water, even at low heads, except those between about 0.60 and 0.75 ft., which had to be avoided because the sheet of water struck the diverter so close to the upper edge that considerable water splashed backward and upward through the clearance space between the diverter and the bulkhead apron.

Wasteway.—The wasteway (Fig. 1) acted as an intercepter for any leakage from the weir bulkhead, so that the measuring tank was unaffected by such leakage. With the highest heads, in Series A, B, C, and Dawson's Series I, II and III (more than 2 ft. over the weir), when the diverter was in the "up" position with water flowing to waste, there was considerable turmoil in the wasteway, and a small quantity of water found its way into the stand-pipe through the hinge and over the bulkhead through the clearance spaces outside the diverter. This small leakage was accounted for in the regular course of the observations for initial and final water levels in the stand-pipe measuring tank. When the diverter was in the "down" position (water flowing into the stand-pipe), there was, at the highest heads of Series A, B, and C, a small back-splash through the clearance spaces out from the standpipe into the wasteway. To account for this, the law of total leakage into the wasteway was found by observing the heads on the 12-in., Cipolletti weir notch (Fig. 1) in a bulkhead across the outer end of the wasteway channel, for various heights of water back of the experimental weir, ranging from several feet below the weir crest to the level of the highest heads used in the experiments.

For water levels above the crest of the weir the diverter was in the "down" position, as during the discharge measurements. Thus, the law of leakage variation through the bulkhead for different heads was clearly established, and any excess was charged to back-splash from the stand-pipe. As a check, actual observations of conditions were made by a man going into the wasteway under the diverter while the flow was proceeding. Both the weir bulkhead and the

bulkhead at the stand-pipe entry were frequently examined, and conditions always found to be as assumed for the correction measurements and calculations.

This back-splash from the stand-pipe into the wasteway at high heads was practically eliminated for the writers' Series D to O, by sealing all clearance cracks of appreciable size with thin wooden strips.

Stand-Pipe Measuring Tank.—This tank (Fig. 1) was a circular steel stand-pipe, 6 ft. in diameter, 60 ft. high, made of cylindrical sections, 5 ft. high. It was calibrated in two ways: (1) By measuring its outside girth by a steel tape with proper allowance for thickness of metal, vertical position of the lap joints, volumes of recesses inside at various attached saddle nozzles with their gate-valves, rivet heads, etc.; and (2) by repeatedly filling with water and then draining off successive quantities into a precisely calibrated tank with a capacity of 400 cu. ft. The initial level and the intermediate levels were varied so that the final calibration points covered the entire 60-ft. vertical range by 1-ft. intervals. These two calibrations were referred to tape and scale readings on the stand-pipe float-gauge.

Stand-Pipe Float-Gauge.—The float was of copper, torpedo-shaped, moving in a 6-in. vertical pipe set alongside the stand-pipe and connected to it at the bottom by a 2-in. pipe. A bronze ribbon tape was attached to the top of the float and passed up out of the 6-in. pipe, over a bicycle wheel and down into a 3-in. vertical pipe which served as a guide for the counterweight on the other end of the tape (Fig. 1). On top of the 6-in. pipe, alongside the vertical tape, was mounted an auxiliary brass scale divided into 0.1 and 0.01 ft. The bronze tape had graduations at 1-ft. intervals. This arrangement permitted readings by estimation to 0.001 ft., which extent of change of level in the stand-pipe and float pipe was readily indicated by a corresponding movement of the tape. From time to time the indications of the bronze tape were checked, in operating position, by comparing the indicated difference of elevation between near-full and near-empty conditions with the difference by steel-tape measurements between water gauges near the top and bottom.

The adopted calibration was that by the water-filling method with direct readings on the float-gauge, just as in the experiments proper. This calibration was based on precise weighings of a succession of 5-cu. ft. quantities into the lower 400-cu. ft. rectangular tank for its calibration. This lower tank was also calibrated by dimensional measurements. The two methods agreed within 0.1 per cent.

The precise determination of the inside dimensions of the stand-pipe involved great difficulties, and yet the two calibrations agreed within 0.2 per cent.

Time Measurements.—The durations of the diversions into the stand-pipe were measured, except for low heads (for which an ordinary watch was used) by a ribbon electric chronograph, one pen actuated by a seconds pendulum and the other by a diverter contact.

This contact device (Fig. 1) consisted of a weight, free to move vertically on a pair of fixed iron guide-rods, and suspended by a wire passing over a

small grooved pulley and fastened to the diverter. The weights carried a brass contact finger moving between two leaves of spring brass mounted on a metal block that could be clamped anywhere along a second pair of vertical guide-rods. The position of the gap was adjusted (for each different head on the weir) so that the contact point closed the circuit just as the lip of the diverter passed through the middle of the sheet of water. In some of the first experiments two contacts were used, one adjusted for the diverter lip at the lower, and the other, at the upper, surface of the sheet of water.

With an effective volume of about 1 200 cu. ft. available in the stand-pipe, a measurement at the highest head (60 cu. ft. per sec.) covered 20 sec. With a head of 1 ft., the duration was about 80 sec. Usually, for the highest heads, the discharge was measured five times in succession. The chronograph was used for measurements up to 2 min. in duration. Low-head measurements lasting 3 min. or more were timed by a well-regulated watch, the second hand of which made 5 visible jumps per sec. To avoid effects of eccentricity of the seconds' dial, the runs were made to cover an exact number of full minutes.

Procedure in a Typical Run

As a rule, neither runs nor zero determinations were made until after the weir bulkhead and canal walls had become thoroughly water-soaked. Customarily, water was flowing over the weir at all times, whether or not experiments were in progress.

At the start of a run the 30-in. valve was opened so as to give the desired head as shown by the weir float-gauge. Time was allowed for the head to become steady; this developed almost as fast as the valve could be opened for the high heads, but required as long as 10 or 15 min. for the extremely low heads. The leakage through the weir bulkhead into the wasteway materially hastened the adjustment for these low heads.

The diverter contact was then adjusted to a point midway between temporary chalk marks made on the guide-rods as the diverter was slowly moved through the sheet of water by the chain-block control. Also, the counterweight was regulated to suit the volume of water flowing.

The stand-pipe, having previously been partly filled with water, was now nearly emptied by throwing into the "open" position the lever of a 4-way valve which controlled the 36-in. hydraulic valve at the bottom of the stand-pipe (60 ft. below the operating floor). While the stand-pipe was emptying, the control lever was thrown into the "close" position, the operation being so timed that the 36-in. valve would be completely closed with at least 5 ft. of water remaining in the stand-pipe. This process of closing "under pressure" materially reduced the leakage from the closed valve.

Usually three or more readings at ½-min. intervals were taken on the stand-pipe gauge for the initial water level; also the weir float and plumb-bob gauges were read several times. The chronograph was then started, the diverter dropped, and the counterweight released to hang free. (Usually one observer read the weir float-gauge while the flow was going into the stand-pipe. For low heads both the float-gauge and the plumb-bob tape were read several times

alternately. For the high heads the duration of the volumetric measurement was too short to permit readings of the plumb-bob gauge.) At the end of the desired interval of time the counterweight was pulled, moving the diverter up through the sheet of water, and the trigger was hooked over the lip of the diverter. The chronograph was then stopped and the ribbon examined to make sure the record had no flaws.

Just 1 min. after the diverter went up, allowing this time for settlement in the stand-pipe and its float-pipe, readings were taken for final water level, usually three or more at ½-min. intervals. Immediately after the diverter went up, readings of the weir head-gauges were taken, as at the beginning. The stand-pipe was then emptied to about the 5-ft. level, ready for another run. Some typical original laboratory notes and primary calculations are given in Table 3.

Primary Calculations from Observed Data

Leakage Corrections.—It was the practice to make corrections systematically even when they seem negligibly small, as in most cases. From Column (3) of Table 3, it is seen that in Run 55, Series D, the surface of the water in the stand-pipe measuring tank was rising at the beginning (before the diversion into the tank) at the rate of 0.032 ft. per min., and at the end (after the run) at the rate of 0.025 ft. per min., both values being recorded in Column (8). This rise was due to some leakage into the stand-pipe at the diverter hinge from splash in the wasteway.

It was known from many observations that there was a negligible leakage from the valve at the bottom of the stand-pipe with low heights of water, increasing to a small but appreciable quantity for the filled stand-pipe. Consequently, as the data show, at the end the diminution in the rate of rise represents the rate of fall (relatively to the beginning) due to leakage from the stand-pipe—in this case, 0.007 ft. per min. With no leakage at the start and 0.007 ft. per min. at the end, an average of 0.0035 ft. per min. is used for the $\frac{39}{60}$ min. of the volumetric measurement. Then to the last of the initial readings (here taken 1 min. before the diverter was dropped) is added 0.032 ft. to give the initial reading at the instant of diversion. To the first of the final readings (here taken 2 min. after the diverter was raised) is added the 0.002 ft. to offset leakage from the stand-pipe during the run; finally, $2 \times 0.025 = 0.050$ ft. is subtracted on account of the leakage into the stand-pipe during the 2 min. elapsed. In this example, the corrections are small, but with heads of more than 2 ft. they were considerable.

The values in Column (9) of Table 3 are taken from the calibration curve of the stand-pipe for the corrected initial and final water levels. This curve permitted readings of heights to 0.005 ft. and of volumes to 0.1 cu. ft. In Column (4) the times of day for diverter "in" and "out" are noted as read on an ordinary watch to the nearest second. The exact duration as scaled from the chronograph ribbon is also recorded. In Column (5) the readings of the weir float-gauge before, during, and after the run are shown. Column (6) gives the readings of the plumb-bob gauge before and after the run, and shows that no readings by this gauge were taken during Run D-55.

Column (7) shows the average gauge readings, and the subtraction of the zero readings to obtain the heads on the weir crest. In Series D it was decided to average all the weir float-gauge readings rather than to use only those taken during the run, although this latter procedure was the usual one when sufficient readings were available. In this case there were five consecutive runs, Nos. 51 to 55, inclusive, at the same valve setting. In only three runs, Nos. 51, 52, and 55, was the float-gauge read during the run, but in all of them readings were taken just before and just after the run, as was the case also for the plumb-bob gauge. The readings during Runs Nos. 51, 52, and 55 by float-gauge as compared to the average of readings before, during, and after the test, showed a deficiency of 0.0009 ft., or 1 part in 2 000; as compared to the grand average by both gauges, the deficiency was only 0.0004 ft. The average head by float-gauge in Runs Nos. 53 and 54 (readings taken only before and after the run) shows exact agreement (h = 1.8039 ft.) with the grand average.

In Run No. 14, Table 3, covering Series J (typical low head), all the weir head readings were taken during the volumetric measurement, which lasted 10 min. The duration was controlled by an ordinary well-regulated watch, the observer moving the diverter to the nearest 0.2 sec. The steadiness of the water surface in the channel of approach tempted the observer to estimate 0.0005 ft. in reading the gauges.

For the very highest heads the leakage into the stand-pipe from the waste-way before and after the measurement was greater than in Run No. D-55. For heads of 2.0, 2.25, 2.50, and 2.75 ft. in Series D the rates of rise in the stand-pipe were, respectively, 0.075, 0.45, 1.5, and 2.5 ft. per min., so that great care was used in noting the exact second the diverter went in and out. Also, at least five readings on the stand-pipe gauge were taken at exact 15-sec. intervals before and after the measurement, in order to determine the rate of rise closely. The weir-head gauges were each read, usually six times, immediately before and, again, immediately after the measurement.

Velocity Measurements

Velocity measurements in the channel of approach were made for the relatively higher heads, just before or just after the volumetric measurements, using a small Price electric current meter with a telephone receiver. The meter was held in position by an iron rod graduated to feet and tenths, and was operated through the same cross-section in which the head was measured. The meter was rated several times during the course of the experiments and found to remain substantially constant in its indications.

Velocities.—For most of the writers' Series A to P, only the velocities along a single vertical element at mid-stream were observed. For Series F, velocities 0.5 ft. from either side-wall were read for a head of 2.36 ft. on the weir. For Series K, velocities in five verticals were observed at 2-ft. head. Fig. 42 shows the horizontal distribution of velocities. Appendix B tabulates the results of all velocity measurements, and Figs. 33 to 47 show the curves of velocity distribution.

For Series N (0.75-ft. weir) and Series K (5.5-ft. weir) additional vertical mid-stream traverses were made 6 ft. up stream from the weir to determine whether any considerable re-arrangement of velocities had been effected as the flow approached the weir between the sections, 11.74 ft. and 6 ft. up stream. Figs. 38 and 43 show the comparative distributions. Little change is seen for the 2-ft. head of Series K; but in three of the four cases of Series N there is an indication of a slowing up of the mid-channel velocities, probably at the expense of increasing wall velocities.

With a weir, 3.76 ft. high and 5 ft. long, and with screens 17.7 ft. up stream from the weir, Fteley and Stearns made three velocity measurements for a head of 0.78 ft., in each of three verticals at 16 ft. and also at 8 ft., up stream from the weir. They conclude* that "8 ft. is not a sufficient distance to cause even a partial re-arrangement, such as might be looked for."

Fig. 48 shows a velocity distribution measured by Fteley and Stearns 5 ft. up stream from their 6.55-ft. weir, 19 ft. long, with a head of 1.304 ft.† This measurement stands alone as a definite velocity traverse showing channel conditions in the classic experiments of Francis, Fteley and Stearns, and Bazin.

Adjustment of Velocities.—The average head on the weir during a set of current-meter measurements usually differed slightly from the head during the corresponding volumetric measurements (Appendix B), so that, to obtain the discharge during the current-meter measurements, the observed discharge by volumetric measurement needed to be corrected slightly, according to the law of variation between Q and h for the particular weir at the particular head. (For the high weirs, Q varies nearly as $h^{\frac{3}{2}}$. For the lower weirs at the high heads, the exponent of h is appreciably more than $\frac{3}{2}$, being 1.85 in Series E. It was found for each weir by logarithmic plotting of the values actually measured.)

The true mean velocity of approach prevailing during the current-meter measurements was then calculated by dividing the adjusted volumetric discharge per foot of width by the depth of water in the channel of approach. In general, the mean velocity as found by current meter (above a single vertical element) differed from this true mean velocity by volumetric measurement. The ratio was computed and assumed to apply to each of the component parts of the curve of velocity distribution in the vertical, such as V_a, the mean velocity above the crest level, and V_b, the mean velocity below the crest level.

In a few cases (see Appendix B (Table 55)), the range of velocities was so extreme that the mean of the velocity heads is sensibly in excess of the head corresponding to the mean velocity. In such cases both values are shown, but the mean of the velocity heads is used in subsequent computations.

New Experimental Data by Others

Other experimental data on weirs without end contraction, herein published for the first time, are parts of the results of experiments made at Cornell University by Messrs. Charles L. Walker and Carl R. Weidner (1904)

* *Transactions*, Am. Soc. C. E., Vol. XII (1883), p. 38.
† *Loc. cit.*, p. 74.

while Senior students; and the following men while Graduate Students in Civil Engineering: William F. Martin (1906); Francis M. Dawson (1913); Henry R. J. Meyer and Russell A. See (1914); Jacob O. Jones (1915); and Charles M. Weber (1915).* All these experiments were on sharp crests except the rounded crests of Dawson and Jones.

The writers by personal association had intimate knowledge of the details of all these experiments. The first mentioned experimenters did their work under Gardner S. Williams, M. Am. Soc. C. E., in charge of Experimental Hydraulics at Cornell University. All the others worked with one of the writers in charge.

Walker and Weidner's Experiments.—These experiments showed the effects on the discharge caused by the width (thickness) of the crest piece ($\frac{1}{64}$ in. to 2 in.) at low heads (0.02 to 0.13 ft.). They were made on a weir 0.6 ft. high, set in a wooden flume, 0.895 ft. wide and 12 ft. long. The weir bulkheads for the $\frac{1}{64}$-in. and the $\frac{1}{8}$-in. thicknesses consisted of brass plates, and the $\frac{1}{4}$-in. crest was the edge of a varnished cherry wood plate set against the brass bulkhead with the $\frac{1}{64}$-in. crest. The water supply was by gravity at low velocity through a 6-in. pipe from an auxiliary low-level tank fed by a 2-in. pipe from a tank 45 ft. above, the water level of which was kept nearly constant by a float-valve. Heads were measured by a hook-gauge in the channel of approach 1.58 ft. up stream from the weir. The scale was graduated to 0.0025 ft. and a vernier permitted readings to 0.0001 ft. Discharges were measured by diverting established flows into a weighing tank of 2 000 lb. capacity. Periods of time were measured with an ordinary watch. The data are presented on Figs. 26 and 29, but are not tabulated.

Martin's Experiments.—Martin made his experiments to study the effects on discharge caused by the width of the channel of approach ($1\frac{1}{2}$ in. to 2 ft.). Only the data for the weir in his widest flume, 2 ft., are given here (Appendix A (Table 28) and Fig. 49). The weir was 1.2 ft. high with a double set of baffles, 10 ft. up stream. The crest piece was a brass plate, $\frac{1}{8}$ in. thick, its edge milled to a straight-edge, set flush with the up-stream face of the weir bulkhead. The water supply was by gravity, from a 12-in. connection at the bottom of the 6-ft. stand-pipe already described. At this connection there was a 12-in. gate-valve and an up-turned elbow feeding a 12-in. riser pipe, 12 ft. long, terminating in the bottom of the flume 2.5 ft. from the up-stream end.

Heads were measured 7.25 ft. up stream from the weir by two gauges: (1) A plumb-bob gauge for direct readings of the water surface in the flume; and (2) a piezometer consisting of a 1-in. hole through the side wall near the bottom. Into this hole a $\frac{3}{4}$-in. pipe was screwed from the outside so as to be exactly flush on the inside. The pipe led into the bottom of a cylindrical glass jar, 8 in. in diameter and 2 ft. high, used as a stilling-well, in which the water surface was read by a point-gauge. The given heads are the average for the two gauges, on each of which three to six separate readings were made during the diversion into the tank.

Discharges were measured by diverting the established flows into a lead-lined, 10 by 16-ft. measuring tank, 5 ft. deep, calibrated by withdrawing suc-

* Messrs. Walker, Weidner, Dawson, Meyer, See, Jones, and Weber are now members of the Society.

cessive 5-cu. ft. batches (by weight). Depths of water in the tank were measured by two plumb-bob gauges. All durations were measured both by a good stop-watch and by an ordinary watch read to 0.2 sec.

Dawson's Experiments.—These experiments relating to effects on discharge caused by small roundings of the up-stream top corner of the crest piece, covered sharp and nearly sharp crests and roundings to radii ranging from $\frac{1}{8}$ in. to $1\frac{1}{2}$ in. (Fig. 3). The same flume, apparatus, and methods were used as in the writers' experiments. Only the data for the sharp and nearly sharp crests are given in Appendix A (Tables 25 to 27), being plotted on Figs. 8 and 49, but the data for some of the roundings are represented on Figs. 27, 28, and 29.

Meyer and See's Experiments.—Meyer and See investigated the effects on discharge caused by the height of the weir (covering somewhat the same ground as Bazin's volumetric experiments). These tests were made in a concrete flume* (Fig. 7) 2 ft. wide, 4 ft. deep, and 30 ft. long. There were two sets of experiments. In Set I, the weir bulkhead was progressively lowered, the fixed concrete bottom of the flume being the bottom of the channels of approach. In Set II, the weir bulkhead remained 2.5 ft. high, as in Series A of Set I, but an auxiliary movable wooden bottom (Fig. 7) was introduced and lowered progressively from near crest level to 1.8 ft. below crest level. The water supply was by gravity from Beebe Lake through a 10-in. pipe leading from the 30-in. pipe.

Heads were measured by two float-gauges each connected, in Set I, to one of opposite piezometer holes formed by 1-in. pipes extending through the concrete sides of the flume close to the bottom. The float-pipes and floats were of the type used in the writers' experiments. In Set II, the piezometer holes were in the wooden bottom and a flexible connection was secured by using short lengths of $\frac{3}{4}$-in. rubber hose between $\frac{1}{2}$-in. pipe nipples screwed into the wooden bottom from below and similar nipples cemented into the piezometer holes used in Set I. The piezometer holes of Set II were located 6 in. on either side of the center line of the flume, the same distance from the weir as in Set I.

Discharges were measured by diversion of the established flow into one of two tanks, either a cylindrical tank of galvanized sheet iron of 70 cu. ft. capacity, or a rectangular concrete tank of 400 cu. ft. capacity. The discharge from the weirs fell into a large hopper funnel (Fig. 7) forming the upper end of a down-spout free to swing at its lower end thus turning the water to waste or into one of the tanks.

Durations of time were measured by an electric chronograph substantially as described for the writers' experiments. Velocities in the channel of approach were measured for only a few cases, in Set I, namely, for three heads each in Series C, E, and G. The data are given in Appendix B (Table 55) and plotted on Fig 47.

Jones' Experiments.†—These tests regarding effects on discharge caused by extremely small roundings of the up-stream top corner of the crest piece

* The flume and equipment were briefly described in *Engineering News-Record*, September 2, 1920, p. 452.

† A synopsis of Jones' results appeared in the *Cornell Civil Engineer*, November, 1917.

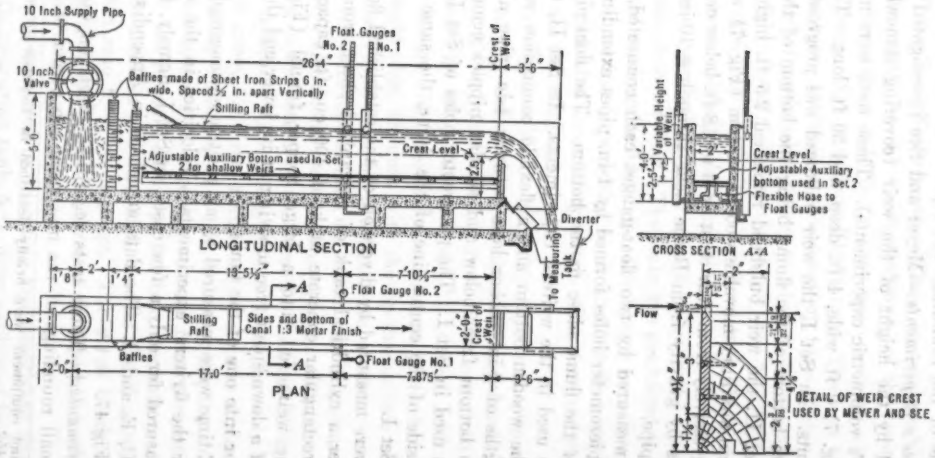

FIG. 7.—PLAN AND SECTIONS, CONCRETE FLUME.

were made with the same flume and measuring devices as used by Meyer and See (Fig. 7), with a weir 2.5 ft. high. The crest piece was a rolled brass plate, ¼ in. by 12 in., and 2 ft. 0 ⅞ in. long—other details as shown on Fig. 7. At first, the up-stream top corner was square and sharp. Then, progressively, the edge was "broken" and approximately rounded more and more for the succeeding series of experiments by light rubbings with a fine emery cloth. To measure the degree of rounding, impressions were taken with dental wax, and a section of the wax was micro-photographed. The data are given in Appendix A (Tables 42 to 49, inclusive) and on Fig. 30. Velocity measurements are given in Appendix B (Table 55), but the data are not plotted.

Weber's Experiments.—The effects on discharge due to the degree of roughness of the up-stream face of the weir near the crest, were made by Weber in conjunction with Jones, using the same height of weir and type of crest piece. The roughness was made by cutting a series of adjoining 60° V-grooves horizontally across the crest plate, starting in Series II, with 96 grooves per in. for 4 in. vertically below the crest, leaving the up-stream top corner square and sharp (Fig. 7). This kept the summits between the grooves in the same plane as for the smooth plate, and avoided a possible criticism of Barr's method of adding shellac and sand to the face.

The next degree of roughness, for Series III, was obtained by cutting 48 grooves per in., removing every other one of the smaller ridges; then, for Series IV, 24 grooves per in. were cut; and, finally, for Series V, as a modification of this last condition, the bottom 8-in. part of the brass plate, hitherto left smooth, was roughened by cutting 15 grooves per in. Series VI reproduced the conditions of Series III, 48 grooves per in. for the upper 4 in. of a 12-in. plate, with the lower 8 in. smooth. Weber's data are given in Appendix A (Tables 50 to 54, inclusive) and on Fig. 32. The velocity measurements are given in Appendix B (Table 55), but are not plotted.

Discussion on the New Data

General

In Appendix A (Tables 9 to 24, inclusive) are given measured heads and discharges per foot of length of weir for the writers' weirs; and also the percentage departures of the measured discharges from those computed for the same head by the simple Francis formula, $Q = 3.33\ L\ h^{\frac{3}{2}}$ (in foot-second units), or $Q = \frac{2}{3} \times 0.623\ L\ h \sqrt{2\ g\ h}$.

The latter part of Appendix A (Tables 25 to 54, inclusive) gives corresponding data for the experiments by Walker and Weidner, Martin, Dawson, Meyer and See, Jones, and Weber.

Figs. 8 to 13 and Figs. 23 to 29, inclusive, and Fig. 49, are plottings of the percentage departures with auxiliary scales of coefficients. This method of plotting places the data a little more definitely on a precision basis, but is really only a slight departure from the type of diagrams used by Fteley and Stearns, Bazin, and Rehbock, in showing variations of coefficients with the heads for various heights of weir.

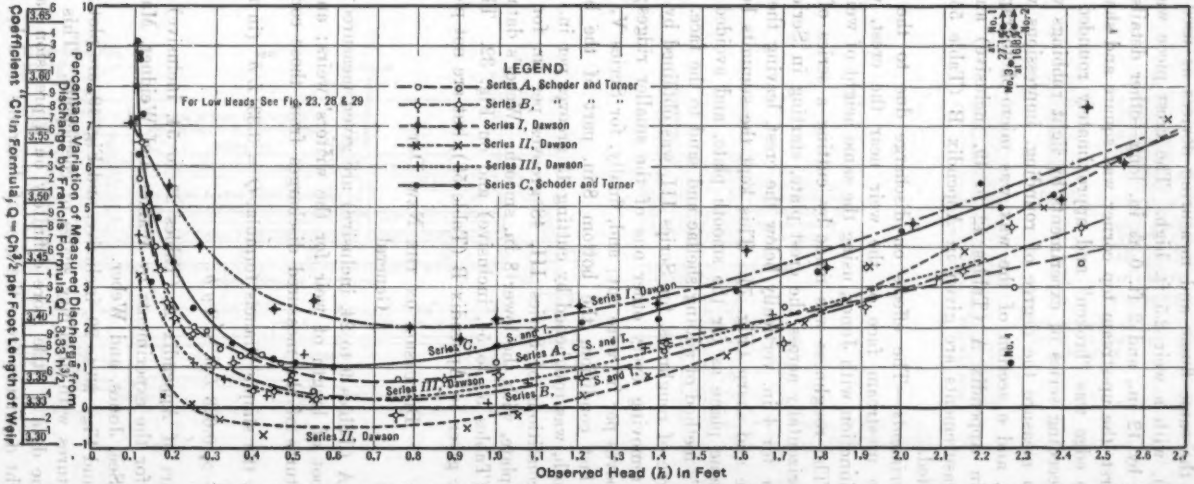

FIG. 8.—COMPARISON OF FLOW OVER SHARP OR NEARLY SHARP-CRESTED WEIRS WITHOUT END CONTRACTIONS. SIMILAR CONDITIONS FOR TESTS EXCEPT SLIGHT VARIATIONS IN SHARPNESS OF UP-STREAM TOP CORNER OF CREST, SMOOTHNESS OF UP-STREAM FACE, AND VERTICAL DISTRIBUTION OF VELOCITIES IN CHANNEL OF APPROACH.

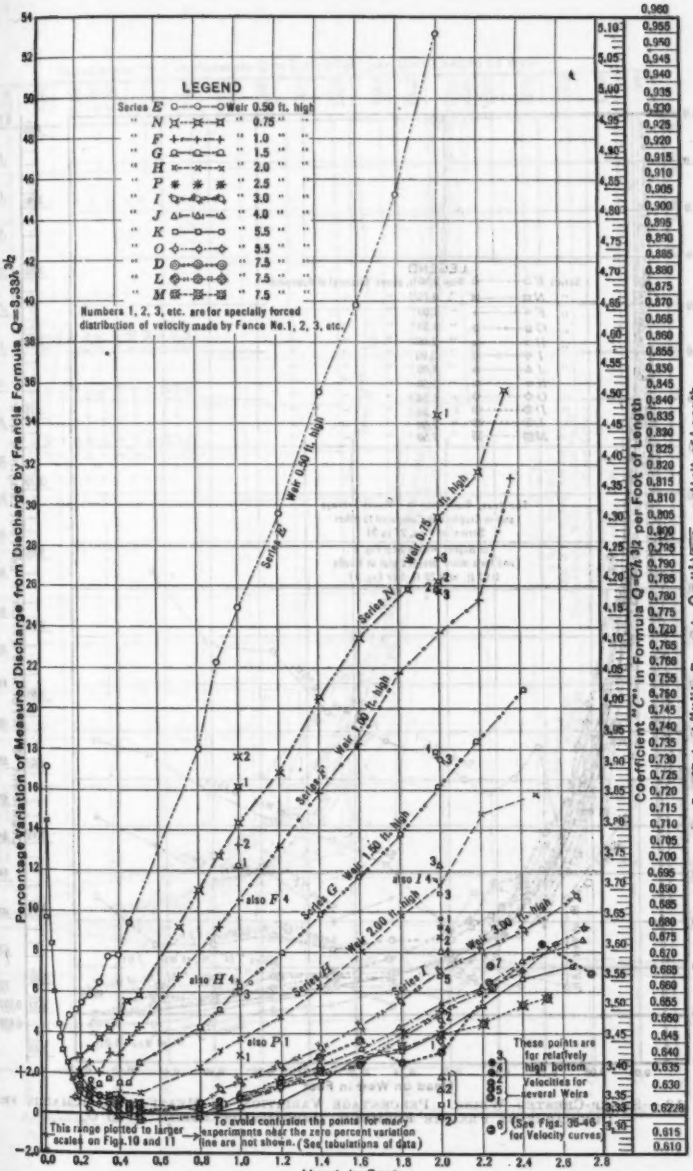

FIG. 9.—SHARP-CRESTED WEIRS. PERCENTAGE VARIATION OF MEASURED DISCHARGE FROM DISCHARGE BY FRANCIS FORMULA, SERIES D TO P.

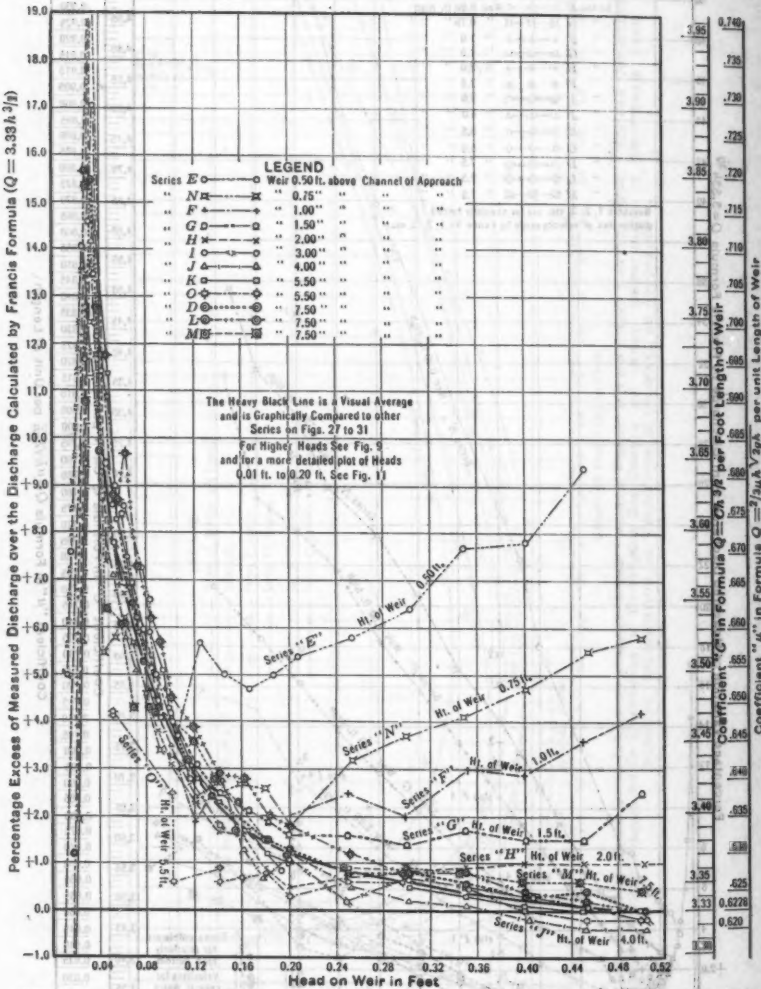

FIG. 10.—SHARP-CRESTED WEIRS. PERCENTAGE VARIATION OF MEASURED DISCHARGE FROM DISCHARGE BY FRANCIS FORMULA. LOW HEADS, SERIES D TO O.

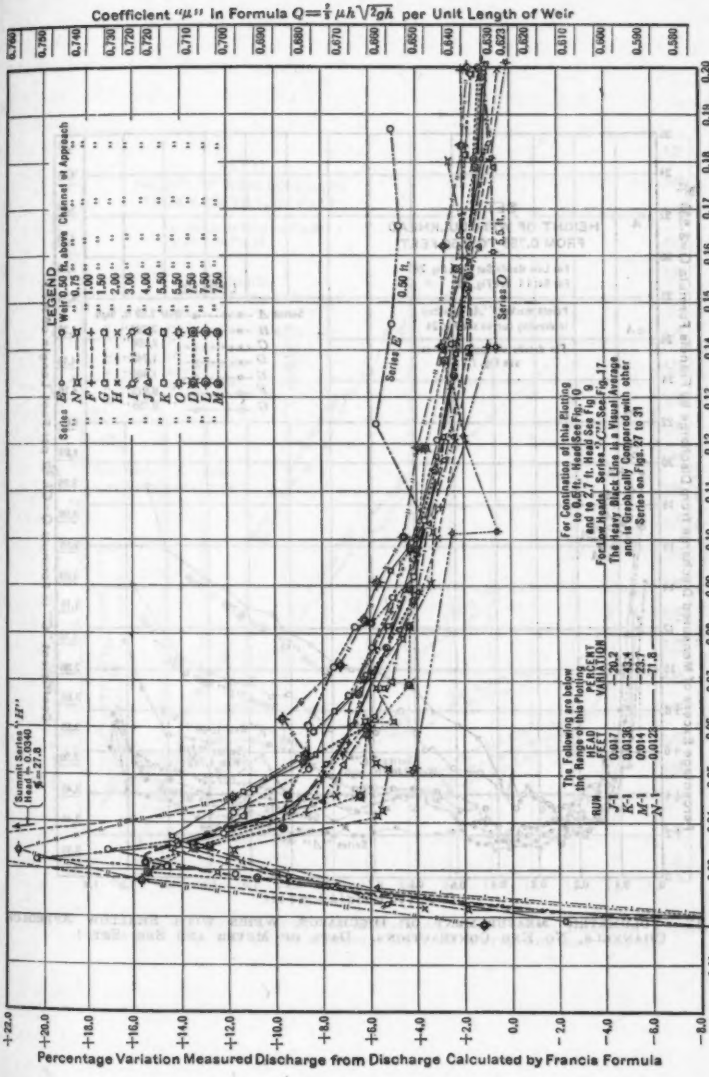

FIG. 11.—SHARP-CRESTED WEIRS. PERCENTAGE VARIATION OF MEASURED DISCHARGE FROM DISCHARGE BY FRANCIS FORMULA. EXTREMELY LOW HEADS, SERIES D TO N.

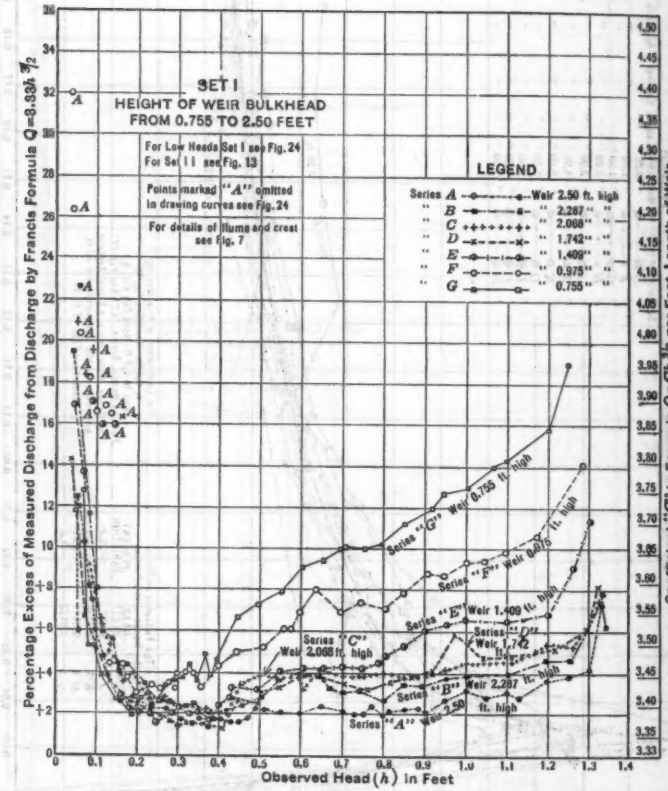

FIG. 12.—VOLUMETRIC MEASUREMENT OF DISCHARGE, WEIRS WITH SHALLOW APPROACH CHANNELS, NO END CONTRACTIONS. DATA OF MEYER AND SEE, SET I.

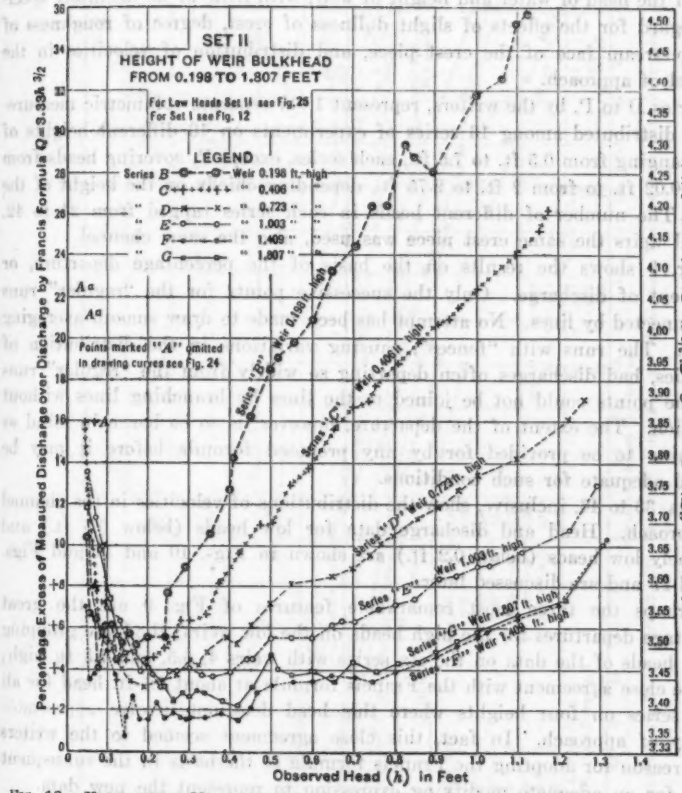

FIG. 13.—VOLUMETRIC MEASUREMENT OF DISCHARGE, WEIRS WITH SHALLOW APPROACH CHANNELS, NO END CONTRACTIONS. DATA OF MEYER AND SEE, SET II.

The Francis formula, as a tentative reference datum, was used for convenience in computations because of the availability of excellent tables* of discharges by this formula for heads differing by 0.001 ft. (interpolation to 0.0001 ft.).

New Data.—The writers' results yield thought-compelling illustrations of the magnitude of percentage variations in discharge. Particularly is this true if one adopts, for the moment, the usual custom of taking quantitative account only of the head of water and height of weir, with little or no definitely specified regard for the effects of slight dullness of crest, degree of roughness of the up-stream face of the crest piece, and distribution of velocities in the channel of approach.

Series D to P, by the writers, represent 1 017 separate volumetric measurements distributed among 13 series of experiments on 10 different heights of weir, ranging from 0.5 ft. to 7.5 ft., each series, except P, covering heads from about 0.02 ft. to from 2 ft. to 2.75 ft., depending chiefly on the height of the weir. The number of different heads in each series ranged from 24 to 42. For all weirs the same crest piece was used, also the same channel.

Fig. 9 shows the results on the basis of the percentage departure, or coefficient of discharge. Only the successive points for the "regular" runs are connected by lines. No attempt has been made to draw smooth averaging curves. The runs with "fences", causing variations in the distribution of velocities, had discharges often departing so widely from the "regular" runs that the points could not be joined to the lines by branching lines without confusion. The extent of the departure, however, is to be borne in mind as something to be provided for by any proposed formula before it may be deemed adequate for such conditions.

Figs. 33 to 46, inclusive, show the distributions of velocities in the channel of approach. Head and discharge data for low heads (below 0.5 ft.) and extremely low heads (below 0.2 ft.) are shown in Figs. 10 and 11 and Figs. 28 and 29 and are discussed later.

Perhaps the three most remarkable features of Fig. 9 are the great percentage departures for the high heads on the low weirs; the close grouping for all heads of the data on the six series with weirs 4, 5.5, and 7.5 ft. high; and the close agreement with the Francis formula at about 0.5-ft. head for all seven series on four heights where this head does not involve appreciable velocity of approach. In fact, this close agreement seemed to the writers ample reason for adopting the Francis formula as the basis in the subsequent search for an adequate modifying expression to represent the new data.

Old Formulas Tested by New Measurements

Figs. 14, 15, and 16 show in detail to what extent the discharges calculated for the measured heads by the formulas of Fteley and Stearns and Bazin, and the weir curves of Lyman, fail to agree with the measured discharges of the writers' "regular" runs of Series A to P. It is obvious that all these old formulas fail to fit even the general trend of the writers' "regular" runs.

* The tables by R. E. Horton, M. Am. Soc. C. E., in *Water Supply and Irrigation Paper No. 200*, U. S. Geological Survey, were used by the writers.

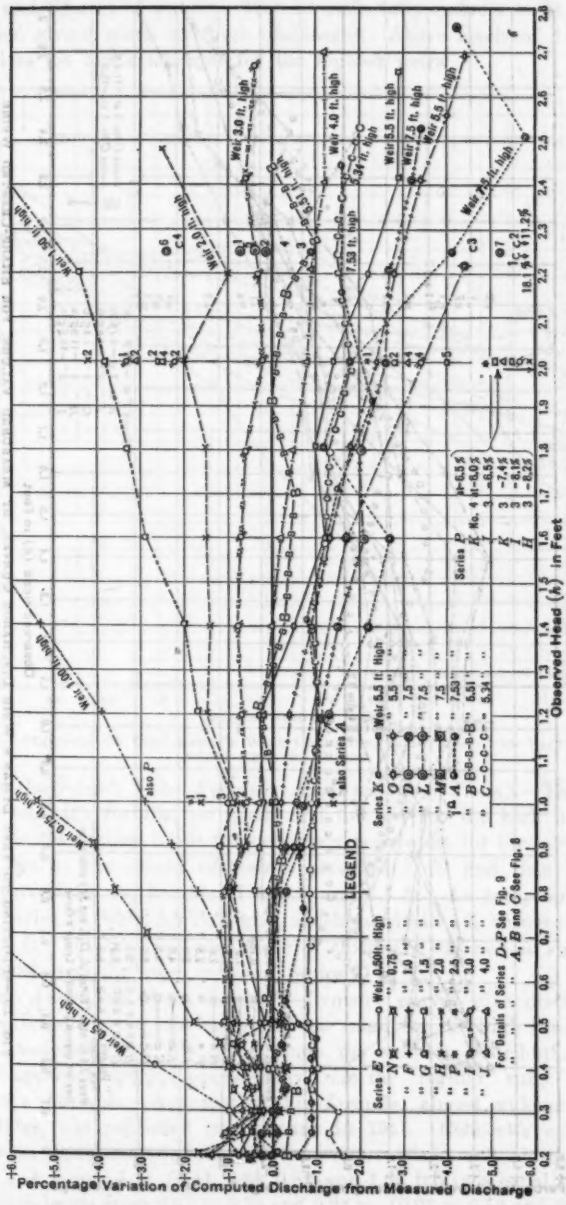

FIG. 14.—PLOTTING TO TEST FTELEY AND STEARNS' FORMULA BY MEASURED VALUES FOR SHARP-CRESTED WEIRS.

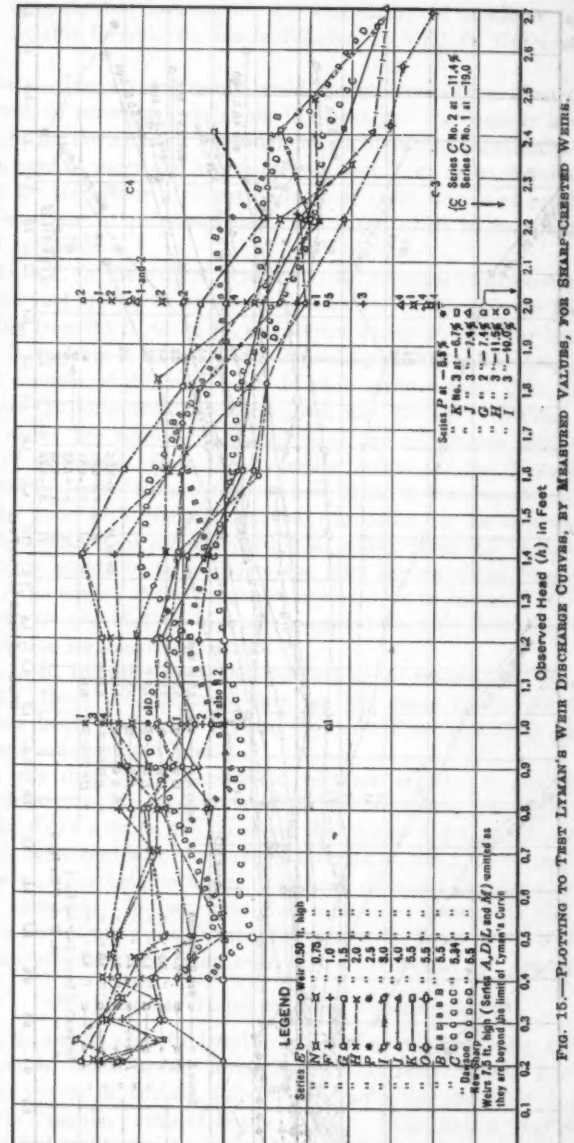

FIG. 15.—PLOTTING TO TEST LYMAN'S WEIR DISCHARGE CURVES, BY MEASURED VALUES, FOR SHARP-CRESTED WEIRS.

Fteley and Stearns' Formula.—This formula fails entirely to fit the four lowest weirs, giving much too high discharges. Above heads of 1.2 ft. the formula gives too low discharges for the highest weirs.

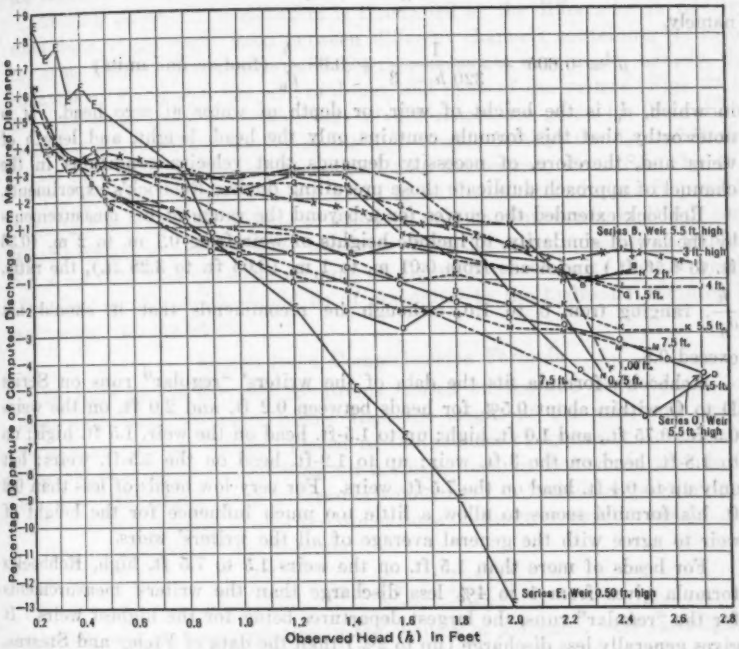

FIG. 16.—PLOTTING TO TEST BAZIN'S WEIR COEFFICIENTS BY MEASURED VALUES FOR SHARP-CRESTED WEIRS.

Bazin's Coefficients (and Formula Approximating Them).—These yield discharges too high for the low heads and too low for the high heads (see Fig. 16). At the highest heads the deficiency is greatest for the lowest weirs, becoming less as the height of weir approaches 3 ft. and then becoming greater progressively for heights of 4, 5.5, and 7.5 ft. An exception is to be noted for Series B (weir, 5.5 ft. high), which is within 1% between heads of 0.8 and 2.5 ft.; but the iron crest-piece of this weir was not as smooth nor as finely finished as the brass crests of Series D to P.

*Lyman's Averaging Weir Curves.**—Lyman's curves give discharges in general too large for the low heads and too small for the high heads. They are quite inadequate for the cases where the velocity distribution in the channel of approach differed considerably from the "regular" runs.

Rehbock's Formula.—Apparently, this formula, almost unknown in the United States, was published in Germany in 1911. Rehbock's experiments were made on sharp-crested, fully aerated weirs, without end contractions, of heights of $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{1}{2}$ m. (0.41, 0.66, 0.82, and 1.64 ft.) in a canal $\frac{1}{2}$ m. (1.64 ft.) wide with heads from 0.01 to 0.18 and 0.23 m. (0.03 to 0.59 and 0.75 ft.).

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), Plate XXI, p. 1195.

In 1912 he published* his revised formula for μ in the equation,

$$Q = \frac{2}{3} \mu L h \sqrt{2 g h}$$

namely,

$$\mu = 0.605 + \frac{1}{320\, h - 3} + 0.08 \frac{h}{d_0} \text{ (foot-second units)}$$

in which, d_0 is the height of weir, or depth of water at zero head. It is noteworthy that this formula contains only the head, height, and length of weirs and, therefore, of necessity demands that velocity conditions in the channel of approach duplicate those prevailing during Rehbock's experiments.

Rehbock extended the curves for μ beyond the range of his measurements by the law of similarity, to include heights of weir from 0.1 m. to 2 m. (0.33 ft. to 6.56 ft.) and heads from 0.01 m. to 1 m. (0.03 ft. to 3.28 ft.), the ratio, $\frac{h}{d_0}$, ranging from 0 to 1.0, although he recommends that it should not exceed 0.8.

Rehbock's formula fits the data of the writers' "regular" runs on Series D to O within about 0.5% for heads between 0.2 ft. and 2.0 ft. on the weirs 0.5 ft., 0.75 ft., and 1.0 ft. high; up to 1.5-ft. head on the weir, 1.5 ft. high; up to 1.8-ft. head on the 3-ft. weir; up to 1.2-ft. head on the 5.5-ft. weirs; but only up to 0.4-ft. head on the 7.5-ft. weirs. For very low heads of less than 0.2 ft. his formula seems to allow a little too much influence for the height of weir to agree with the general average of all the writers' weirs.

For heads of more than 1.5 ft. on the weirs 1.5 to 7.5 ft. high, Rehbock's formula gives from 1 to 4% less discharge than the writers' measurements for the "regular" runs, the largest departures being for the highest weirs. It gives generally less discharge (up to 2%) than the data of Fteley and Stearns, Martin, and Meyer and See.

Considering, however, only those runs of the writers' tests with "fences" of such a construction as to cause a nearly uniform distribution of velocities from surface to bottom of the channel of approach (omitting most of the runs with highest heads on the highest weirs) Rehbock's formula gives closer agreement.

Comments.—Of course, if the same sort of limitations be imposed the older formulas would also appear to better advantage. This brings up the matter of choice (where choice is possible in using a weir or dam for precise measurements of discharge) between (1) making velocity conditions in the channel of approach agree with the specified conditions for which a particular formula applies; and (2) making the formula suitable for such variations in velocity conditions as may actually occur between the numerous different cases that arise in practice.

One phase of the situation is illustrated by the actual conditions of velocity distribution and discharge in the writers' Series A to P for which a fixed baffle system was used, the same for all heads on any one weir, and with seemingly small changes between the different weirs. These changes,

* Handbuch der Ingenieurwissenschaften, III Teil, Wasserbau, Band 2 (Stauwerke), Vierte Auflage, 1912, p. 59.

if any, were not in the main baffles shown on Fig. 1, but possibly in the angle made by small fender boards fastened between the main baffle-boards in order to bring about a distribution of velocities approximately symmetrical across the canal.

Another phase of the situation is illustrated by the differences in velocity conditions at the same head between different channels containing weirs of the same height. In some cases direct measurements were made; namely, the channels of Meyer and See, and of Jones, and those of the writers (Figs. 33 to 47). In other cases the indications of differences are given by the various trends of the coefficient curves at the high heads; namely, the data of Bazin, Fteley and Stearns, Martin, Meyer and See, the writers, etc. (See Fig. 49.)

The practical question would seem to be "to what extent is it possible to build a weir and its channel of approach of such dimensions, and with such a baffle system and stilling-raft, as to reproduce the velocity conditions implied for a formula that takes no account of differences in velocity distribution?" The data in this paper should be of assistance to the hydraulic engineer in answering this question.

Search for a Comprehensive Formula

In spite of the extreme conditions caused on the one hand by the low weirs with heads of water higher than the height of the weir, and on the other hand, by the "fences" placed in the channel of approach, considerable time has been spent in searching for a single formula that would provide for all cases. Of course, such a formula would have to include a velocity term, and could not contain merely the dimensions of the weir and the head.

The possibilities of the formula,

$$Q = 3.33\ L \left(h + a \frac{v^2}{2g}\right)^{\frac{3}{2}}$$

in which, v is the mean velocity in the channel of approach, were investigated in spite of the poor showing of the older formulas that follow this type or use it as a basis. It was thought that a suitable formula for a might be found. Consequently, the values of a were computed for all the runs, and plotted against various functions of the heads, heights of weir, ratios of head to height, ratios of head to total depth, etc. Note that this a is not the same as Bazin's α, which latter implies a variable μ (value of m for a weir of infinite height in $Q = m\ L\ h \sqrt{2\ g\ h}$).

There is a general tendency toward an increase in the value of a as the height of the weir increases, as found by earlier experimenters. Apparently, however, unless the distribution of velocities in the channel of approach be rigidly controlled (a matter of difficulty even for a laboratory weir with long approach), a simple law for a through a wide range of heights and heads is hardly to be expected.

Low Weirs with High Heads.—If only the five low weirs, 0.5 ft. to 2.0 ft. in height, of the writers' Series D to O be considered with only the high heads (head as great or greater than the height), the formula,

$$Q = 3.33\ L \left[h + (1.2 + 0.12\ d_0) \frac{v^2}{2g}\right]^{\frac{3}{2}} \text{ foot-second units} \ldots\ldots (A)$$

fits closely for the "regular" runs. In only 3 cases out of 50 is the calculated discharge more than 1% from the measured values.

The writers recognized that the influence of the distribution of velocities in the channel of approach to a weir needed experimental study.* Consequently, they made current-meter measurements of velocities a part of their program. It seemed reasonable to suppose that the chief assistance to the static head on a weir crest is that given by the velocity head of that part of the approaching water above the crest level. Therefore, the formula,

$$Q = 3.33\, L \left(h + \frac{v_a^2}{2g}\right)^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (B)$$

was tested by the new data. In this formula, v_a represents the true mean velocity in the channel of approach above the crest level, or, more strictly, $\frac{v_a^2}{2g}$ is the mean of the velocity heads above crest level, in case the difference between the two values is appreciable. The velocities are to be measured in the same cross-section as that in which the static head is measured.

Fig. 17 shows this formula tested by the new data, including all cases with specially forced velocity distributions by "fences" placed in the channel of approach. The formula fails chiefly, for the "regular" runs, by giving too low discharges for the weirs less than 3 ft. high when the head is greater than the height of weir. For the weirs more than 2.5 ft. high, including Series A, B, and C, all discharges, except 3 out of 126, are computed within 2% and the 3 exceptions are within 3 per cent. This includes all heads and all cases of abnormal velocity distributions for the weirs more than 2.5 ft. high.

For the five low weirs (Series E, N, F, G, and H), with heads higher than the weir, considered in an independent group, it appears that the formula,

$$Q = 3.33\, L \left[h + \left(1 + \frac{\sqrt{d_0}}{4}\right)\frac{v_a^2}{2g}\right]^{\frac{3}{2}} \text{ foot-second units} \ldots\ldots\ldots (C)$$

fits closely, but not so well as Equation (*A*).

After numerous trials with other functions of $\frac{v_a^2}{2g}$, it seemed obvious that the energy of that part of the approaching water below the crest level could not be disregarded. It seemed logical to assume that some function of $\frac{v_b^2}{2g}$ (v_b is the mean velocity in the channel of approach below the crest level) could be regarded as assisting the static head, but no suitable formula with a multiplier or other function of $\frac{v_b^2}{2g}$ within the same parenthesis as h and $\frac{v_a^2}{2g}$ was found. Perhaps the best tentative formula found was:

$$Q = 3.33\, L \left[\left(h + \frac{v_a^2}{2g}\right)^{\frac{3}{2}} + \frac{h}{3.33} \times \frac{v_b^2}{2g}\right] \text{ foot-second units} \ldots\ldots (D)$$

This formula seems to have no exact theory supporting it. However, the additive quantity, $\frac{h}{3.33} \times \frac{v_b^2}{2g}$, is at least in the nature of a volume.

* Some interesting quotations from hydraulic literature on this topic are given in Appendix C.

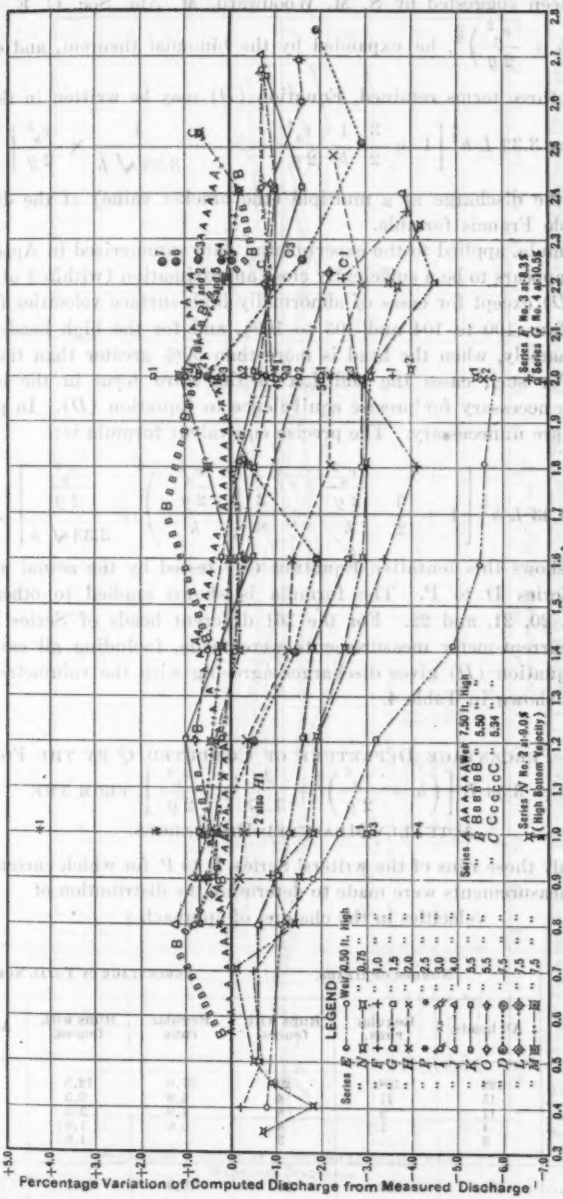

FIG. 17.—SHARP-CRESTED WEIRS. PERCENTAGE VARIATION OF DISCHARGE COMPUTED BY EQUATION (B) FROM MEASURED DISCHARGE.

It has been suggested by S. M. Woodward, M. Am. Soc. C. E., that, if the term, $\left(h + \frac{v_a^2}{2g}\right)^{\frac{3}{2}}$, be expanded by the binomial theorem, and only the first two or three terms retained, Equation (*D*) may be written in the form,

$$Q = 3.33\ L\ h^{\frac{3}{2}}\left[1 + \frac{3}{2}\ \frac{1}{h}\ \frac{v_a^2}{2g} + \ldots + \frac{1}{3.33\sqrt{h}} \times \frac{v_b^2}{2g}\right]$$

This gives the discharge as a multiple (the bracket value) of the discharge by the simple Francis formula.

This formula, applied to the experimental data summarized in Appendix B (Table 55) appears to be a sufficiently close approximation (within ¼ of 1%) to Equation (*D*) except for cases of abnormally high surface velocities (such as Series C, Runs 100 to 104 and 105 to 109), and for the high heads on the low weirs, namely, when the head is more than 50% greater than the height of weir. For such cases the addition of the third term in the binomial expansion is necessary for precise equivalence to Equation (*D*). In practice, more terms are unnecessary. The precise equivalent formula is:

$$Q = 3.33\ L\ h^{\frac{3}{2}}\left[1 + \frac{3}{2}\ \frac{\frac{v_a^2}{2g}}{h} + \frac{3}{8}\left(\frac{\frac{v_a^2}{2g}}{h}\right)^2 + \frac{\frac{v_b^2}{2g}}{3.33\sqrt{h}}\right] \ldots\ldots (E)$$

Fig. 18 shows this tentative Equation (*D*) tested by the actual measurements in Series D to P. The formula is shown applied to other series in Figs. 19, 20, 21, and 22. For the 161 different heads of Series D to P for which current-meter measurements were made, including all cases with "fences", Equation (*D*) gives discharges agreeing with the volumetric measurements as shown in Table 4.

TABLE 4.—PERCENTAGE DEPARTURE OF COMPUTED Q BY THE FORMULA, $Q = 3.33\ L\left[\left(h + \frac{v_a^2}{2g}\right)^{\frac{3}{2}} + \frac{h}{3.33} \times \frac{v_b^2}{2g}\right]$, FROM THE ACTUALLY MEASURED DISCHARGES.

(Includes only those runs of the writers' Series D to P for which current-meter measurements were made to determine the distribution of velocities in the channel of approach.)

Low Heads on Sharp-Crested Weirs.—Fig. 10 shows in detail the percentage departures and coefficients for Series D to O for low heads (less than 0.5 ft.), and Fig. 11 gives the magnified detail at extremely low heads (less than 0.2 ft.).

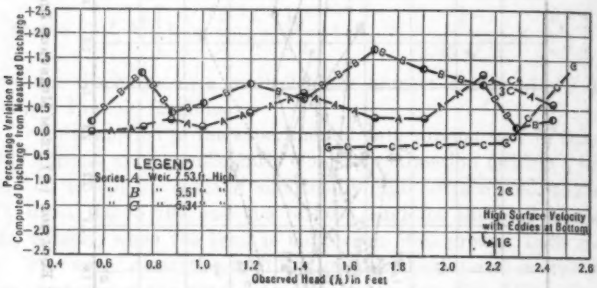

FIG. 19.—TEST OF EQUATION (*D*) BY SCHODER AND TURNER, SERIES A, B, AND C.

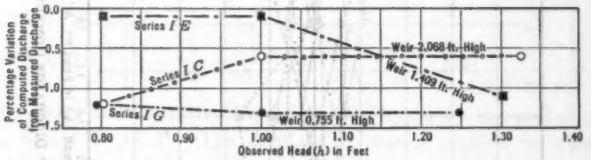

FIG. 20.—TEST OF EQUATION (*D*) BY MEYER AND SEE'S DATA.

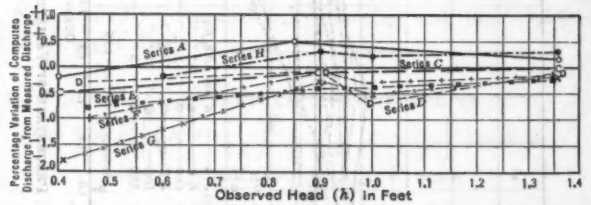

FIG. 21.—PLOTTING TO TEST FORMULA, EQUATION (*D*), BY JONES' MEASURED VALUES.

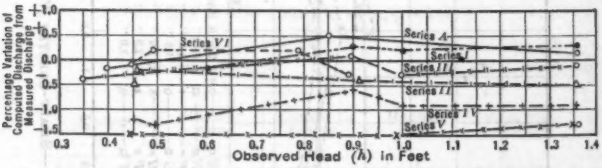

FIG. 22.—PLOTTING TO TEST FORMULA, EQUATION (*D*), BY WEBER'S MEASURED VALUES.

The lines for the low weirs appear to merge into the narrow zone common to all weirs at a head equal to about one-fifth the height of the weir.

In studying Figs. 10 and 11, the considerable effect of small errors in measurement is to be remembered; for example, an error of 0.0005 ft. in

measuring a head of 0.05 ft. causes an error of 1.5% in the computed discharge. If the width of the zone of lines for the various weirs covers 2% at 0.1 ft. head, or if the extreme edges are only 1% from the average line, it indicates that the low heads have been correctly measured within two-thirds of 1%, or 0.0007 ft. (assuming all the error to be in the head).

The writers' data on low heads in Series C (crest width = $\frac{3}{8}$ in., edge dulled by service) are shown on Fig. 23. The peculiar clinging phenomena at the extremely low heads are illustrated. The details of the conditions at the crest in the various tests of Fig. 23 are, as follows:

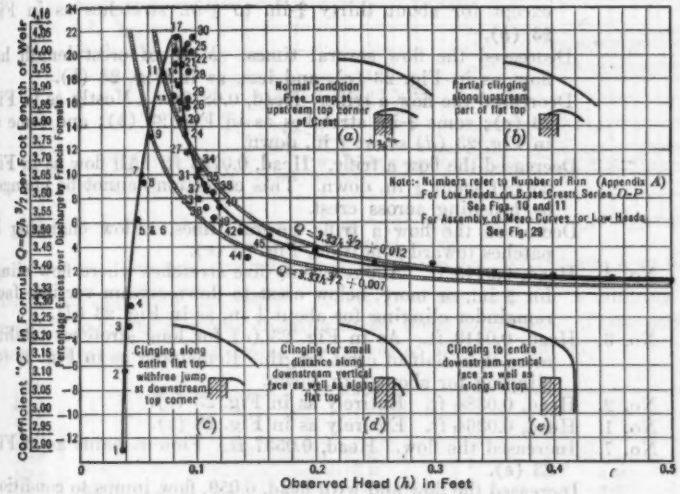

FIG. 23.—LOW-HEAD WEIR EXPERIMENTS, PART OF SERIES C, SHOWING DEPARTURES FROM DISCHARGE LAWS APPLICABLE TO HIGHER HEADS AND UNCERTAIN DISCHARGE CONDITIONS IN CRITICAL REGIONS OF VERY LOW HEADS.

Tests of March 16, 1914:

No. 24. Head, 0.0912 ft. Flow conditions as in Fig. 23 (*c*) for three-fourths of crest length and as in Fig. 23 (*b*) for remainder in local stretches $\frac{1}{2}$ in. long.

No. 20. Head, 0.0879 ft. A little more clinging than in Test No. 24.

No. 13. Head, 0.0813 ft. As in Fig. 23 (*c*), except for about ten $\frac{1}{2}$-in. stretches as in Fig. 23 (*b*).

No. 19. Head, 0.0878 ft. Less clinging than in Test No. 13, but more than in Test No. 20.

No. 26. Head, 0.0927 ft. As in Test No. 19. Considerable more clinging than in Tests Nos. 24 or 20.

No. 33. Head, 0.1020 ft. As in Fig. 23 (*b*) in stretches totaling one-half of crest length. Remainder as in Fig. 23 (*c*).

No. 36. Head, 0.1083 ft. As in Fig. 23 (*b*) for more than half of length. As in Fig. 23 (*c*) in short stretches $\frac{1}{4}$ in. long.

No. 39. Head, 0.1156 ft. As in Fig. 23 (*b*), except an occasional patch as in Fig. 23 (*c*).

Tests of March 17, 1914:

No. 28. Head, 0.0936 ft. Flow conditions as in Fig. 23 (*c*).

Increased flow a trifle. Head held 0.0035 ft. higher than in Test No. 28 as in Fig. 23 (*c*) for a few moments, but then broke into condition, Fig. 23 (*b*), in short stretches totaling more than one-fourth of crest length. Head then settled at 0.1037 ft., or 0.0101 ft. higher than in Test No. 28.

Decreased flow a trifle. Head, 0.099 ft. No change apparent.

Decreased flow a trifle. Head, 0.0955 ft. Flow as in Fig. 23 (*c*) for a little more than half of length, with remainder as in Fig. 23 (*b*).

No. 27. Decreased the flow a trifle. Head, 0.0934 ft. As in Fig. 23 (*c*) except for about thirty ¼-in. to ½-in. stretches as in Fig. 23 (*b*).

Decreased the flow several times. More of crest length has flow, as in Fig. 23 (*c*), and less, as in Fig. 23 (*b*).

Decreased the flow a trifle. Head, 0.0833 ft. Mostly as in Fig. 23 (*c*); some ¼-in. stretches as in Fig. 23 (*b*); and some as in Fig. 23 (*d*) scant ¼ in. down.

Decreased the flow a trifle. Head, 0.0793 ft. All flow as in Fig. 23 (*d*) scant ¼ in. down. This condition cannot be changed by brushing across crest.

Decreased the flow a trifle several times. Flow changing in patches toward condition, Fig. 23 (*e*).

No. 4. Head, 0.0445 ft. About twenty-five stretches where flow clings for ¾ in., or more, below crest to down-stream vertical face, remainder clinging for about ¼ in. as in Fig. 23 (*d*).

No. 3. Head, 0.0419 ft. As in Fig. 23 (*e*) for long stretches totaling more than half of crest length. Remainder as in Fig. 23 (*d*) clinging for about ¼ in. down.

No. 2. Head, 0.0384 ft. Entirely as in Fig. 23 (*e*).

No. 1. Head, 0.0364 ft. Entirely as in Fig. 23 (*e*).

No. 7. Increased the flow. Head, 0.0537 ft. Flow remains as in Fig. 23 (*e*).

Increased the flow and with head, 0.059, flow jumps to condition, Fig. 23 (*d*), clinging to vertical down-stream face for second ¼ in.

Increased the flow several times, but no further change.

No. 18. Head, 0.0853 ft. Flow as in Test No. 7.

Increased the flow several times and in patches it changes to condition, Fig. 23 (*c*), with head of 0.099 ft. Then, with head of 0.102 ft., flow changes to condition, Fig. 23 (*c*), for one-third of crest length and as in Fig. 23 (*b*) for remainder in forty-eight patches, ¼ in. to 1¾ in. long, and head settles at 0.1053 ft.

Increased the flow. Head, 0.118 ft. One-fifth of length as in Fig. 23 (*c*), remainder as in Fig. 23 (*b*).

Increased the flow. Head, 0.132 ft. As in Fig. 23 (*b*), except for some short patches as in Fig. 23 (*c*).

No. 44. Increased the flow. Head, 0.1438 ft. Flow jumps free as in Fig. 23 (*a*), except for $\frac{1}{16}$ in. to ⅛ in., where it clings to flat top as in Fig. 23 (*b*).

Increased the flow. Head, 0.168 ft. As before, but clings to flat top for $\frac{1}{16}$ to ⅛ in. only in spots.

Increased the flow. Head, 0.196 ft. Conditions as before (for 0.168-ft. head).

Similar data on low heads, down to about 0.04 ft., from Meyer and See's experiments, are shown on Figs. 24 and 25. On these diagrams, the points marked *A* represent measurements from a series of progressively increased low

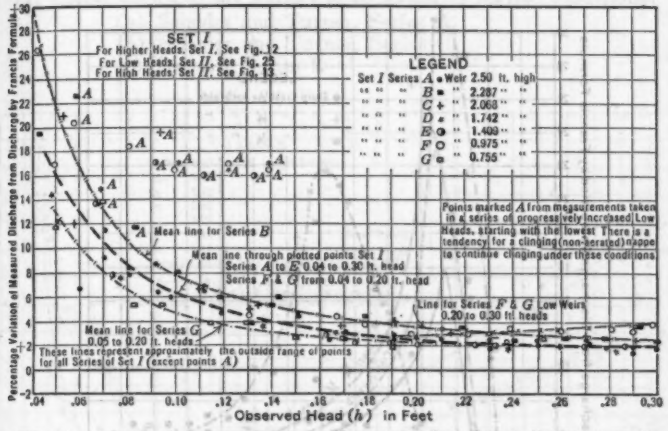

FIG. 24.—LOW-HEAD EXPERIMENTS BY MEYER AND SEE, SET I, SERIES A TO G.

heads, starting with the lowest. There is a tendency for a clinging (non-aerated) nappe to continue clinging under these conditions. These points, *A*, were not considered in drawing the curves of Figs. 24 and 25.

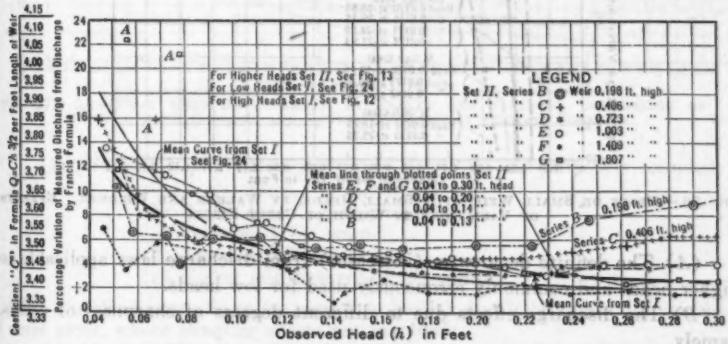

FIG. 25.—LOW-HEAD EXPERIMENTS BY MEYER AND SEE, SET II, SERIES B TO G.

Data from Walker and Weidner's experiments at low heads on several widths of crest piece are shown on Fig. 26. Fig. 27 shows Fteley and Stearns' observed data* for low heads and the basis for the averaging curves used in other plottings. Fig. 28 is a partial assembly of low-head data, showing the observed values of Bazin in comparison with those of others. The crests ranged from known definitely sharp conditions through known dulled corners and uncertain cases to known definitely rounded corners.

* *Transactions*, Am. Soc. C. E., Vol. XII (1883), pp. 25–28.

Fig. 29 is a general assembly of curves representing all the low-head data on crests with sharp, dull, uncertain, and slightly rounded, top, up-stream, corners. It shows:

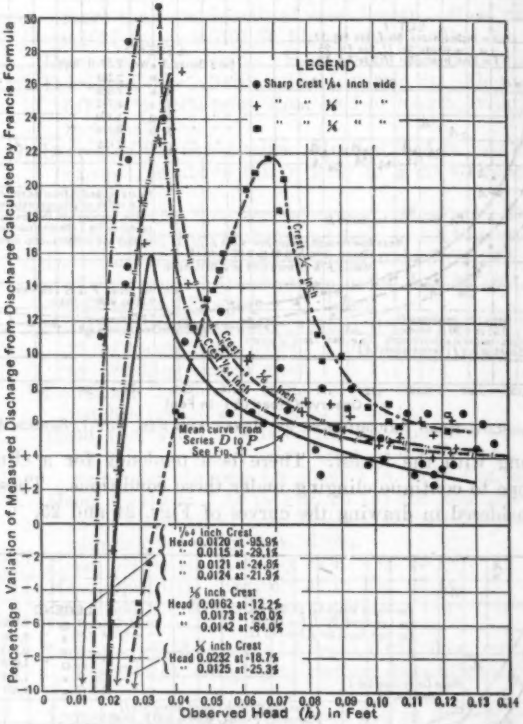

FIG. 26.—TESTS ON SMALL WEIR WITH SMALL HEADS, BY WALKER AND WEIDNER. EFFECTS OF VARIATIONS IN WIDTH OF CREST PIECE.

(*A*) The definite departures (increases) from discharge laws applicable to higher heads and commonly erroneously used for low heads.

(*B*) The discharge effects due to different degrees of sharpness of crests, namely,

(1) Crests generally accepted as strictly sharp and so described by experimenters:

(*a*) Francis.
(*b*) Fteley and Stearns.

(2) Crests generally accepted as strictly sharp, but with experimenter's description incomplete and indefinite:

(*a*) Bazin.

(3) Crests known to the writers to be strictly sharp:

(*a*) Schoder and Turner, Series D to P.
(*b*) Schoder and Turner, Series B.

(*c*) Meyer and See, Series I and II.

(*d*) Dawson, $\frac{1}{4}$ in., round.
(*e*) Fteley and Stearns, $\frac{1}{4}$ in., round.

(*C*) The discharge effects (at very low heads) due to different top widths of crest piece, where clinging effects are involved:
(*a*) Walker and Weidner, $\frac{1}{64}$ in. wide.
(*b*) Walker and Weidner, $\frac{1}{8}$ in. wide.
(*c*) Walker and Weidner, $\frac{1}{4}$ in. wide.
(*d*) Schoder and Turner, Series D to P, $\frac{3}{32}$ in. wide.
(*e*) Schoder and Turner, Series B, $\frac{3}{8}$ in. wide.
(*f*) Schoder and Turner, Series C, $\frac{3}{8}$ in. wide.

All these new data show a general agreement with the findings of earlier experimenters that there is an increasing percentage increase in discharge as the head decreases below about 0.4 ft. for sharp-crested weirs having heights of more than 2 ft. The law of increase in discharge according to Fteley and

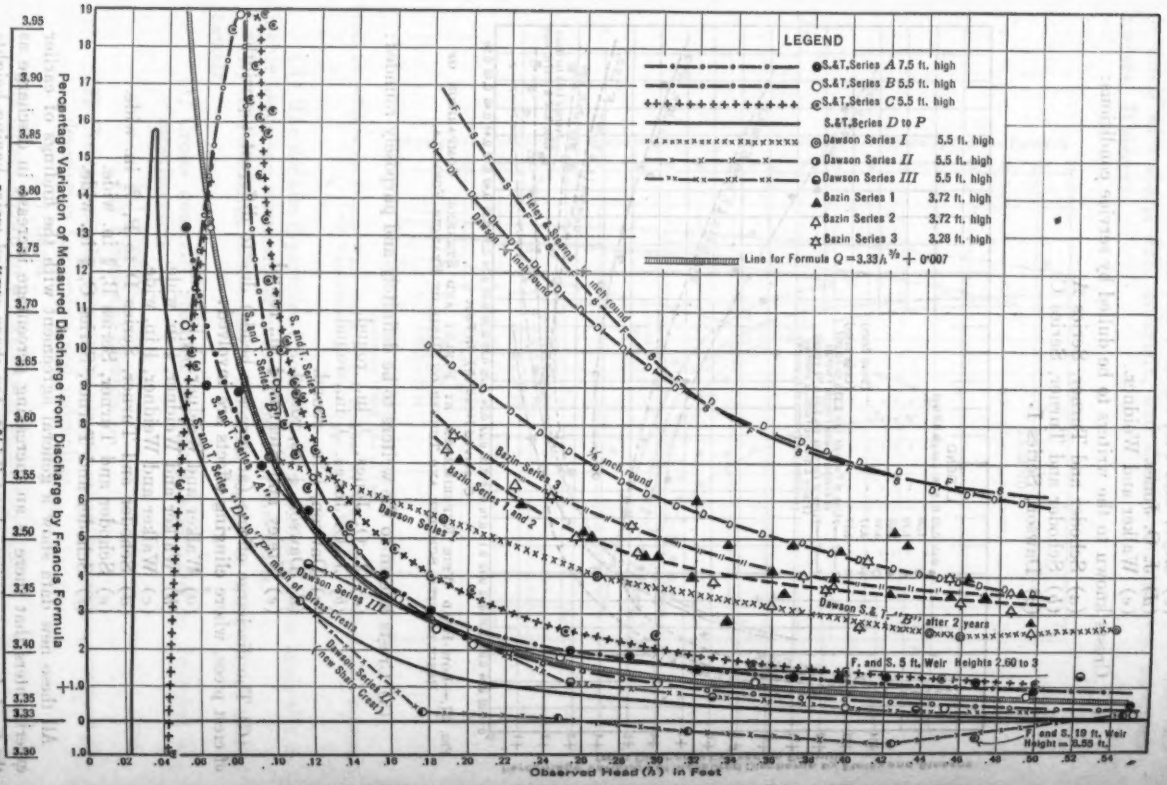

FIG. 28.—LOW-HEAD WEIR EXPERIMENTS, SHOWING VALUES OBTAINED BY VARIOUS EXPERIMENTERS.

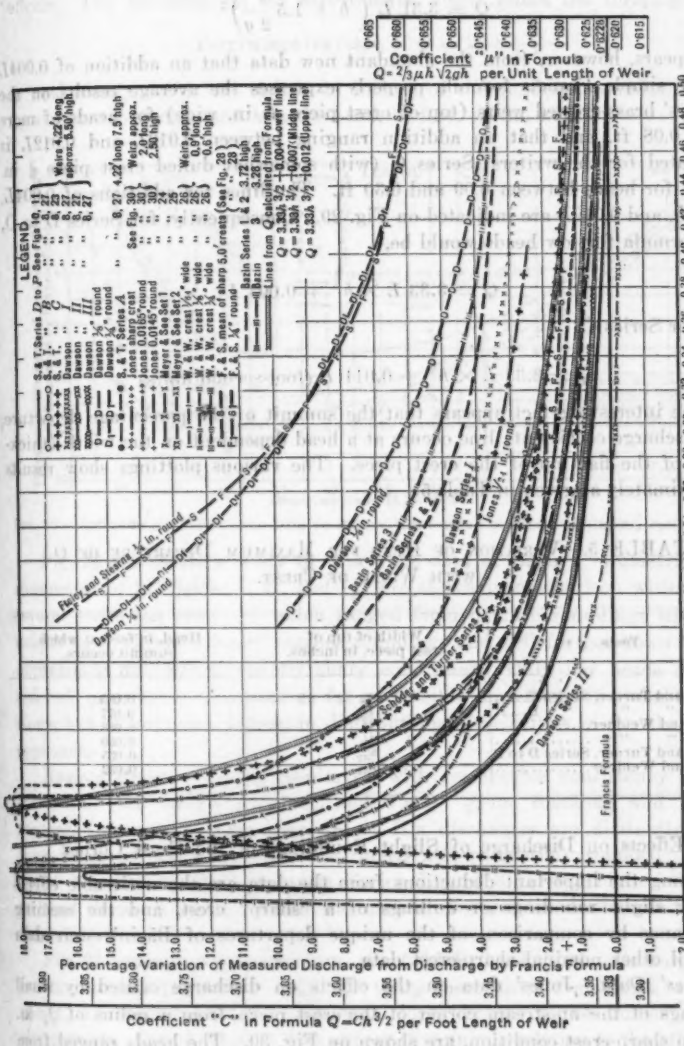

FIG. 29.—LOW-HEAD WEIR EXPERIMENTS. ASSEMBLY OF MEAN CURVES.

FIG. 28.—LOW-HEAD WEIR EXPERIMENTS, SHOWING VALUES OBTAINED BY VARIOUS EXPERIMENTERS.

Stearns is expressed by adding $0.007L$ (foot-second units) to their basic expression,

$$Q = 3.31\ L\left(h + 1.5\frac{v^2}{2g}\right)^{\frac{3}{2}}$$

It appears, however, from the abundant new data that an addition of $0.004L$ to the simple Francis formula properly expresses the average results on the writers' brass-crested weirs (top of crest piece $\frac{3}{32}$ in. wide) for heads of more than 0.08 ft. and that an addition ranging between $0.010L$ and $0.012L$ is indicated for the writers' Series C (with somewhat dulled crest piece $\frac{1}{8}$ in. wide) for heads between 0.09 and 0.30 ft. The lines for additions of $0.004L$, $0.007L$, and $0.012L$ are indicated on Fig. 29. Consequently, for Series D to O, the formula for low heads would be,

$$Q = 3.33\ L \times h^{\frac{3}{2}} + 0.004\ L$$

and for Series C,

$$Q = 3.33\ L \times h^{\frac{3}{2}} + 0.011\ L \text{ (foot-second units)}$$

The interesting fact appears that the summit of the percentage departure (or discharge coefficient) line occurs at a head dependent on the width (thickness) of the flat top of the crest piece. The various plottings show results approximately as given in Table 5.

Effects on Discharge of Slight Roundings of the Crest Corner

Among the important deductions from the data are the noticeable effects of very slight roundings or dullings of a "sharp" crest, and the seeming significance by comparison, of the unique departures of Bazin's weir data from all other nominal sharp-crest data.

Jones' Data.—Jones' data on the effects on discharge caused by small roundings of the up-stream corner of the crest piece, from a radius of $\frac{1}{4}$ in. down to sharp-crest condition, are shown on Fig. 30. The heads ranged from 0.18 ft. to 1.36 ft. on a weir 2.5 ft. high and 2 ft. long. The percentage increase in discharge, due to rounding, over sharp-crest values is seen to decrease with the head. It amounts to 1.6% for the $\frac{1}{24}$-in. radius rounding at 0.5-ft. head, and to 0.7% at 1.0-ft. head. A rounding with $\frac{1}{60}$-in. radius

causes an increase of 0.85% at 0.5-ft. head and 0.45% at 1-ft. head. Still smaller roundings with less than $\frac{1}{100}$-in. radius, cause definitely measurable effects. For the range of his experiments, Jones found the formula,

$$\text{Percentage increase in } Q = 22.8 \frac{R}{h^{\frac{3}{4}}}$$

to hold closely. R is the radius, in inches, of the quadrant rounding of the up-stream top corner, and h is the head, in feet, on the weir.

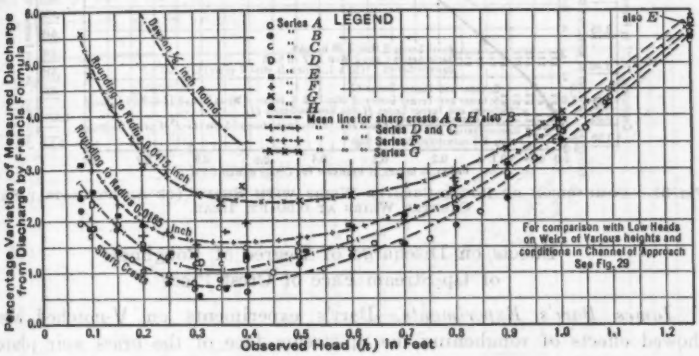

FIG. 30.—EFFECTS ON DISCHARGE DUE TO SMALL ROUNDINGS OF EDGE OF CREST, JONES' DATA.

Fig. 28 represents a study in which the data of Bazin's volumetric measurements* of his Series I, II, and III are shown in comparison with data of several weirs the crests of which ranged from definite roundings with $\frac{1}{4}$-in. radius down through Jones' smaller roundings and still further down through appreciable dullings to strictly sharp conditions. Only low heads are considered, in order to eliminate as far as possible the effects of probable variations, but of unknown degree, in distributions of velocities in the channels of approach.

Bazin's Results.—These results lie with remarkable consistency between Dawson's $\frac{1}{8}$-in. radius rounding and Jones' $\frac{1}{24}$-in. rounding and are far separated from the sharp-crest data. His discharges are distinctly higher than those of crests known to be dulled and perceptibly rounded; namely, about 1% higher than Dawson's Series I, and 3 to 4% higher than the writers' Series A and C, which themselves have greater discharges than the sharp crests.

Fig. 31 represents a comparison, all at 0.5-ft. head, of the discharges over crests rounded to various radii for weirs more than 3 ft. high, and also shows the discharges for crests with edges known to be dulled and for sharp crests. Again, Bazin's data appear in a unique relation to the other data.

* Bazin described his crest piece as an iron plate "bien dressée," 0.007 m. (0.276 in.) thick. The "bien dressée" is translated by Marichal and Trautwine in *Proceedings*, Engineers Club of Philadelphia, January, 1890, as "carefully straightened." The drawing, Fig. 9, Plate 2, in *Annales des Ponts et Chaussées*, October, 1888, shows the plate to be about 7.4 in. wide, with top edge square and flat. The title reads, "Section of the crest of the weir of sharp-edged type" ("type à arête vive").

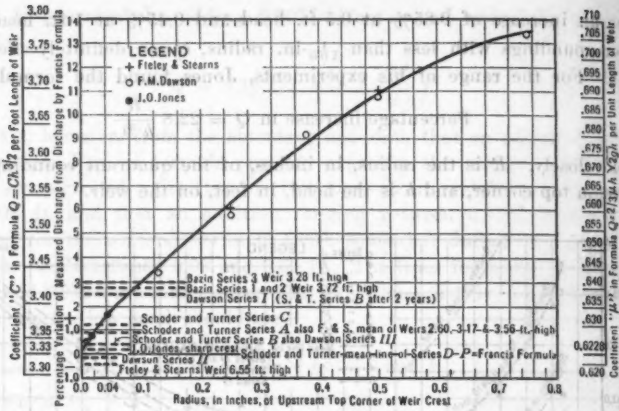

FIG. 31.—COMPARISON OF ROUND-CRESTED WEIRS WITH SHARP (OR APPROXIMATELY SHARP) CRESTED WEIRS AT 0.50-FT. HEAD.

Effects on Discharge of Degree of Roughness of Up-Stream Face of Crest Piece

James Barr's Experiments.—Barr's experiments on V-notched weirs* showed effects of roughening the up-stream face of the brass weir plate as given in Table 6.

TABLE 6.—RELATION OF DISCHARGE TO ROUGHNESS OF UP-STREAM FACE OF WEIR.

Condition of up-stream surface of notch.	PERCENTAGE INCREASE IN DISCHARGE OVER VALUE FOR PLAIN SURFACE.	
	Head = 8 in.	Head = 4 in.
Plain surface	0.	0.
One coat varnish (shellac)	0.39	0.26
Coated with medium emery	1.8	1.2
Coated with coarse emery	2.4	1.7

Weber's Data.—These data are represented on Fig. 32. The percentage increases in discharge, due to roughening the up-stream face, do not seem to decrease as rapidly with the increase of the head as for the slight roundings of the crest edge. Thus, Series V at 0.5-ft. head shows 1.85% increase over smooth-plate conditions, and even at 1.35-ft. head the increase is still 1.2 per cent.

The part of the plate near the crest appears to have more influence than that farther removed, although the addition of 8 in. of rough surface below the top 4 in. caused a further increase of discharge averaging fully 0.5% for heads between 0.3 ft. and 1.35 ft.

* *Engineering* (London), April 8 and 15, 1910.

Bazin's Discharges Too High for Sharp-Crest and Smooth-Plate Condition

Again returning to Bazin's data (see Table 7), it appears that a combination of slight rounding at the edge and rusting of the up-stream face could have produced just such a percentage effect as Bazin's measurements show when compared with other sharp crests. In fact, Dawson's Series I as compared with the writers' Series B, using the same weir and crest piece, shows nearly the same increase of discharge as Bazin's departure from all the other known sharp crests.

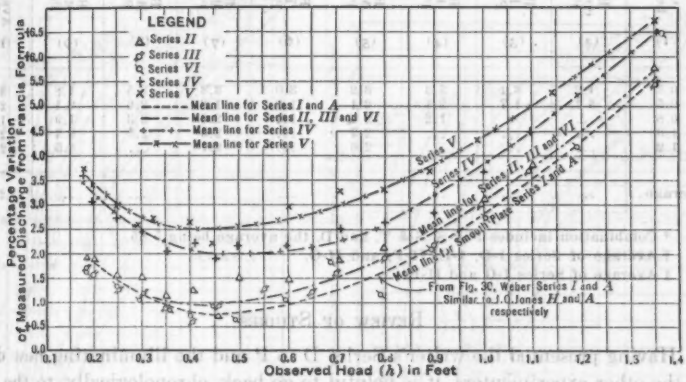

FIG. 32.—RELATION OF DISCHARGE TO ROUGHNESS OF UP-STREAM FACE OF CREST PIECE. WEBER'S DATA.

The writers see no reason for questioning Bazin's measurements of heads and discharges in the ratings of his "standard weir" by Series I, II, and III. The fact that he did not divert an already established flow into his measuring basin, but started with a static head, seems to be amply offset by the long duration of his measurements, from 10 to 20 min. Consequently, there is no implied criticism of the great mass of subsequent measurements made by Bazin, using his "standard weir" as a reference except as this may have deteriorated. The only point suggested is that his data on Series I to X do not appear to belong in the sharp-crest, smooth-plate category.

Rehbock* (and Hansen† before him), has supplied experimental evidence showing that Bazin's discharges are too high as compared to their values for sharp-crested weirs. Bazin himself tabulated‡ the excesses of his values over those of Fteley and Stearns for both the latter's 1877 and 1879 experiments.

It should be mentioned that Gardner S. Williams, M. Am. Soc. C. E., reached the conclusion long ago§ that the data of Francis and of Fteley and Stearns were more reliable than those of Bazin.

REVIEW OF STUDIES

Having presented the writer's Series D to P and the illuminating new data of the other experimenters, it is helpful to go back, chronologically, to the situation that confronted the writers and, to some extent, the engineering public since the publication of Bazin's volumetric measurements in 1888.

Among the preliminary studies made by the writers, three comparisons may be of some interest.

First Comparison: Six Weirs in Same Channel.—Fig. 8 shows results on a group of six weirs set in the same canal and for which general conditions seemed nearly the same. Among them one might expect close agreement in discharges for the same heads. The averaging lines for the several series show among themselves extreme variations for all heads from 2 to 4 per cent. This is for the "regular" experiments; that is, those made with the regular deflector baffles and stilling-raft arranged to secure a minimum of irregularity in velocities in the channel of approach.

These variations in discharges seem to be rather less than might have been expected if different channels of approach had been used involving the judgments of different men as to sufficiency of baffle systems and proper fineness of finish of crest pieces for correct designation as "sharp-crested."

The reason for these variations in discharges might lie (1) in the water; or (2) in the weir. In detail, assuming no challenging question as to the general arrangement, dimensions, heads, and discharges, and relying on recent precise investigations, such as Rehbock's, as assurance that effects of temperature changes in the water are exceedingly small at heads above the very lowest, the reasons might lie (*a*) in velocity conditions in the channel

of approach; or (*b*) in the mechanical conditions at the weir, particularly the sharpness of crest and degree of roughness of the up-stream face.

(*a*).—Examining the distribution of velocities for Series A, B, and C (these are shown on Figs. 33 to 35, and the velocity curves from other series as Figs. 36 to 48, inclusive (see, also, Appendix B (Table 55)), it is seen that the high weir of Series A has an average ratio of about 1.74 between the mean velocity above the crest level and the mean velocity in the whole channel of approach, as compared with an average ratio of about 1.38 for Series B and 1.32 for Series C (the "regular" runs).

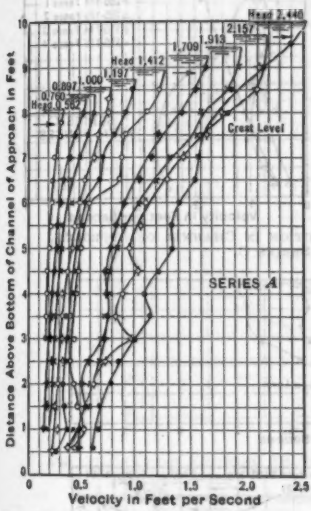

FIG. 33.—CURVES SHOWING VELOCITY DISTRIBUTION IN CHANNEL OF APPROACH, SCHODER AND TURNER, SERIES A.

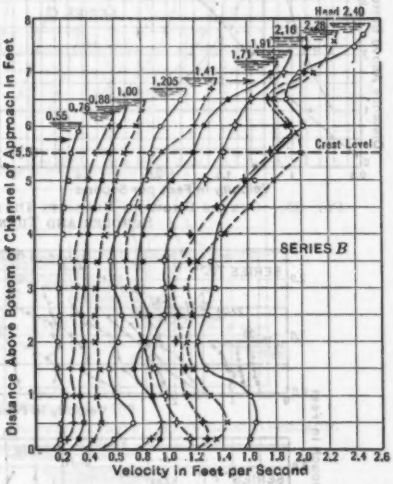

FIG. 34.—CURVES SHOWING VELOCITY DISTRIBUTION IN CHANNEL OF APPROACH, SCHODER AND TURNER, SERIES B.

The mean velocities above the crest level, when plotted against the heads, show practically one line for the three series, whereas one would expect somewhat lower velocities for the deeper channel of Series A. (No velocity measurements were taken for Dawson's experiments, but the channel conditions were the same as in Series B.)

By the old formulas, which correct for the velocity of approach, such as those of Fteley and Stearns, or Bazin, a weir 7.5 ft. high would show less discharge than one 5.5 ft. high by an amount about 1.6% for 2.5-ft. head, 0.7% for 1.5-ft. head, 0.4% for 1-ft. head, and 0.1% for 0.5-ft. head. The experiments in Fig. 8 show a decrease only for the highest head as compared with the weirs 5.5 ft. high. This may be due, in small part, to the obstruction offered by the deflector hood to the formation of bottom velocities of normal free-channel magnitude, causing, in effect, flow conditions similar to those for a weir less than 7.5 ft. high in a long canal free from obstructions at the bottom for a much longer distance than 25 ft. up stream.

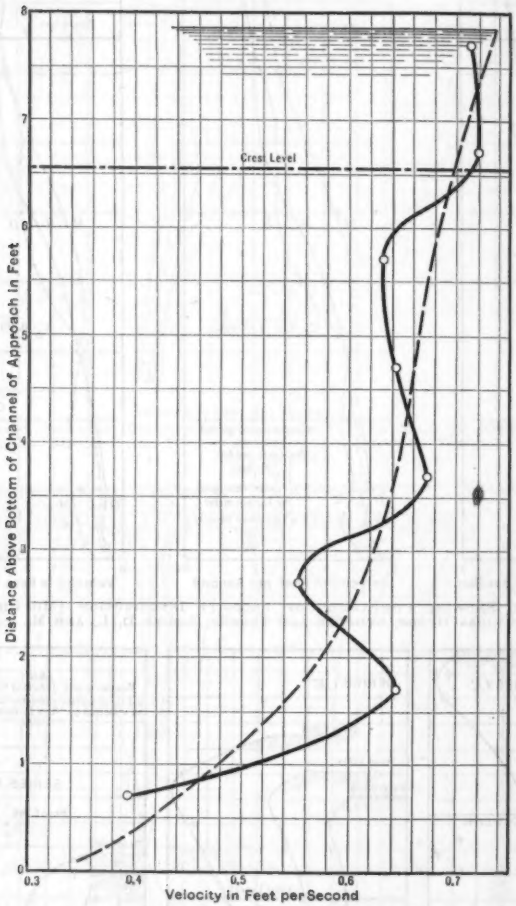

FIG. 48.—FTELEY AND STEARNS' WEIR EXPERIMENTS, SHOWING MEAN VELOCITY DISTRIBUTION IN VERTICAL 5 FEET UP STREAM FROM WEIR, 19 FEET LONG. MEAN VELOCITY BY WEIR MEASUREMENT, 0.63 FOOT PER SECOND.

This effect, however, could not account for the entire lack of conformity. There was a difference in sharpness and smoothness of crest plates, and there was probably a lack of perfect proportionality in the velocity distribution for all heights and heads in a free channel of a length less than four times the highest weir.

(*b*).—Examining the mechanical condition at the weir crests minutely, it is obvious from the descriptions that only two of the weirs, the writers' Series B and Dawson's Series II, deserve to be called strictly sharp-crested; but neither of these two crest pieces had a strictly smooth up-stream face.

It is seen on Fig. 8 that these two series agree within 1% for heads between 0.5 ft. and 2.4 ft.

The considerable effect on discharge due to rusting of an iron crest plate by six weeks' exposure to water in May and June is seen by comparing Dawson's Series II and III. The discharge was increased 1.1, 0.8, 0.75, and 0.6%, respectively, at heads of 0.3, 0.5, 1.0, and 1.5 ft. Above a head of 1.9 ft. the effect seems to be a decrease.

Second Comparison: Old and New Data.—On Fig. 49 are shown the averaging lines for the experimental data (all volumetric measurements on nominally strictly sharp crests) of Fteley and Stearns, Bazin, Martin, the writers' Series B, Dawson's Series II, and Meyer and See.

A cursory inspection of Fig. 49 shows that Bazin's data fall in a group by themselves and indicate distinctly higher discharges than the others. This is true for all heads and heights of weir, as detailed in Table 7. Comparisons have been made with weirs of nearly the same height, except for Column (2), where only the lowest heads are considered. For the other seven comparisons, Bazin's weirs were slightly higher in three cases and slightly lower in four cases.

Other anomalies are apparent. Fteley and Stearns' 1.00-ft. height, at 0.8-ft. head, shows 4.5% excess over the average of Meyer and See's Series 1-F and 2-E of the same height; although at a low head of 0.3 ft., they are in almost exact agreement. The Fteley and Stearns 0.50-ft. weir shows greater discharge at all heads than the Meyer and See 0.41-ft. weir, where the reverse would be expected.

Third Comparison: Effect of Velocity of Approach.—For the 2.25-ft. head in Series C the writers built "fences" to produce in different runs high surface velocities and high bottom velocities, carrying the distribution of velocities up to perhaps the extremes that may be found in practice. Fig. 35 shows the velocity curves. For the same head, an extreme difference of 26% in discharge was produced by variations in the velocity distribution. Data for head, discharge, and velocities are given in Appendix A (Table 11), and Appendix B (Table 55). Even with the lesser re-arrangements of the velocities (such as the "regular" run at the 2.25-ft. head, Series C, compared with the run with Fence No. 3) there is seen to be more than 3.5% difference in discharge.

No doubt careful inspection of the appearance of the flow in the channel of approach would enable cases of extremely high surface or bottom velocities to be noticed by an experienced engineer. It seems certain, however, that no visual inspection could distinguish between discharges that differ as much

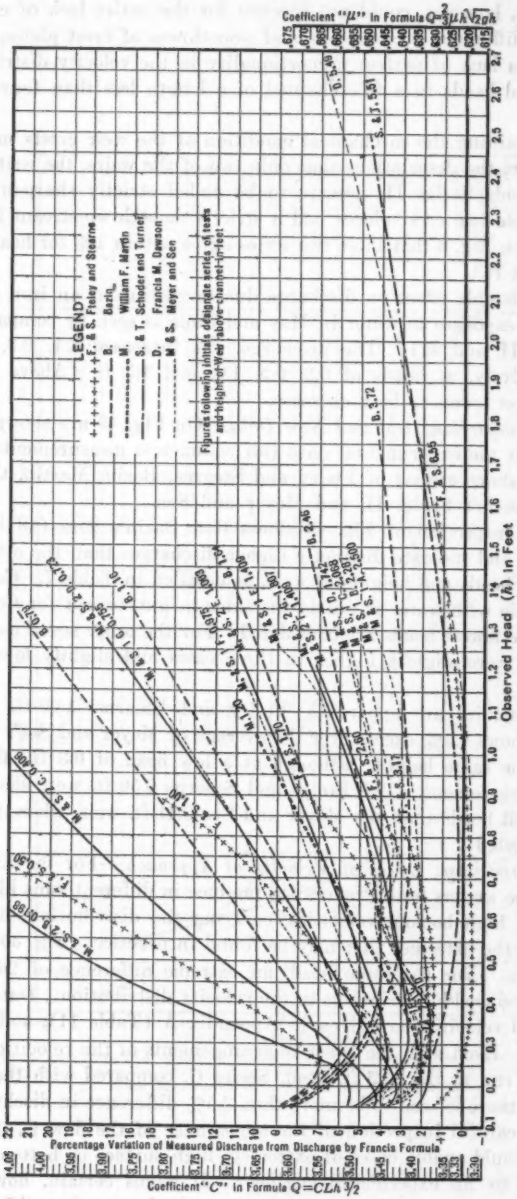

FIG. 49.—SHARP-CRESTED WEIR EXPERIMENTS. COMPARISON OF EARLIER NEW DATA AND THOSE OF FTELEY AND STEARNS AND BAZIN, ALL REFERRED TO FRANCIS FORMULA.

as 4 or 5% at the same head due solely to different distributions of velocities in the channel of approach.

The writers, in view of such conflicts and variations, and needing as reliable an estimate as possible for the discharge over a large reference weir already used by them in other investigations, decided to undertake the studies covered by Series D to P as an auxiliary work.

General Comparison of Old and New Data.—In Table 8 is given a fairly comprehensive comparison of discharges at various heads (0.2-ft. to 2.5-ft.) by various experimenters (old and new) on weirs of various heights, all weirs of the sharp or nearly sharp-crested type. The data are given in terms of the percentage departure from discharges calculated by the simple Francis formula,

$$Q = 3.33\ L\ h^{\frac{3}{2}}, \text{ or } Q = 0.623 \times \frac{2}{3}\ L\ h\ \sqrt{2\,g\,h}$$

All values of the percentage variation are taken from the diagrams, averaging the plotted points, except in the case of the writers' Series D, I, J, K, L, M, N, and O, for which the data are from the actual measurements or interpolated between measurements.

Perhaps this comparison serves best to emphasize the present state of weir hydraulics when refinements of one sort or another are disregarded.

Conclusions Indicated

Supplementary to the main findings given in the Synopsis and to the conclusions stated in the text, or made obvious by tables and diagrams, a few other deductions are of interest.

Condition of Crest Piece.—The data clearly show that both the roughness of the up-stream face and the rounding of the up-stream top corner of the crest plate increase the discharge for the same head, over that for smooth, sharp conditions. A combination of the two effects each in slight degree, could easily amount to from 1 to 2 per cent.

In tests and routine measurements demanding the utmost precision it seems quite necessary to have the crest plate very smooth in order to avoid uncertainties as to the degree of roughness. Whether it is preferable to try to maintain a sharp corner or one definitely rounded to a very small radius may be as much a practical as a hydraulic question. A difficulty with a slightly rounded corner is to have it exactly to dimension and form, but this would not apply to a rounding to, say, $\frac{3}{16}$ or $\frac{1}{4}$ in. radius.

Velocity Distribution in the Channel of Approach.—It seems hardly sufficient to state, as did Bazin, that a certain precision is attainable "provided, however, that the arrangements of our standard weir are exactly reproduced", unless it is indicated clearly which of the arrangements are essential to the "standard weir", which are to be minutely copied, and which are left to the necessities of the particular case or to the judgment of the engineer.

The velocity conditions in the channel of approach should be standardized to some degree for those cases where control is possible. If this were done the use of a formula involving only the head, height, and length of weir

would probably be permissible. A uniform distribution of velocities is not a natural condition for an open channel. Then, too, a measuring weir can seldom be placed conveniently at the down-stream end of a long canal. In practice, the demand is for the shortest possible canal. Often, also, the entry conditions are turbulent, sometimes violently so. The use of baffles seems essential.

In many cases it would be out of the question to depend entirely on the length of the channel of approach to re-arrange the velocities. The measurements of Fteley and Stearns and of the writers indicate that a particular distribution, once started, persists surprisingly in a deep channel. For low weirs with heads higher than the weir, and, consequently, with high velocities of approach, the evidence shows a regularity of a high order as far as discharge is concerned. Figs. 44 and 46 show the differences found by the writers in channels nominally the same.

Measurements of Head.—The side-wall piezometer connected to a stilling-well seems to be an excellent device. However, in addition to the usual precautions concerning perpendicular boring of the hole and avoidance of projections into the channel, the matter of freedom from centrifugal and suction effects due to cross-currents is of some consequence. In recent construction the stilling-well has been connected symmetrically to a pair of opposite side-wall piezometers.

The writers have found the float-gauge, as described, very convenient. A separate setting for each reading is avoided and all the surges can be noted. The use of a glass stilling-pipe allows precise work with a hook-gauge or point-gauge with visibility from below the water surface for the former.

The plumb-bob gauge has the advantages of simplicity, ease of construction, and direct contact with the water surface in the channel of approach. However, it requires a separate setting for each reading.

Friction in the Channel of Approach.—Ordinarily, the effect of friction between the point where the head is measured and the weir is negligibly small; but in an extreme case, as for the writers' Series E (2-ft. head on a weir 0.5 ft. high), the surface fall in 12 ft. for open-channel flow amounts to nearly 1% of the head, and the decrease of discharge for this case is about 1.5% because of friction. For a 1-ft. head the effect on the discharge is still 1 per cent.

For very narrow channels, Martin's experiments indicate that allowances for friction, by open channel laws, between the head gauge station and the weir, are adequate subtractive corrections for the head. The writers' large-scale experiments furnish more evidence on this point.

Acknowledgments

It is not intended to imply that there may not long have been available to a few engineers and scientists working information on the points mentioned in the paper. The writers know that all the points specified in the title have been the subjects of not a little consideration and some experimentation previously. To some extent due acknowledgment is made in the paper, but it is undoubtedly inadequate and incomplete. The writers would welcome additional prior or contemporaneous evidence.

The completion of this paper has been greatly assisted by grants from the Heckscher Research Foundation of Cornell University in 1922, 1923, and 1925. Professor Francis M. Dawson was Research Assistant under these grants. The great aid rendered by him in the preparation of the paper is appreciatively and gratefully acknowledged.

(Professor Schoder wishes to record his profound regret and sense of a great loss to engineering science in that Professor Turner's life was cut short before the completion of these studies for publication; and yet it was a great privilege to enjoy the long scientific comradeship and deep friendship that existed between the writers as partners during the strenuous experimentation involved in these and the other (still unpublished) researches.)

APPENDIX B

TABLE 55.—Velocities in Approach Channels (at Head Gauge Station Unless Otherwise Noted).

(Data refer to conditions approximately as for the volumetrically measured runs noted, Column (1). Head, h, determined during current-meter observations. Mean velocity, v, for entire channel obtained by volumetric measurements, $\frac{Q}{A}$, corrected to agree with head, h. Other velocities by current meter. Corrected values (Columns (5), (6), and (7)), obtained from current-meter vertical traverses divided by ratio, $\frac{v_m}{v}$ (see Figs. 33 to 47). Head, in feet; velocities, in feet per second.)

Runs No.	Heads on weir, (h).	Velocities in Approach Channel.					Runs No.	Heads on weir, (h).	Velocities in Approach Channel.				
		True mean (v).	Mean in mid-channel, vertical (v_m).	Corrected Values.					True mean (v).	Mean in mid-channel vertical (v_m).	Corrected Values.		
				At surface (v_s).	Mean above crest level (v_a).	Mean below crest level (v_b).					At surface (v_s).	Mean above crest level (v_a).	Mean below crest level, (v_b).

APPENDIX C

Velocity of Approach

This topic has been considered by many hydraulic experimenters. Seemingly, each generation in turn has studied it anew, has placed the thought on record, and forthwith has abandoned it again to the realm of speculation.

A few interesting quotations from hydraulic literature follow:

Hamilton Smith states:*

"The question to be solved is, what portion of the kinetic energy, due to the head, $\frac{v^2}{2g}$, * * * produces a useful effect at the opening of discharge [*i. e.*, above the crest-level]. * * * This subject has engaged the attention of many great minds during the past two centuries, and the discussions and controversies, if collected, would fill several good-sized volumes. If the same amount of thought and time, devoted to these almost fruitless discussions, had been employed in ascertaining what the *facts* really were, we would know a good deal more about the effect of velocity of approach than we do at present."

* * * * * * * *

"It seems reasonable to suppose that the additional force produced by the velocity of approach is chiefly due to the velocity of the section of the feeding stream nearest or in line with the section of discharge where the particles of water fairly begin to form into the escaping vein. This velocity is unquestionably greater than v (the mean velocity)."

Francis states:†

"It not infrequently happens that, in consequence of the particular form of the canal leading to the weir, or from other causes, the velocity of the water in the canal is not uniform in all parts of the section; this is a frequent cause of serious error, and is often entirely overlooked. If great irregularities exist they should be removed by causing the water to pass through one or more gratings, presenting numerous small apertures equally distributed, or otherwise, as the case may require, through which the water may pass under a small head; these gratings should be placed as far from the weir as practicable."

Francis, in deriving his theoretical expression involving velocity of approach, assumes a uniform velocity throughout the cross-section of the channel of approach. This condition is, so to speak, not a natural one, as had been recognized early in the Nineteenth Century by Lesbros, Boileau, and others.

Bazin states:‡

"* * * in varying the height of a weir, we modify not only the mean velocity, v, of approach, but also the distribution of the velocities in the water above the weir, the thickness of the falling sheet, its contraction on the sill, etc."

Bazin, however, apparently made no measurements to ascertain the extent of (or the degree of constancy in the law of) the modifications in the distribution of velocities for different heights of weir.

DISCUSSION

H. W. KING,* M. AM. SOC. C. E. (by letter).—These experiments explain possible causes of discrepancy in the results of earlier investigators and show quite clearly some of the conditions that affect the discharge over weirs. The most important of these conditions appear to be: (1) Sharpness of crest; (2) degree of roughness of face of weir; and (3) distribution of velocities in channel of approach. Although it has been known for some years that all these factors affect the discharge over thin-edged weirs their importance had not before been pointed out so clearly.

The new experiments indicate that opinions regarding the accuracy of weir measurements must be modified and also that the operations of measurement are more complicated than has heretofore been supposed. It still appears that the weir is a useful device for measuring water where a probable error of 2 to 5% is permissible. The statement of the authors that:

"The use of such a weir properly built, of good head measurements and good auxiliary velocity measurements in the channel of approach, should insure discharge values within 2% of the truth, and in most cases within 1 per cent."

is undoubtedly a fair conclusion. The standard requirements of a sharp crest and smooth up-stream face, however, are not easy to obtain and maintain and the additional requirement of measuring velocities in the channel of approach takes much from the usefulness of what has heretofore been considered a simple means of measuring water.

The new experimental data consistently give smaller discharges than were obtained by Bazin, and thus, in general, conform to the results of Francis, Fteley and Stearns, and Rehbock. The evidence appears to be overwhelmingly in favor of the smaller values. In this connection, however, it should be noted that Nagler's experiments,† which were performed on a weir, duplicating Bazin's standard weir, agreed substantially with the results obtained by Bazin. Although the discharges were not measured volumetrically, they were measured in a manner and under conditions such that their accuracy can hardly be doubted. It seems more likely that in duplicating approximately the conditions of the two sets of experiments the discharges obtained in each case were substantially the same.

In the discussion‡ of Professor Nagler's paper, the late Frederic P. Stearns, Past-President, Am. Soc. C. E., makes the following statement:

"In view of these large differences in the results of carefully conducted weir experiments, two conclusions seem to be warranted:

(1) That in the present state of the art the weir is not an accurate instrument for the measurement of water;
(2) That the art should be developed so that the causes of the variation in results may be discovered and eliminated."

* Prof. of Hydr. Eng., Univ. of Michigan, Ann Arbor, Mich.

† "Verification of the Bazin Weir Formula by Hydro-Chemical Gaugings," by Floyd A. Nagler, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 105.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 172.

The first of these conclusions holds to-day. The later experiments only raise the query as to whether it is worth while to follow the suggestion contained in Mr. Stearns' second conclusion, or whether it will be more profitable in the end to let the sharp-crested weir rest temporarily and take up the investigation of other more promising means of measuring flowing water.

There is undoubtedly great need for some device of the weir or "obstruction" type for measuring discharges in open channels. The question arises as to whether this need is best met by the sharp-crested weir, or whether some other form of weir or obstruction in the channel can be designed for which the discharge will not be so greatly affected by minute variations in standard conditions. This is a field worthy of thorough investigation. In the past, many engineers appear to have accepted the sharp-crested weir as a panacea, and it has been investigated to the exclusion of other devices of a similar character.

The Society's Special Committee on Irrigation Hydraulics is investigating methods of measuring water in open channels, and is making a special study of devices for producing flow at critical depth. No recommendations as to a standard design have yet been made. It appears, however, from the work of the Committee to date* that discharges can be measured with great accuracy by a proper utilization of the critical-depth principle.

The discharge over a broad-crested weir occurs at critical depth. If the up-stream edge of such a weir, Fig. 50(*a*), and the up-stream edges of the ends of the weir are well rounded so as to prevent contraction, the discharge will be given very nearly by the formula,

$$Q = 3.087\ L\ H^{\frac{3}{2}}$$

This formula has the inherent objection, in common with formulas for sharp-crested weirs, that the head, H, must be corrected for velocity of approach and that this correction is affected by the distribution of velocities in the channel of approach. It has advantages, however, over the sharp-crested weir in not requiring a sharp crest which is difficult to maintain and in being much less sensitive to conditions affecting roughness of crest.

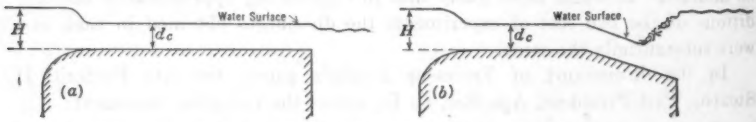

FIG. 50.—TYPES OF BROAD CRESTED WEIRS.

If the weir crest, Fig. 50(*a*), has a slope a little greater than is required to overcome the loss of head due to friction for discharge at critical depth, the water should flow at very nearly the critical depth, d_c, over the entire surface of the weir. Near the up-stream edge of the weir, just below the place where the drop in water surface occurs, the depth should be the critical depth

* "The Improved Venturi Flume," by Ralph L. Parshall, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 841; particularly discussions by Julian Hinds and J. C. Stevens, Members, Am. Soc. C. E., pp. 859 and 872.

within the limits in accuracy of measurement. The discharge is then given by the theoretical formula,

$$Q = L \sqrt{g}\, d_c^{\frac{3}{2}}$$

This formula is independent of conditions affecting velocity of approach and appears to have many advantages. It still lacks a thorough experimental test.

The broad-crested weir has a distinct advantage in that the discharge is not affected when the water surface on the down-stream side is a distance, d_c, or less, above the weir crest. A still greater submergence is permissible if the down-stream portion of the crest is given a steep slope, Fig. 50(*b*). This permits the water to obtain a velocity greater than the velocity at critical depth, and a hydraulic jump results. The loss of head in a low jump is comparatively small, and by proper design most of the energy of the water can be converted into static head. The utilization of the critical-depth principle gives promise of providing a simple, accurate, and comparatively inexpensive method of measuring water.

An unpublished thesis, by C. J. McLean, Assoc. M. Am. Soc. C. E., submitted in connection with graduate work at the University of Michigan, contains the results of a series of experiments for determining the variation in head measured at different places in the channel leading up to a weir. A summary of Mr. McLean's experiments is contained in Table 56. These experiments supplement similar experiments by Fteley and Stearns,* and show clearly the existence of the "angle of pressure".

The experiments were performed in the experimental flume at the University of Michigan, which is fully described in Professor Nagler's paper. Heads were measured with hook-gauges that gave a range in reading of 4 ft. Open-

* *Transactions*, Am. Soc. C. E., Vol. XII (1883), p. 1, and Vol. LXXXIII (1919–20), p. 174.

ings were made in the face of the weir and on one side of the channel, at places selected for measuring heads. In these openings short pipes, 2 in. in diameter, were placed so as to be flush with the inner surface of the channel. The pipes were connected by a $\frac{3}{4}$-in. rubber hose to 5-gal. galvanized-iron pails. The pails were raised and lowered to positions that were convenient for

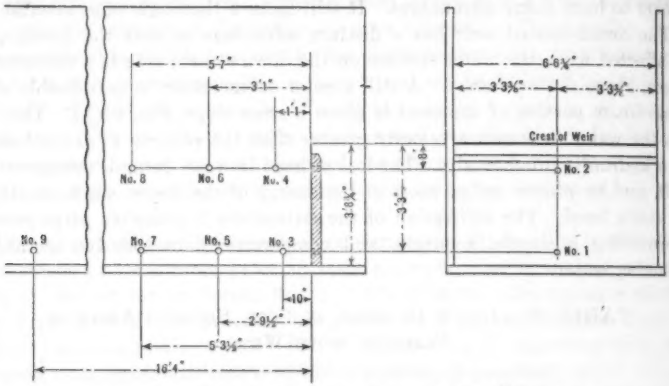

FIG. 51.—LOCATION OF CONNECTIONS TO HOOK-GAUGES.

reading the gauges. Nine connections were made at the positions indicated in Fig. 51. The location of the connection for Gauge No. 9 corresponds to that used by Bazin. Gauges Nos. 7 and 8 are connected at points corresponding approximately to points used, respectively, by Francis and Fteley and Stearns.

FLOYD A. NAGLER,* M. AM. SOC. C. E. (by letter).—The outstanding contribution to the knowledge of the hydraulics of weirs made by this excellent paper exists in the investigation of the effect of irregular channel velocities on the quantity of water flowing over the crest. Some of the divergence between the results of standard experiments could no doubt be attributed to such a cause if the precise knowledge of the velocity conditions in the approach channel were available. Certainly, far different conditions existed in the long unobstructed channel leading to the Bazin weir than in the short, wide, and turbulent channel approaching the Fteley and Stearns 19-ft. weir, the actual current velocities of which were only partly described by the results of the current-meter measurements recorded with their experiments. The writer believes that future experimenters will use extra caution in securing a satisfactory distribution of flow in the approach channel. This distribution of flow will be examined by preliminary velocity measurements, and the discharge will be determined by some standard weir formula rather than by methods allowing a poor distribution of flow to exist, which would require the measurement of current velocities for every observed head on the weir in order to solve for discharge in the authors' formula.

The experiments cited by the authors on the effect of rounding the weir crest and roughening the weir plate are also important, and are in good

* Prof. of Hydr. Eng., Univ. of Iowa, Iowa City, Iowa.

agreement with investigations which have been conducted since 1923 at the hydraulic laboratory of the State University of Iowa.

The Iowa investigations were performed on a sharp-crested weir, 2 ft. long and 3 ft. high. The crest of the weir plate was made of brass with a sharp and well maintained edge. The procedure followed by James Barr was used in roughening the weir plate by coating it with sand of several degrees of fineness. Care was exercised to file the crest after applying each coat so as to leave an irregular but sharply defined up-stream edge on the weir. How effective the roughening near the crest was in comparison with that some distance below it, was tested by stripping the roughened coat from the plate to various distances below the edge of the plate.

The appearance of the weir plate as prepared for several of the experiments is shown in Figs. 52 and 53. The weir in Fig. 52 was covered with coarse sand that was retained on a No. 8 standard Tyler sieve, but passed the No. 4 sieve. The weir in Fig. 53 is studded with hardware.

While these experiments were performed primarily to determine the effect of the roughening on the profile of and velocities within the nappe, volumetric measurements were made to compare the discharge of the weir with its flow when its crest was sharp and the weir plate smooth. A summary of the results of these measurements are given in Table 57.

It is interesting to note that the roughening of the weir plate near the crest was much more effective in increasing the discharge than the roughening more than ½ in. away, and that roughening the wooden bulkhead by heavy hardware caused no alteration in discharge.

TABLE 57.—PERCENTAGE OF INCREASE IN DISCHARGE DUE TO ROUGHENING OF WEIR PLATE.

Series No.	Condition of weir plate.	HEAD ON WEIR.			
		0.2 ft.	0.3 ft.	0.4 ft.	0.5 ft.
	Coarse sand:				
2	(Retained on No. 8 standard sieve and passing No. 4) to crest	6.5	6.0	6.0	4.7
3	To crest with bulkhead studded	6.5	6.0	6.0	4.7
4	To ¼ in. from crest	0.2	1.0	2.3	2.9
	Medium sand:				
5	(Retained on No. 28 sieve and passing No. 14) to crest	4.0	2.4	2.0	1.5
6	To 1/16 in. from crest	1.2	1.5	1.5	1.5
7	To ⅛ in. from crest	0.7	0.7	0.6	1.5
9	To ½ in. from crest	0.3	0.3	0.0	0.0

Experiments performed by the writer* have demonstrated that the Bazin formula may be used in computing discharges for heads even higher than those included in the writer's experiments, securing results much nearer the truth than those obtained by the solution of the Francis formula. The authors' experiments seem to substantiate this conclusion. Under low heads the results obtained with the Bazin formula are higher than those obtained by most other experimenters, but the explanation of the authors seem somewhat presumptuous and misleading with regard to the true condition of the

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 105.

Bazin weir. After considerable study and investigation the writer has come to the conclusion that the Bazin weir plate was unquestionably sharp and smooth, and for the following reasons:

(1) Hydraulic science has never known a more careful and better trained observer than M. Bazin, and it appears almost unthinkable that a man who had spent a large part of his life carefully studying into every small detail of the phenomena of the nappe passing over the standard weir, should have carelessly allowed the weir plate to become rough and the edge other than sharp. When Bazin used the words "arête vive",* an expression was used such as would correctly be applied to the sharp and well-defined knife-edge of a fine chemical balance, and it has been correctly applied to the weir in translating it as a sharp edge. Also, the words, "bien dressee"† applied to the weir plate indicate that considerable attention was given to the condition of the face of the weir plate itself.

(2) A few years ago the writer raised the question of the condition of the Bazin weir plate in some correspondence with M. Hegly, who it will be recalled was associated with Bazin in his weir experiments.‡ M. Hegly made reply in no uncertain terms, which the writer has translated as follows:

"No special photographs were taken of the crest of the standard weir used in the Bazin experiments. I only know he gave much attention to the question of assuring himself that the edge, where the under surface of the nappe escaped, was level and corresponded to a straight line. And, several times, the crest, that is to say, the plate of wrought iron 7 mm. thick, which rested on top of the wooden bulkhead, was removed and laid on the side of the experimental canal, in order that he might by touch as well as by sight determine the sharpness of the up-stream edge of the plate. He never permitted any doubt on this question.

"From time to time he cleaned the top and up-stream face of the weir plate in order to remove small deposits of algæ and rust which might have affected the accuracy of the crest."

These statements of M. Hegly leave no doubt as to the condition of the Bazin weir crest. In fact, Bazin was probably more meticulous in maintaining a sharp edge on the weir crest than any of the other early investigators.

(3) Bazin's measurements on the profile of the lower face of the weir nappe unknowingly demonstrate both the sharpness of the crest and the smoothness of the weir plate.

Measurements of the weir nappe made in the hydraulic laboratory of the State University of Iowa, have shown that the value of ϵ (Fig. 54) varies not only with the height of the weir, but with both the degree of sharpness of the crest and also the roughness of the up-stream face of the weir. A summary of the results of these experiments is given in Table 58. The weir was 3 ft. high and 2 ft. long.

Bazin obtained an average value of ϵ equal to 0.112 on a weir 3.72 ft. high, and an average value of 0.099 on a weir 1.15 ft. high.§ Arithmetical interpolation between the values for the Bazin weirs gives a value for ϵ of

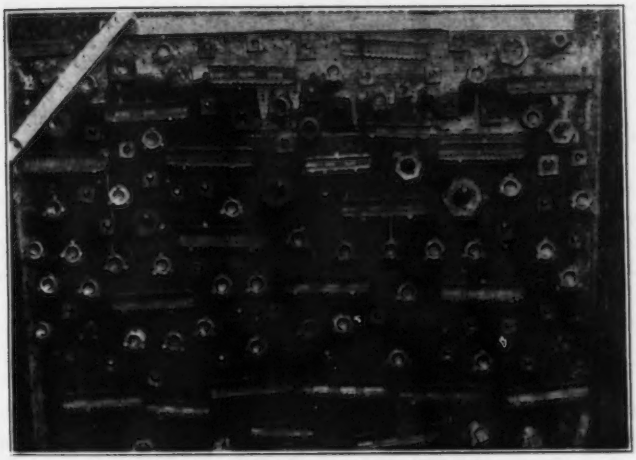

FIG. 53.—WEIR BULKHEAD FOR SERIES 3.

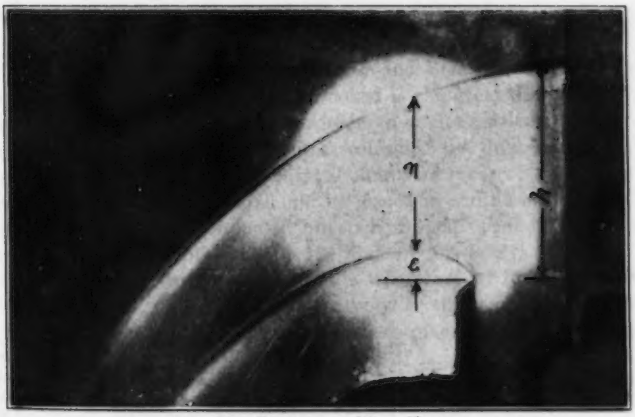

FIG. 54.—PROFILE OF WEIR NAPPE.

0.108 for a weir 3 ft. high, similar to that of the writer, but with a crest condition duplicating that of Bazin. This value is exactly that obtained on the weir at the University of Iowa, which the writer can affirm was thoroughly sharp.

TABLE 58.—MAXIMUM ELEVATION OF LOWER SURFACE OF WEIR NAPPE.

Series.	Condition of weir.	Value of $\frac{e}{h}$.
1	Standard sharp crest	0.108
5	Sand to crest	0.092
6	Sand to 1/16 in. from crest	0.097
7	Sand to 1/8 in. from crest	0.099
8	Sand to 1/4 in. from crest	0.102
9	Sand to 1/2 in. from crest	0.103

These facts make it appear conclusive that the Bazin weir had a truly sharp edge, and it is regretted that the authors' ingenious explanation of the divergence of the Bazin low-head experiments seems untenable.

The type of formula proposed by S. M. Woodward, M. Am. Soc. C. E.,* has many practical advantages in solution, which make it far more usable than that proposed by the authors; and if this formula had been checked against the original data instead of against the authors' Equation (*D*), it probably would be found to represent these data with equal accuracy.

For work in preparing the tables in this discussion, acknowledgment is due to Messrs. J. W. Howe,† E. T. Schuleen,‡ and Glen N. Cox,‡ Graduate Students at the State University of Iowa.

A. STREIFF,§ M. AM. SOC. C. E. (by letter).—Ever since Trautwine in 1889 published a translation of Bazin's experiments, Bazin's formula has been widely used in this country, and hence experiments tending to prove its somewhat large results are of importance.

As Professor Schoder so conclusively shows, the distribution of the velocity of approach is of vital importance in a weir, and it is, therefore, not easy to determine whether Bazin's or Francis, Fteley and Stearns, or Rehbock's formula is the correct one. Not to be overlooked is the great difficulty involved in calibrating a large measuring basin properly, such as a lock with more or less rough walls, as used by Francis, or a section of the Sudbury conduits, as used by Fteley and Stearns. It is easy to obtain an error of 1 or 2 per cent. Professor Rehbock's experiments should be placed in a different class. These are "indoor" experiments, conducted on such a small scale that this latter circumstance may easily introduce results that are 1% or 2% too small. The writer is well acquainted with the hydraulic laboratory of Professor Rehbock, and believes that the measurements were very accurate; but the small size of the flume no doubt caused the experiments to give somewhat small results, if the formula was applied to the measurement of larger discharges.

* See p. 1040.

‡ Now Jun. Am. Soc. C. E.

§ Cons. Engr., Jackson, Mich.

It is of interest to quote the experiments made at the Amsteg Power House of the Swiss Federal Railways.* The results are given in Table 59.

Seemingly, Table 59 would show the greater accuracy of the Rehbock formula over those of Frese or Bazin, especially since the volumetric measurement is closely checked by the titration method and the current meter. Nevertheless, the table shows the tendency of the Rehbock formula to be on the small side, and the Swiss "S. I. A." ("Schweizerische Ingenieur und Architekten Verein") formula is shown to check more closely than that of Rehbock.

TABLE 59.—RESULTS OF EXPERIMENTS AT AMSTEG POWER HOUSE.

Discharge, in volumetric liters per second.	PERCENTAGE ERROR OF WEIR.		
	Frese.	Bazin.	Rehbock.
1 182	+ 1.7	+ 1.5	+ 0.2
2 128	+ 1.9	+ 1.4	− 0.1
3 204	+ 2.5	+ 1.9	+ 0.2
4 371	+ 1.5	+ 0.7	− 0.8

More comparable with the Francis, Fteley and Stearns, and Schoder experiments than the Rehbock formula are the Frese experiments. In Hanover, Germany, Professor Frese (like Francis) made "full-sized" tests in a lock chamber,† which are practically unknown in this country, and are, for instance, not mentioned by R. E. Horton, M. Am. Soc. C. E., in the well-known *Water Supply Paper No. 200.* It happens that the Frese formula also gives results tending to be on the large side, and, hence, excluding Rehbock's formula, there are also the following formulas based on large-scale experiments: Francis, Fteley and Stearns, Schoder, on the small side, and Bazin and Frese, giving larger discharges.

It is of importance that Professor Schoder has demonstrated so conclusively that the weir is a very sensitive contrivance. On the Continent of Europe the inherent instability of the weir has been known and appreciated for a long time. Dr. J. Epper, former Director of the Hydrometric Survey in Switzerland, in correspondence with the writer, in 1914, stated:

"Here we do not use weirs unless they are first calibrated by the current meter. It appears that, no matter how closely the standard weir is copied, differences will creep in due to differences in the distribution of flow above the weir."

In a work published by that Survey, Dr. Epper quotes‡ the water supply of the City of Berne where weirs gave different results due to varying flow.

For measurements that are not continuous the obvious conclusion from Professor Schoder's experiments is, therefore, to discard the weir and use the current meter instead. If the weir must be supplemented by meter measure-

† "Versuche über den Abfluss des Wassers bei vollkommenen Ueberfallen," *Zeitschrift* des Vereines Deutscher Ingenieure, 1890.

‡ "Die Entwickelung der Hydrometrie in der Schweiz," Berne, 1907.

ments, the use of the meter only is obviously indicated. The weir naturally is more practical in cases where a long series of measurements is to be made. A weir arranged for continuous observation is often found, therefore, which is calibrated beforehand by other means, such as the moving screen. At the hydro-electric plant at Ackersand, Switzerland, and at the testing flume of the J. M. Voith Company, in Heidenheim, Germany,* such a combination of weir and moving screen may be found.

As a rule, however, careful observation of standard weir specifications, especially if the velocity of approach is low or, in other words, if the weir is high, will result in good measurements that are reliable. In Table 60 the writer gives the results of hitherto unpublished tests made by William G. Fargo, M. Am. Soc. C. E., and a comparison of relative turbine discharges, as measured by current meters and Francis weir, at the Loud Development on the Au Sable River, in Michigan, run on October 16 and 17, 1913. They are presented by courtesy of William W. Tefft, M. Am. Soc. C. E., Vice-President of the Consumers Power Company, present owners of the dam (1927). The weir was of the standard Francis type, probably the largest ever built. It was 117.583 ft. long; the average weir crest elevation was 216.040 ft. The concrete bottom was at Elevation 207.47, the height of the weir, therefore, being about 8.5 ft. It was solidly constructed of a steel frame set in a concrete foundation and covered with wooden gates having a steel-plate face. The weir crest was made in strict accordance with Francis' specifications. The leakage was determined by lowering the tail-race with the penstock gates closed, allowing the leakage through the gates to fill up the penstocks. It amounted to not more than 5 cu. ft. per sec. The head was measured in six places, 21 ft. 9 in. to 23 ft. 6 in. apart, by means of pipe connections placed in concrete pedestals on the bottom of the tail-race. These communicated with six barrels at which the head was measured by six hook-gauges. An aeration pipe was placed on the down-stream side. The flow was measured simultaneously by current meters just up stream from the penstock head-gates.

Two sections were selected, one being measured by Price meters, the other with an Ott meter. The meters had been carefully calibrated in the Naval Tank at the University of Michigan by Professor Herbert C. Sadler. Since the tests of S. Hajós, of the Hungarian Hydrographic Service, published in 1901,† there can be little doubt that a still-water rating is fully equivalent to one in ordinary flowing water, without cross-currents or eddies. Although these tests were made many years ago, they were not widely published and hence the same question has been re-opened many times.‡ The theory and behavior under conditions of oblique flow; the influence of different mountings; and the size of the measuring section of the Ott meters used, had been extensively investigated, and the writer, therefore, could recommend, with

full confidence, a comparison test of the Ott meter with the weir.* The rating curves for the Ott meter had been computed by Dr. Epper, of Berne, Switzerland, who wrote that the Naval Tank, at Ann Arbor, apparently was very accurate, as shown by the small probable error. The results of the test which was conducted with great care, are shown in Table 60. It appears that the Price meters gave discharges much too great, but the agreement between the weir and Ott meter was very satisfactory. The present Ott meter (Type V), is a great improvement over that used in these tests, and gives a rating curve that is practically a straight line from the start.

After it had thus been proved conclusively that the Ott meter is fully equivalent to the weir, no more testing weirs were built, and the measurements were conducted with Ott meters exclusively. In order to make such measurements quickly and accurately, the writer introduced the use of the Tchebycheff formula, as mentioned by Dr. Staus in his recent work on the accuracy of current-meter measurements.†

R. L. PARSHALL,‡ ASSOC. M. AM. SOC. C. E. (by letter).—The measuring weir has been one of the most popular subjects investigated by hydraulic engineers.

Flowing water is not always what it appears to be from the standpoint of consistency of motion. Engineers are apt to make certain assumptions as to the line of travel and rate of displacement of the filament in the water mass, that conditions do not fully justify. All parts of a mass of water moving under the influence of gravity do not advance uniformly. For instance, that portion touching the confining surfaces is slowed down, while at some point within the mass the rate of motion may be either accelerated or retarded. This unequal movement disturbs the flow and sets up cross-currents which result in boils or eddies. This disturbed condition of flow becomes less apparent, however, with slower velocities, and at an extremely slow rate of translation the effects of the cross-currents are inappreciable, although they are present. When the stream is led over a weir notch, the velocity of the water is then sufficient to produce unequal variations of movement in the approach section, causing a departure from the ideal. The contracting vein introduces other complications which, in combination, set up a condition far from the ideal conception of stream lines curved gracefully over the crest and reaching through into the nappe of the falling sheet of water.

Flowing water is endowed with still another very troublesome characteristic. The water surface is considered fixed and constant as to elevation or depth, when in reality this is not its condition. An oscillating pulse is set up when the mass of water begins to move in an open channel. This changes

the depth or pressure and causes an unsteadiness of movement over the crest of a weir. Screens, baffles, barriers, skimmers, and all known mechanical means of damping this effect do not totally eliminate the incessant rise and fall of the surface. Experience seems to indicate that under laboratory conditions and refinement of control, certain combinations of flow conditions very greatly affect the accuracy or dependability of measurement, and for this reason exactness in weir measurement is extremely difficult to attain, if attainable at all.

The authors' experience, as indicated by the various diagrams, is that all observations do not plot along the ideal curve, and the writer's experience with weirs under laboratory conditions shows the same difficulty. It might even be stated that it is doubtful if there is any such thing as precise weir measurements.

The writer is not in full accord with the authors' method of determining the effective head on the weir crest to the limit of accuracy stated. Two methods are described. In one, a sharp-pointed plumb-bob is attached to a steel tape graduated to hundredths of a foot; in the other a float-gauge is used. The least known graduation marked on either tape or gauge is 0.01; by estimation the nearest 0.001 part is determined, and the nearest 0.0001 part is recorded as a mean. In the original notes (Test 55) the observations of heads are shown where the variation is 0.013 ft. for the plumb-bob determination, while the float-gauge readings varied between limits of 0.023 ft. The attempt to determine the mean head to 0.0001 ft. for this range of fluctuation appears to be going beyond precision, as the word should be understood in such work. However, it is to be noted in this case that the agreement of the means of the two independent measurements is remarkably close. As shown in the original notes (Test 14), both float and plumb-bob gauge readings are recorded to the nearest 0.0005 ft., which calls for the estimation of one-twentieth of the 0.01 division of the scale. This seems to claim an accuracy not to be credited.

Examination of the recorded data shows that the variation or trend of the law of discharge is not perfectly uniform. The variations are not due to inaccurate measurement of the physical constants, but to the inherent characteristics of the flowing water. In Table 42 are given results of discharge over a sharp-crested weir for heads of less than 0.02 ft., and a corresponding discharge, in second-feet, to a limit of 0.00001, with a direct comparison to a computed discharge by means of Francis' formula. There seems to be no logical reason in setting up a comparison of observed and computed free-flow discharge over a sharp-crested weir for a head of only 0.02 ft. The writer's laboratory experience with weirs indicates that about 0.07 ft. for a rising head is required to prevent adherence to the downstream face of the weir crest. A stream which adheres to the crest certainly can not follow the same law called for by the Francis formula. Perhaps it might be said with equal propriety that there is no justification for setting up comparisons of discharges, thus determined, with those computed by the Francis formula, where the heads exceed one-third the crest length.

An extensive series of tests on various types of weirs was conducted at the Hydraulic Laboratory of the Colorado Agricultural Experiment Station, at Fort Collins, for the purpose of extending the law of flow over weirs

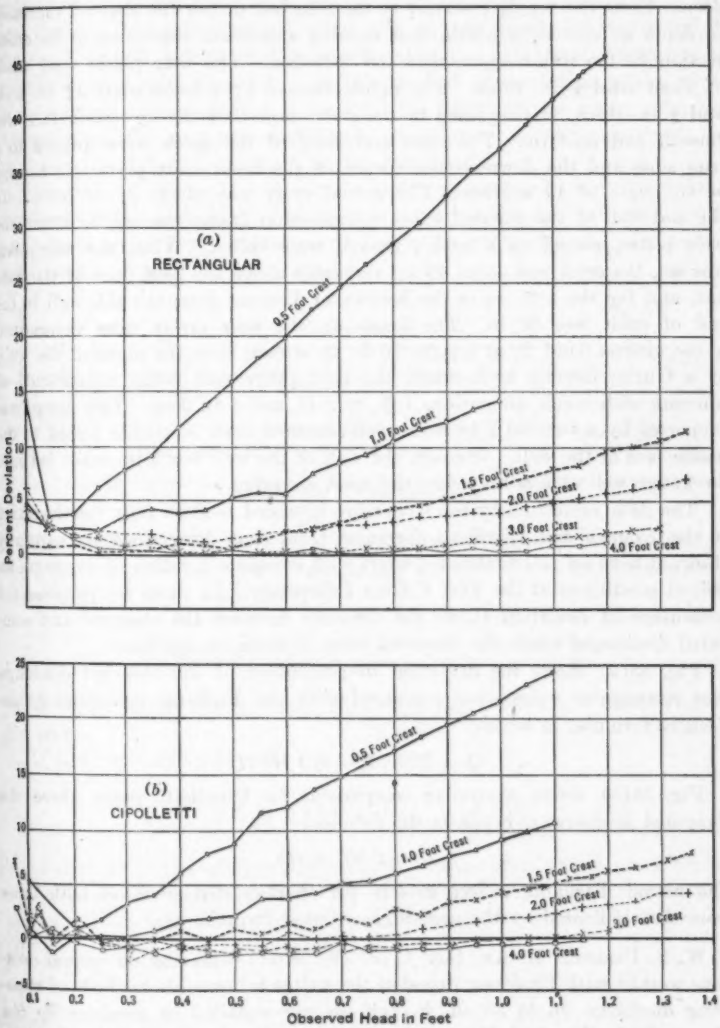

FIG. 55.—PERCENTAGE OF VARIATION OF DISCHARGE, SHARP-CRESTED WEIRS.

for depths greater than one-third the length of the crest, as recommended by Francis. The general features of this laboratory and method of conducting

the tests, together with a complete report of the results, have been described.* The weirs tested were mounted in the end wall of a concrete channel about 80 ft. long which leads to the source of the water supply. For a distance of 20 ft. back from the plane of the weir this channel is 10 ft. wide and 6 ft. deep. From the supply reservoir to the weir box proper the channel increased in depth as well as in width, thus causing a constant expansion of its cross-section as the water approached the weir box. The weir plates were made of sheet steel $\frac{1}{8}$ in. thick. The notch, formed by a brass plate $1\frac{1}{4}$ in. wide and $\frac{1}{4}$ in. thick, was so fitted to the steel sheet that the up-stream face was smooth and uniform. The crest and sides of the notch were dressed to a true adge and the down-stream corner of the brass crest plate was beveled to an angle of 45 degrees. The actual crest was about $\frac{1}{64}$ in. wide. In the end wall of the channel a heavy angle-iron frame was set, to which the weir plates, seated on a rubber gasket, were bolted. When the weir plate was set, the crest was about 42 in. vertically above the level floor of the weir box, and for the 4-ft. weirs the horizontal distance from the side-wall to the end of crest was 36 in. The heads on the weir crests were determined to the nearest 0.001 ft. at a point 10 ft. up stream from the plane of the weir, by a Gurley-Boyden hook-gauge, the hook-gauge well being constructed of concrete with inside dimensions 1 ft. by 2 ft. and 4 ft. deep. This gauge was supported by a vertical 2 by 6-in., well-seasoned stick of timber bolted to the inside face of the well. Through the wall of the weir box 1-in. tubes led into the gauge well at a point below the crest elevation.

The data submitted by the writer are intended to show only the deviation of the Francis and Cipolletti formulas from that determined by carefully observed tests on full contracted weirs with complete aeration of nappe under refined conditions at the Fort Collins Laboratory. In these comparisons the percentage of deviation shows the disparity between the observed and computed discharges where the observed value is taken as the base.

Fig. 55(*a*) shows the deviation in percentage of the observed discharge over rectangular weirs when compared with the discharge computed by the Francis formula, in which,

$$Q = 3.33\ (L - 0.2\ H)\ H^{\frac{3}{2}}$$

Fig. 55(*b*) shows a similar comparison for Cipolletti weirs where the computed discharge is based on the formula,

$$Q = 3.367\ L\ H^{\frac{3}{2}}$$

The actual discharge differs greatly for short-crested weirs of both types from that indicated by the generally accepted formula.

W. S. Pardoe,† M. Am. Soc. C. E. (by letter).—Having on several occasions worked with Professor Schoder, the writer believes his methods of measuring discharge up to 50 cu. ft. per sec. are equalled in accuracy by few laboratories and exceeded by none. His method of measuring the head, h, by means of a float and pointer reading to hundredths and interpolating

* *Journal of Agricultural Research*, U. S. Dept. of Agriculture. Vol. 5, March, 1916.

† Prof. of Hydr. Eng., Univ. of Pennsylvania,, Philadelphia, Pa.

thousandths of feet does not seem as accurate as the use of a hook-gauge with a vernier reading to thousandths and interpolating to ten thousandths.

Professor Schoder does well to call attention to the possible errors in the use of the weir in field work. An error of 2½%±, due to the condition of the crest as shown in Fig. 8 between Series I and II (Dawson), is enough to give one pause. The enormous variation due to the height of weir and to the conditions of baffling and approach make the field results obtained by means of weirs more uncertain. If this method of measuring water, which is not a cheap or easy method, is used, all the circumstances surrounding the derivation of the proposed coefficients should be carefully examined and slavishly copied if any degree of accuracy is desired.

The authors' Formula (*D*) for velocity of approach is a "jewel"; it lacks both rhyme and reason, but, as it is purely empirical, it should, like the pudding, be judged by the eating and not by its synthesis. Fig. 18 shows a remarkable accuracy for this formula.

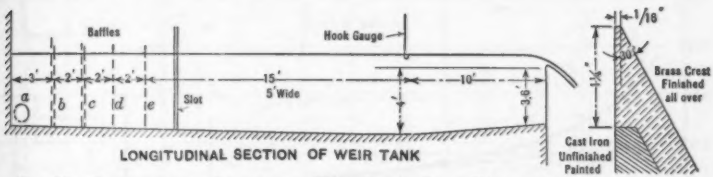

FIG. 56.—LONGITUDINAL SECTION OF WEIR TANK, CIVIL ENGINEERING DEPARTMENT, UNIVERSITY OF PENNSYLVANIA.

Francis derived his correction for velocity of approach rationally from the following expression for a rectangular orifice under a low head with an appreciable velocity of approach:

$$Q = 3.33\, L \left[\left(h_2 + \frac{v^2}{2g} \right)^{\frac{3}{2}} - \left(h_1 + \frac{v^2}{2g} \right)^{\frac{3}{2}} \right]$$

in which, h_1 and h_2 are the heads on the top and the bottom, respectively, of the orifice.

If h_1 is zero, as in the weir, this becomes:

$$Q = 3.33\, L \left[\left(h + \frac{v^2}{2g} \right)^{\frac{3}{2}} - \left(\frac{v^2}{2g} \right)^{\frac{3}{2}} \right]$$

v is the main velocity of approach, and the formula gives values much too low.

The authors cheerfully change the minus sign to plus and then re-vamp the formula to take account of the mean velocity above and below the crest, putting it in the form of Equation (*D*):

$$Q = 3.33\, L \left(h + \frac{v_a^2}{2g} \right)^{\frac{3}{2}} + L h \frac{v_b^2}{2g}$$

This formula is not homogeneous; that is, it adds peaches to pears and gets apples. The term, 3.33, by derivation includes $\sqrt{2g}$, hence the quantity involv-

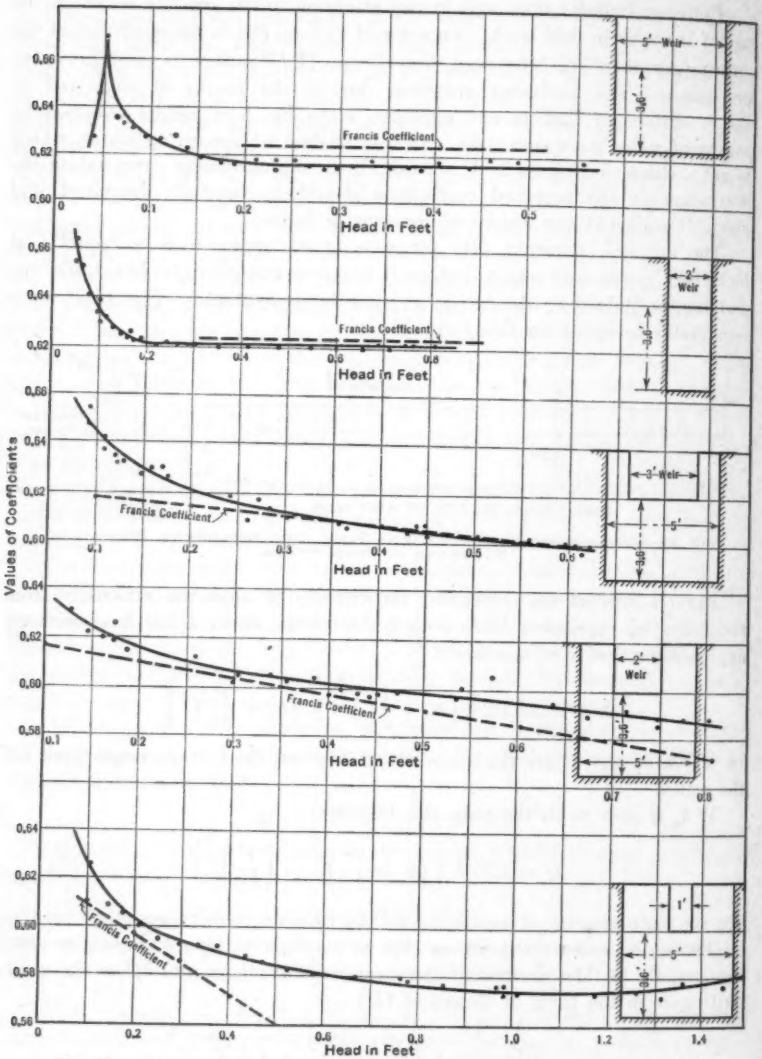

FIG. 57.—COEFFICIENTS OF RECTANGULAR WEIRS SUPPRESSED AND CONTRACTED.

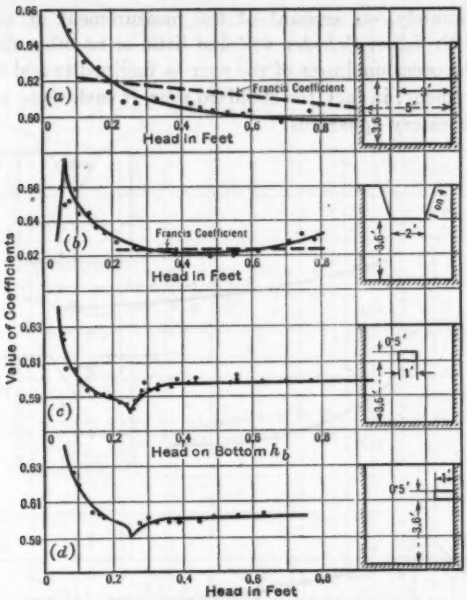

FIG. 58.—SECTIONS OF SEVERAL FORMS OF WEIRS.

ing (v_a) is $\sqrt{\frac{\text{feet}}{t^2}} \times \text{feet} \times \text{feet}^{\frac{3}{2}}$, or cubic feet per second, as it should be; but the quantity involving (v_b) is feet $\times$ feet $\times$ feet, or cubic feet. However, in spite of this, the formula gives excellent results and should be judged by

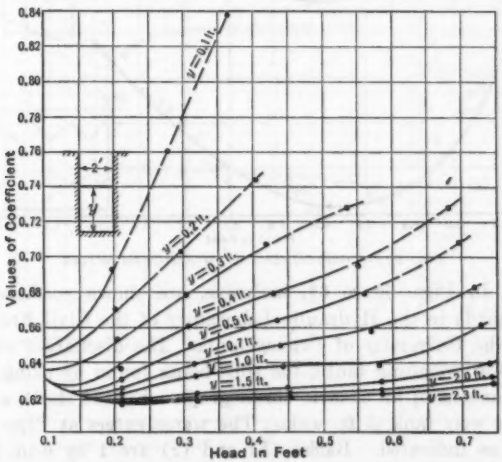

FIG. 59.

them. Unfortunately, on account of the measurement of velocities in the approach canal Professor Schoder will find little or no other data to check his own, nor will the occasional user of the weir be inclined to add to his field work by such measurement; in fact, the standard weir, if such there is, is fast becoming a bit of laboratory apparatus.

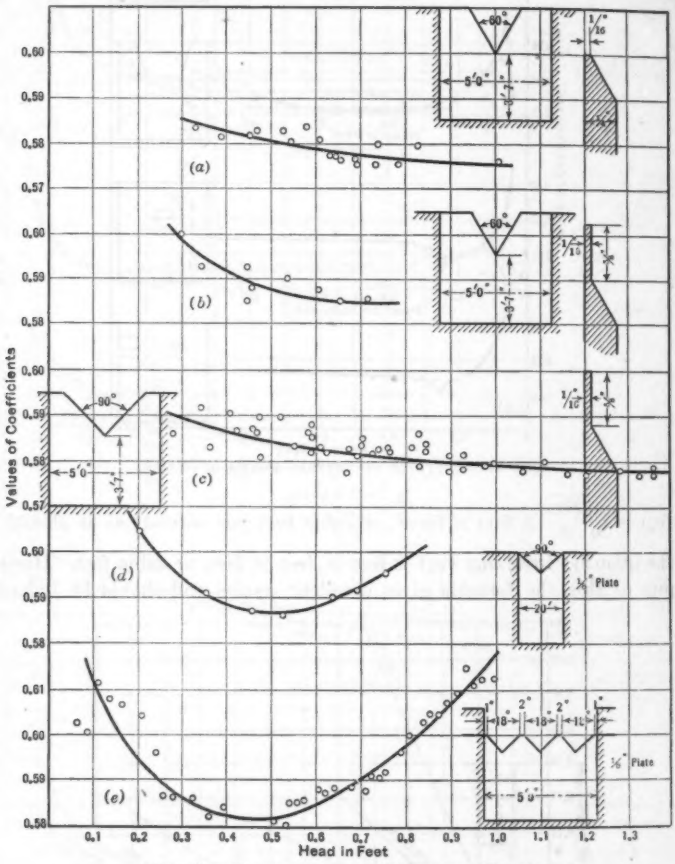

FIG. 60.—COEFFICIENTS OF V-NOTCHED WEIRS.

Herewith, in Figs. 56 to 61, inclusive, are shown coefficient curves of experiments made in the Hydraulic Laboratory of the Civil Engineering Department of the University of Pennsylvania. The discharges were measured in two 16 000-lb. weighing tanks, the time being found by using stop-watches calibrated by means of an electric chronograph. Fig. 56 shows a longitudinal section of the weir tank, 5 ft. wide. The water enters at Pipe (*a*), through drilled holes as indicated. Baffles (*b*) and (*c*) are 1 by 6-in. boards, 4 in. apart vertically and 2 in. apart horizontally. Baffles (*b*) and (*c*) are cross-

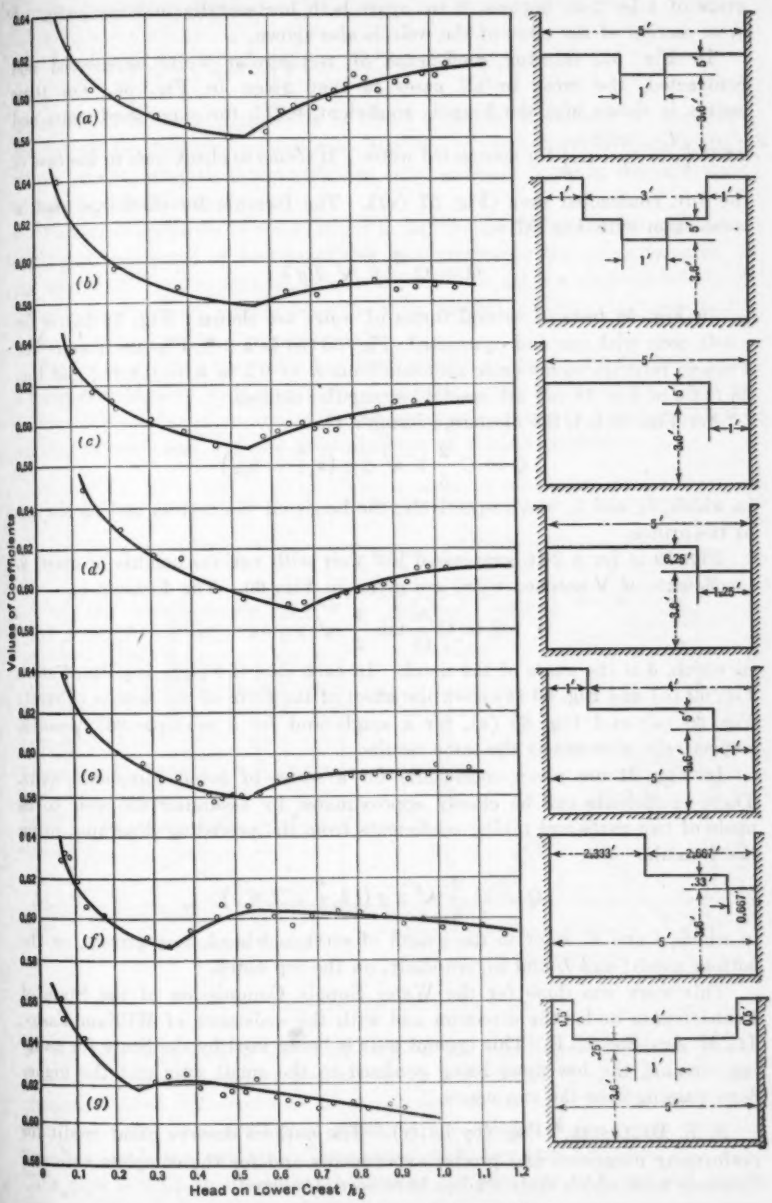

FIG. 61.—COEFFICIENTS OF COMPOUND WEIRS.

grids of 1 by 2-in. battens, 2 in. apart both horizontally and vertically. A cross-section of the crest of the weir is also shown.

In Fig. 57, showing coefficients of rectangular weirs suppressed and contracted, the crest in all cases is that given in Fig. 56. On these curves is shown also the Francis coefficient, 0.623, for suppressed weirs and $0.623\left(\frac{L-0.02\,h}{L}\right)$ for contracted weirs. It seems to check best in the case of the 3-ft. contracted weir (Fig. 57 (*e*)). The formula for discharge used in connection with Fig. 57 is,

$$Q = C\,\frac{2}{3}\,b\,\sqrt{2\,g}\,h^{\frac{3}{2}}$$

In Fig. 58 tests of several forms of weirs are shown. Fig. 58 (*a*) is for a 3-ft. weir with one end contracted; Fig. 58 (*b*) is a 2-ft. Cipolletti weir—the Francis formula seems quite accurate from $h = 0.2$ to $h = 0.8$ ft.; and Fig. 58 (*c*) and Fig. 58 (*d*) are special rectangular orifices.

For Fig. 58 (*c*), the discharge formula is,

$$Q = C\,\frac{2}{3}\,b\,\sqrt{2\,g}\left(h_b^{\frac{3}{2}} - h_t^{\frac{3}{2}}\right)$$

in which, h_b and h_t are, respectively, the heads on the bottom and on the top of the orifice.

Fig. 59 is for a 2-ft. suppressed low weir with various heights of crest, y. Coefficients of V-notched weirs are given in Fig. 60. The formula is,

$$Q = C\,\frac{8}{15}\tan\frac{\theta}{2}\,\sqrt{2\,g}\,h^{\frac{5}{2}}$$

in which, θ is the angle of the notch. In each case the plate is painted steel. Fig. 60 (*a*) and Fig. 60 (*b*) show the effect of the form of the section of crest; Fig. 60 (*d*) and Fig. 60 (*e*), for a single and for a multiple 90° V-notch, respectively, give nearly the same results.

In Fig. 61 are given coefficients for a series of seven compound weirs. These coefficients can be closely approximated by assuming the weir to be made of two parts and taking coefficients from the preceding diagrams, using the formula,

$$Q = C\,\frac{2}{3}\,\sqrt{2\,g}\left(l\,h_b^{\frac{3}{2}} + L\,h_t^{\frac{3}{2}}\right)$$

in which, l and h_b refer to the length of crest and head, respectively, on the bottom notch; and L and h_t, similarly, on the top notch.

This work was done for the Water Supply Commission of the State of Pennsylvania under the direction and with the assistance of William Easby, Jr., M. Am. Soc. C. E. This type of weir is being used by the State for gauging streams, the low flows being confined to the small weir and the higher flows passing over the two crests.

R. E. BALLESTER,* ESQ. (by letter).—The authors deserve great credit for performing numerous and precise experiments and for the complete care and clearness with which their studies have been described.

* Chf. Engr., Rio Negro Irrig. Works, Fuerte General Roca, Argentine Republic.

The tentative formula:

$$Q = 3.33\, L\left[\left(h + \frac{v_a^2}{2g}\right)^{\frac{3}{2}} + \frac{h}{3.33} \times \frac{v_b^2}{2g}\right]$$

shows that it is almost impossible to frame a general formula that takes into account all the factors that influence the flow of water over a weir, because "if the velocity conditions are unknown it is necessary to make measurements to find the distribution."

With this new series of observations it may be possible to find an expression or formula composed of two quantities, one expressing the characteristics of the weir itself, as to roughness, height, etc., and the other giving the effects of velocity conditions up stream from the weir, instead of including them in the constant, 3.33, as in the Francis formula.

With this in mind, the writer has determined the formula for discharge over a broad-crested weir with a cylindrical up-stream face (Fig. 62(*d*)), and he wishes to present the results of his observations as to the influence of the velocity of approach, and the determination of Bazin's coefficient, α.

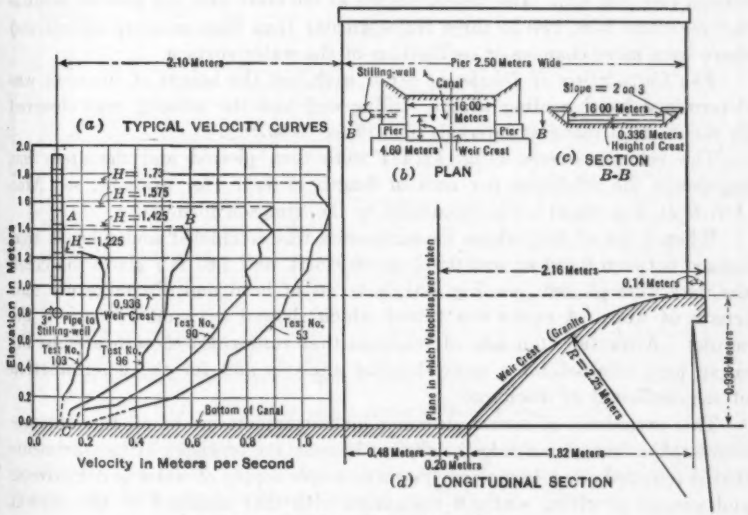

FIG. 62.—SECTIONS OF CANAL AND WEIR.

The weir is located in the main canal of the Rio Negro Irrigation Works, Argentina. Its dimensions are shown in Fig. 62(*b*), (*c*), and (*d*). The channel is lined with concrete for a distance of 200 m. (656 ft.) up stream from the weir. The scale that measures the height of the nappe over the crest is placed in a stilling-well connected with the canal by means of a pipe. This pipe is 3 in. in diameter, reduced at the entrance to 1 in., and placed 4.60 m. (15.09 ft.) up stream from the weir.

Discharge Measurements.—When the Irrigation Service was started, the discharge table was computed by means of the weir formula. The coefficient of discharge was determined from a weir with a crest similar in form to that described in the "Experiments of United States Deep Waterways Board at Cornell University, 1899".*

In attempting to control the distribution of water, some discrepancies were found, so it was decided to make discharge measurements by means of a current meter. The measurements were made by reading velocities all in the same vertical plane. At each point in the plane selected for observation, readings were taken one above the other from 0.10 m. (0.33 ft.) above the bottom of the canal (see Fig. 62).

The current meter used was an Ott Model IV. It was not possible to measure the velocity at the bottom and at the surface and these points were estimated on the curve (see Fig. 62(*a*)). The current meter was rated several times during the measurements, and no appreciable change of the constant occurred.

At first, two vertical planes for measuring velocities were used for each test, one at the vertical face at the crest and the other 2.16 m. (7.09 ft.) up stream (see Fig. 62). The measurements at the crest were not precise, because the velocities were two to three times greater than they were up stream and there were more changes or oscillations of the water surface.

The Calculation of Discharge.—For each test the height at the crest was determined by a reading at the stilling-well and the velocity was observed in the vertical plane at intervals of 0.10 m. (0.33 ft.).

The velocity curves (Fig. 62(*a*)) were then plotted and the area that represents the discharge per unit of length of weir (for example, see Area *A B C D*, Fig. 62(*a*)), was calculated by the Simpson formula.

When a set of forty-three measurements was completed under heads that ranged between 0.282 m. and 0.815 m. (0.926 ft. and 2.67 ft.) above the crest, the data were plotted (see Fig. 63) in terms of head and discharge per unit length of weir. A curve was traced which showed a visual average of the results. After this, ten sets of readings that conformed most nearly to the curve were selected for a more detailed analysis and for the determination of the coefficient of discharge.

This procedure, of course, does not make complete use of all the measurements taken, but it was judged sufficient because the precision of measurements that is required on an irrigation system of ample supply of water is not extreme and greater precision was not consistent with that obtained by the current meter measurements.

No extreme care was taken in measuring the height of water above the crest by means of floats or other devices, but methods were used throughout that were considered adequate for irrigation purposes.

The Coefficient of Discharge.—The general formula used in determining the value, *m*, was:

$$Q = m\,L\,H\,\sqrt{2\,g\,H}\left[\left(1+\frac{a\,h}{H}\right)^{\frac{3}{2}}-\left(\frac{a\,h}{H}\right)^{\frac{3}{2}}\right] \quad \ldots\ldots\ldots (1)$$

* *Water Supply Paper No. 200*, U. S. Geological Survey, Series 19, p. 90.

in which,

Q = discharge, in cubic meters per second.
m = coefficient of discharge.
L = length of weir, in meters.
H = height of water above the crest, in meters.
g = acceleration of gravity (= 9.81 m. (32.18 ft.) per sec.^{2}).
h = velocity head $\left(= \frac{U^2}{2g}\right)$.
α = coefficient to correct the influence of the different velocities in the vertical plane.
U = mean velocity in the canal at 2.16 m. (7.09 ft.) up stream from the vertical face of the crest.

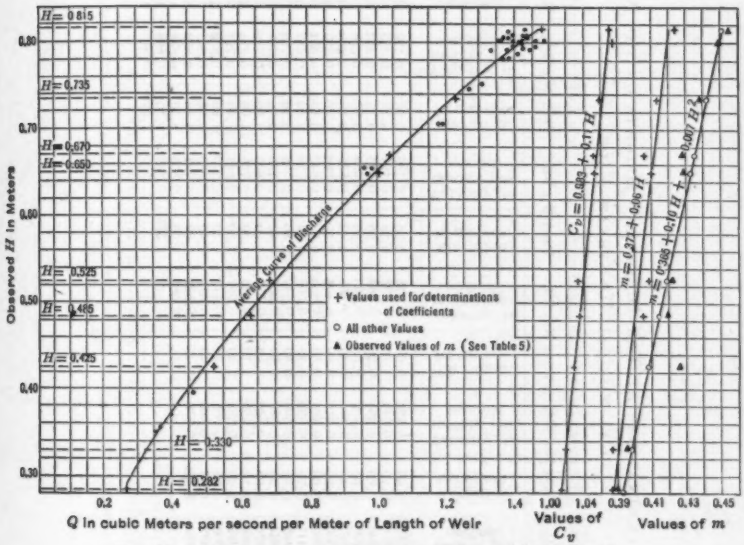

FIG. 63.—CURVES FOR THE DETERMINATION OF COEFFICIENTS.

If all water filaments had the same velocity, U, the kinetic energy would be expressed as $U^3 H$. Considering each water filament as having its own velocity, the corresponding kinetic energy is $\Sigma u^3 \Delta H$. Then,

$$\alpha = \frac{\Sigma u^3 \Delta H}{U^3 H} \quad \ldots\ldots\ldots\

Table 61 shows all the velocities measured in each run. The readings in each test were taken one directly above the other and all tests were confined to the same vertical cross-section plane. The depth, H_1 (Column (3), Table 62), is somewhat different than the elevation from the bottom of the canal (that is: H + height of crest) because at the place were H_1 was measured there was a depression of the water surface. Moreover, the water surface was oscillating, so that it was difficult to take an exact measurement of the depth.

The principal values in Table 62 have been plotted in Fig. 63, as functions of H (height above the crest). The coefficient, C_v, dependent on the velocity of approach, may be represented by a linear function of H with sufficient precision, within the range of measurements. The equation of the curve is,

$$C_v = 0.983 + 0.11\ H \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Columns (15), (16), and (17), Table 62, show that there is sufficient agreement between computed and observed values for practical purposes.

The coefficient of discharge, m, may be also represented by a linear function of H. (See Fig. 63.) This does not mean that it must be necessarily so because the number of observations is not great enough to prove it. The equation of the m-curve in Fig. 63 is:

$$m = 0.371 + 0.06\ H \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

within the range of measurements given.

The results are shown in Columns (20), (21), and (22) of Table 62. Except for $H = 0.425$, in which the percentage difference is 4.6, the variation does not exceed 1.7 per cent. It seemed a good approximation for measurements of discharge by means of a current meter, especially in view of the intended use of the weir, and, therefore, the corresponding values of C_v and m were adopted.

By multiplying these two coefficients a general coefficient, m_1, may be obtained. There is no object in doing this, however, because it obscures the separate effects of velocities of approach and the characteristics of the weir itself. This value will be (see Fig. 63):

$$m_1 = 0.365 + 0.10\ H + 0.007\ H^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The variations of this formula with Francis' simple weir formula:

$$Q = \frac{2}{3}\ \mu\ L\ h\ \sqrt{2\ g\ h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

are given in Columns (25), (26), and (27) of Table 62, in which $\mu = 0.623$.

GARDNER S. WILLIAMS,* M. AM. SOC. C. E. (by letter).—This paper goes a long way toward settling many of the questions that have agitated experimenters dealing with the measurement of water in open channels. In the writer's judgment it is entitled to a place beside the classic experiments of Francis and Fteley and Stearns in this country and those of Bazin abroad, and in precision of measurement it exceeds them all.

To evaluate its position in the series properly it may be well to recall that quantitative knowledge of the flow of water over weirs, before the publication of this paper, was dependent on 93 experiments of Francis made at the

* Cons. Engr., Ann Arbor, Mich.

Lower Locks at Lowell, Mass., in 1852; 41 experiments of Fteley and Stearns, made on the Sudbury Aqueduct, near Boston, Mass., in 1877 and 1878; and 153 experiments of Henri Bazin made at Dijon, France, in 1886. The work of Rehbock, published in 1911, however interesting, was with weirs of such small dimensions as to be hardly entitled to a place with the others, and 86 of Bazin's determinations might be logically rejected on the same ground. However, accepting all those volumetric determinations, they make a total of 287 to be compared with 1 276 made by the authors, and to these may be added the 1 162 additional volumetric measurements made by their collaborators.

The writer, as a result of his own experiments and the study of those of others, came to the conclusion long ago that the then accepted discharges of sharp-edged weirs were likely to be questioned and modified for causes at that time unknown. In preparing for publication the results of his experiments on weirs with irregular crests he expressed the coefficients for them in terms of the discharge of a sharp-edged weir under similar conditions, instead of presenting a coefficient to be introduced directly in the Francis or some other formula.* While he is not entirely sure that there may not be more in the method of reading head than the authors seem to indicate, the writer believes this paper has carried the subject of weir measurement many steps farther toward definite evaluation than anything else done in the past thirty years.

The importance of the protection of a sharp-edged weir from the effects of corrosion was apparently appreciated by Francis whose custom it was to dry the weir crest and coat it with grease at the conclusion of the day's work. Other experimenters do not seem to have been so particular. The determination of the magnitude of the corrosion effects has never been attempted before and, without the very ideal measuring apparatus used by the authors, it could not now have been successfully evaluated.

Perhaps the most interesting and valuable conclusion of the authors is that approving the use of weirs under heads greater than the height of the weir. This will often make the application of the weir as a measuring device much less difficult.

Dr. Ing. Th. Rehbock† (by letter).—Accurate and reliable measurements are among the most important requirements in the field of experimental hydraulics. In the field of practical hydraulic engineering, discharge measurements which are correct within 1 to 2% are entirely satisfactory. In field measurements in time of floods, errors of from 2 to 5% and even more are unavoidable and inconsequential. Stream flow measurements are generally made by means of current meter gaugings, although weirs are sometimes used to gauge the flow of the smaller streams.

Hydraulic Gaugings by Means of Sharp-Crested Weirs.—In experimental work the engineer is confronted not only with the problem of measuring accurately the quantity of water, but, in general, he also faces the problems of regulating the flow in such a manner that a given quantity of water is dis-

* "Hydraulic Tables," by Gardner S. Williams and Allen Hazen, Members, Am. Soc. C. E. Wiley & Sons, New York; and American Civil Engineers' Pocket Book, edited by the late Mansfield Merriman, M. Am. Soc. C. E., Wiley & Sons, New York, N. Y.

† Prof., Technische Hochschule, Karlsruhe, Germany.

charged in a unit of time. Weirs are particularly useful gauging devices in case a predetermined rate of discharge is to be maintained, for it is necessary only to fix the water level above the weir crest at an elevation which can be calculated in advance.

Weir gaugings, because of their simplicity and their accuracy over a wide range of discharge, are better adapted for use in the laboratory than any other method that has been proposed to the present time.

In the writer's opinion, the best weirs for use in field measurements are nearly triangular in cross-section with a sloping down-stream face and with rounded (preferably cylindrical) crest. This type of weir is most satisfactory because it is stable, it is not easily damaged, and its accuracy is not affected by floating material in the water. In the laboratory, however, where the factors just mentioned are of no consequence, the sharp-crested weir is to be preferred because of the greater precision of discharge measurements.

Of the sharp-crested weirs, the rectangular suppressed weir with a horizontal crest, built between vertical side walls, is particularly suitable, if the jet is fully aerated and not affected by back-water. In a few cases the triangular weir (Thomson weir) may be more satisfactory, if very small rates of discharge are to be measured. It has the disadvantage, however, that the head-discharge relation is affected to a certain extent by the shape of the crest and by the size of the approach channel in a manner that cannot be clearly determined.

The discharge over a vertical suppressed weir with a horizontal crest, as shown by experiments at Karlsruhe, Germany, is exactly proportional to the length of the crest. The rate of discharge, q, per unit length of crest is, therefore, merely a function of the two variables, h_0, the head of the weir, and p, the height of the weir crest above the bottom of the approach channel, if the following conditions are satisfied:

(*a*) The velocity in the approach channel should be as nearly the same at all points in a cross-section as practicable.
(*b*) The head should be large enough so that the jet is entirely free and does not cling to the weir plate.
(*c*) The jet should be fully ventilated so that the pressure in the space between the lower nappe and the weir plate is practically the same as that in the open air.
(*d*) The water level below the weir should be so low that the heads are not affected by back-water.

Observations made in the Karlsruhe Hydraulic Laboratory, extending over a period of more than twenty-five years, have shown no measurable fluctuations in the head on a given weir for a given constant rate of discharge, if these conditions were satisfied.

Although widely different coefficients of discharge, μ_0, have been reported by various observers for presumably similar conditions, it is the writer's opinion that discrepancies of this kind are traceable either to inaccuracies in measurements or to unsatisfactory arrangement of the testing equipment. If, for a given constant rate of discharge, fluctuating heads are observed which are not due to errors in measurements, it must be assumed either that eddies that affect the flow are formed in the approach channel, or that the

jet is not properly aerated and the nappe is depressed. The most common cause of disturbances in the flow over a sharp-crested weir, particularly under high heads, is inadequate aeration of the jet. These disturbances occur if the pipes which supply the air below the jet are too small, or if they are partly closed by water. In this case the μ_0-values are too large. It is the writer's experience that a sharp-crested, vertical, suppressed weir with adequate provisions for fully aerating the jet at all times, built between parallel side walls, is the best measuring device for hydraulic laboratories in spite of the fact that the necessity of adequate aeration adds difficulties to the construction of the weir.

The experimental layout should meet the following requirements if accurate measurements are to be assured:

1.—The approach channel should be of sufficient length and of the same width throughout.
2.—The water should enter the approach channel axially.
3.—The approach channel should be elevated high enough above the floor that the necessary measurements can be made easily and accurately, and it should be accessible on all sides so that any leaks in the channel can readily be detected and remedied.
4.—The approach channel should have a horizontal bottom and vertical, plane walls, the latter preferably made of plate glass.
5.—The up-stream face of the weir plate should be a vertical plane. It should have a horizontal crest 0.25 mm. to 1 mm. in thickness.
6.—The ventilation of the space under the jet must be adequate so that the water level above the weir is not affected by partial vacua under the jet.
7.—An auxiliary hook-gauge (with vernier scale) should be provided near the up-stream face of the weir plate to be used in transferring the height of the crest to the master gauge, that is, for determining the "zero reading" of the master gauge precisely.
8.—The master gauge with vernier scale which is used to determine the heads on the weir, should be above the draw-down curve of the water surface, or at a distance above the up-stream face of the weir at least four times the maximum head to be measured. The master gauge may be either a needle-gauge in the approach channel, or a hook-gauge in a special chamber connected with the approach channel.
9.—A sensitive float-gauge should be provided in a chamber built at one side of the approach channel to permit the reading of very small fluctuations of the water surface to fractions of 0.1 mm.

A careful and skilled observer is able to make discharge measurements with a high degree of precision if he has a measuring apparatus which fulfills, substantially at least, the requirements just enumerated, and if he uses a reliable weir formula.

The duties of the observer in making weir measurements are:

1.—To determine the length, b, of the weir crest. An accuracy of 1/2 000 is desirable.
2.—To determine the height of weir, p, above the horizontal bottom of the approach channel. An accuracy of 1/200 is sufficient.
3.—To determine the "zero reading" of the hook-gauge, or that reading for which the point of the hook is at the level of the weir crest. This determination involves the following operations:

(*a*) Bringing the point of the auxiliary hook-gauge to the elevation of the weir crest with the aid of a spirit level, and noting the gauge reading.

(*b*) Bringing the points of the auxiliary gauge and the master gauge simultaneously to a motionless water surface below the level of the weir crest and noting the readings on both gauges.

(*c*) Calculating from these measurements the "zero reading" of the master gauge, or the reading when the point of the master gauge is at the level of the weir crest.

This determination of the zero reading of the principal hook-gauge is of great importance and should be made before and after each series of tests. The precision of every measured head depends on the precision of this measurement.

4.—To determine the head on the weir by the master gauge. The point of the gauge is brought to the surface of the water in the approach channel or to the surface of the water in a chamber at one side which is connected to the approach channel by a pipe. The head, then, is the difference between the gauge reading and the zero reading.

5.—To watch the entire gauging layout very carefully at all times in order to detect any disturbances at once and to remove the causes immediately.

After the zero reading of the principal hook-gauge has been determined, it requires only a fraction of a minute to determine the head on the weir for a given quantity of flow. A skillful observer can soon learn to make these measurements quickly and accurately. Often repeated observations have shown that the heads can readily be measured within 0.1 to 0.2 mm. An exceptionally skilled observer can even, in many cases, check his measurements by repeated observations within 0.05 mm. In the case of larger quantities of flow, however, discrepancies of a few tenths of a millimeter may occur, since the water level does not remain perfectly quiet.

Formulas for Calculating the Discharge Over Sharp-Crested Suppressed Weirs Without End Contractions.—The determination of the head of water on a weir is relatively simple if one has a well-arranged layout and accurate apparatus. On the other hand, the derivation of a reliable and accurate formula for calculating quantities of discharge from these measured heads is very difficult indeed

Since the time of Poleni and Dubuat, who in the Eighteenth Century attempted to solve the problem of flow over weirs, many engineers have spent years of careful study and experiment to determine accurate formulas for the flow of water over sharp-crested weirs. The problem is a particularly difficult one, because the basic experimental work which includes volumetric measurements, must be quite precise, and because an empirical equation with three variables, h_0, p, and q, must be found, which is in substantial agreement with the results of the test.

All well known formulas which have been used in the past are of the type proposed by Poleni and Dubuat, namely:

$$Q = \frac{2}{3} \mu_0 \sqrt{2g}\, b\, h_0^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

This formula is based on the fallacious assumption that water flows through the entire cross-section, $F = b\ h_0$, over the weir crest, whereas the actual cross-section of the jet, because of the draw-down which is equal to approximately 0.15 h_0, is only about $F' = 0.85\ b\ h_0$. In the derivation of this formula a pressure distribution within the jet itself is assumed, which is altogether different from that which exists in the actual jet. The fact that, in the case of a sharp-crested weir, the nappe rises to a point about 0.11 h_0 above the weir crest is neglected entirely. Despite the illogical assumptions on which Formula (7) is based, it is adaptable because all errors in the derivation can be nullified by the proper selection of the discharge coefficient, μ_0. As a consequence it has remained the foundation of all well known weir formulas.

Weisbach attempted to improve the formula by expressing μ_0 as a function of the depth of flow in the approach channel, or, what amounts to the same thing, as a function of the mean velocity of approach. His formula (1844) is of the type:

$$\mu_0 = \mu \left\{ a + b \left(\frac{h_0}{p + h_0} \right)^2 \right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which, μ is the coefficient for a very high weir, and a and b are constants. Most of the weir formulas which have subsequently been proposed are of the Poleni-Dubuat-Weisbach form and differ essentially only in the values of μ, a and b.

The following formulas for μ_0 in terms of h_0 and p, in meters, are those most commonly used in Europe:

Bazin's formula (1888):

$$\mu_0 = \left(0.6075 + \frac{0.0045}{h_0} \right) \left\{ 1 + 0.55 \left(\frac{h_0}{h_0 + p} \right)^2 \right\} \quad \ldots\ldots\ldots (9)$$

Frese's formula (1890):

$$\mu_0 = \left(0.615 + \frac{0.0021}{h_0} \right) \left\{ 1 + 0.55 \left(\frac{h_0}{h_0 + p} \right)^2 \right\} \quad \ldots\ldots\ldots (10)$$

The formula of the Swiss Society of Engineers and Architects (1924):

$$\mu_0 = 0.615 \left(1 + \frac{1}{1\,000\ h_0 + 1.6} \right) \left\{ 1 + 0.5 \left(\frac{h_0}{h_0 + p} \right)^2 \right\} \quad \ldots\ldots (11)$$

The writer's formula (1912):

$$\mu_0 = 0.605 + \frac{1}{1\,050\ h_0 - 3} + 0.08 \frac{h_0}{p} \quad \ldots\ldots\ldots\ldots\ldots (12)$$

The writer had tried in vain for many years to determine a reliable discharge formula of the Weisbach type which agreed with the results of experiments made in the Karlsruhe Hydraulic Laboratory, even on weirs with small values of p and h_0. Formula (12), which was finally proposed, differs from the type presented by Weisbach, but is in close agreement with the writer's tests.

For heads greater than 0.03 m., that is, for practically all cases which are met in practice, this formula can be simplified into:

$$\mu_0 = 0.605 + \frac{1}{1\,000\ h_0} + 0.08 \frac{h_0}{p} \quad \ldots\ldots\ldots\ldots\ldots (13)$$

The differences between the μ_0-values of Formulas (12) and (13) are approximately 0.25% for $h_0 = 0.03$ m., while for $h = 0.04$ m., this discrepancy between the formulas is only about 0.10% and becomes still smaller for higher heads.

Strictly speaking, Formulas (9) to (13) are not dimensionally correct. Some disturbance, which is not yet clearly understood, arises in the case of flow of water over sharp-crested weirs, which adds materially to the difficulties of determining a formula for the coefficient of discharge. In consequence of this disturbance the law of similarity cannot be strictly applied in the case of sharp-crested weirs because the coefficient, μ_0, is not exactly the same for any two sharp-crested weirs of different absolute heights, p, even if the ratios, $\frac{h_0}{p}$, are identical.

The fact that the writer's discharge formula,

$$Q = \frac{2}{3}\left(0.605 + \frac{1}{1\,050\,h_0 - 3} + 0.08\,\frac{h_0}{p}\right)\sqrt{2\,g}\,b\,h_0^{\frac{3}{2}} \quad \ldots\ldots(14)$$

determined from the results of experiments, gives for the metrical system values almost identical with those obtained from the formula,

$$Q = \frac{2}{3}\left(0.602 + 0.0832\,\frac{h}{p}\right)\sqrt{2\,g}\,b\,(h_0 + 0.00125)^{\frac{3}{2}} \quad \ldots\ldots(15)$$

may lead to a possible explanation. A comparison of these two formulas indicates that the disturbance influences the discharge in such a way that the discharge is not directly proportional to the $\frac{3}{2}$ power of the head measured on the master gauge, but rather to that of an effective head which is about 1.25 mm. greater than that actually observed.

L. Prandtl has expressed the opinion that capillarity might be responsible for the form of the second term of Formula (12) and that the behavior may possibly be comparable to the rise of the water surface along a vertical wall, $h' = \sqrt{\frac{K}{\gamma}}$, in which, K is the coefficient of capillarity and γ, the density of the fluid.

Since h' is equal to 0.00267 m., Formula (12) may be changed accordingly to read:

$$\mu_0 = 0.605 + \frac{0.36}{h_0\sqrt{\frac{\gamma}{K}} - 1} + 0.08\,\frac{h_0}{p} \quad \ldots\ldots(16)$$

The values obtained from Formula (16) are only about $\frac{1}{3}$ of 1% less than those obtained from Formula (12) for heads of 0.01 m., and the difference between the formula values does not exceed 0.25% for heads greater than 0.015 m. These discrepancies are meaningless in the case of such low heads and practically disappear at higher heads.

Formula (15) may also be rewritten to take account of the capillarity coefficient, as follows:

$$Q = \frac{2}{3}\left(0.602 + 0.0832\,\frac{h_0}{p}\right)\sqrt{2\,g}\;b\left(h_0 + 0.47\sqrt{\frac{K}{\gamma}}\right)^{\frac{3}{2}} \ldots\ldots (17)$$

It is evident that Formulas (15), (16), and (17) are dimensionally correct, because $\sqrt{\frac{K}{\gamma}}$ is a length.

It is not yet definitely known, however, whether this disturbance is due to capillarity or to some other cause. In any event some phenomena exist which have the same effect on the discharge as a constant increase of head on the weir equal to 1¼ mm.

Formula (15) can be simplified and expressed in second-feet (with sufficient exactness) as follows:

$$Q = b\left(3.22 + 0.445\,\frac{h_0}{p}\right)(h_0 + 0.004)^{\frac{3}{2}}\ \text{sec-ft} \ldots\ldots\ldots\ldots (18)$$

Formulas (9), (10), and (11) have been considered applicable with the following limitations:

(*a*) Formula (9):

$$0.1 < h_0 < 0.6\ \text{m.}$$

(*b*) Formula (10):

$$0.1 < h_0 < 0.6\ \text{m.}$$

(*c*) Formula (11):

$$0.025 < h_0 < 0.8\ \text{m.};\ p \geqq 0.3\ \text{m.};\ h_0 < p$$

Formulas (12) to (19), inclusive, are not necessarily restricted between any given limits. They apply in general to any sharp-crested vertical weir without end contractions as long as the jet is perfectly free, fully aerated, and not affected by back-water. Since a free overfall does not exist for heads less than about 0.01 m., this head is automatically the lower limit of applicability of the formulas. Obviously, the accuracy of measurements with heads so small is not very great.

The formulas are applicable even to weirs of very low height, p, and have been found to agree with the tests of a weir only 0.056 m. high.

These formulas seem applicable, too, for all great heights and large heads in practical use, as long as it is possible to aerate the nappe fully. This may be deduced from the law of similarity. However, the writer advises against building sharp-crested weirs higher than 1.2 m. (4 ft.), for gauging purposes, and using such weirs for heads much greater than 0.6 m. (2 ft.).

If the bottom of the channel below the weir is at the same level as the bottom of the approach channel, the heads, h_0, on the weir should not be much greater than the height of the weir, p, because there is danger of the heads being affected by the back-water in the discharge channel. If the bottom of the discharge is lower than that of the approach, the formulas are in substan-

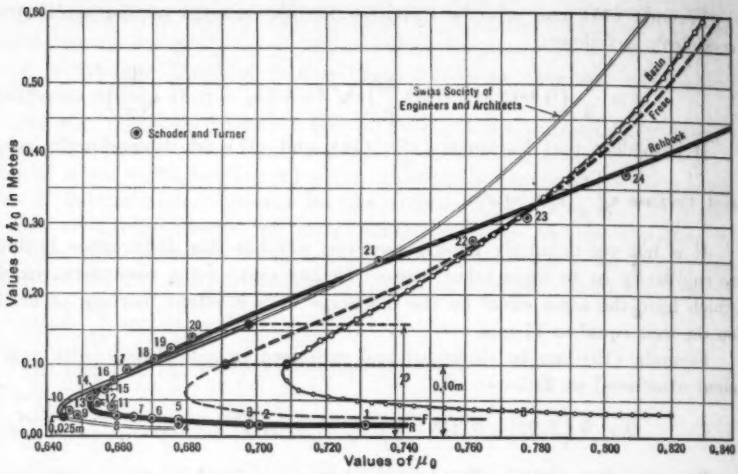

FIG. 64.—μ_0-VALUES FOR WEIRS 0.5 FEET HIGH.

tial agreement with the tests even if the heads are two to four times the weir height and perhaps still more. This may be seen clearly in Fig. 64.

The best agreement between the formulas and tests may be expected, however, if 0.1 m. $< p <$ 1.00 m. and 0.025 m. $< h_0 <$ 0.60 m. Weirs, therefore, should preferably be designed so that the heights and heads, under which they

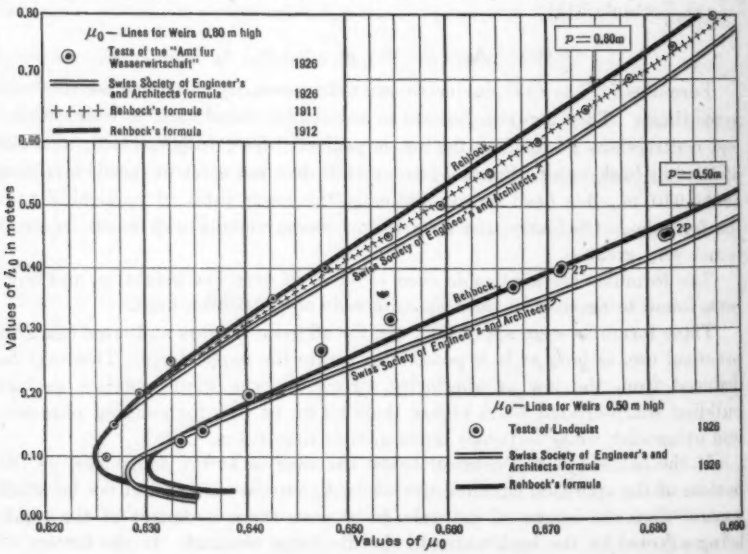

FIG. 65.—COMPARISON OF THE μ_0-VALUES.

will be used, fall between these limits. In general, this can be attained through proper selection of the length of the weir crest. Weirs of ordinary spillway section with a cylindrical crest are to be preferred to sharp-crested weirs if very large rates of discharge are to be measured, for if the discharge over a sharp-crested weir becomes very great, it is difficult to provide adequate ventilation of the jet.

The tests of the Swiss Government Department of Hydraulics have shown that weir measurements for heads of 0.8 m. are still reliable and Fig. 65 shows that the writer's formulas give values differing from these measurements by only fractional parts of 1% up to heads of 0.8 m.

Comparison of Formulas in Use in Europe with Recent Tests.—The writer has restricted himself to a comparison of the four formulas for the flow of water over sharp-crested weirs, which are in common use in Europe (Formulas (9), (10), (11) and (12)). A comparison of the formulas of Francis, Fteley and Stearns, and H. W. King, M. Am. Soc. C. E., which are commonly used in the United States, has not been made.

Relatively few new tests have come to the writer's attention in recent years. Most of them were for only one height of weir and, therefore, did not permit a thorough comparison. Since the publication of the writer's formulas, the only European tests which have come to his knowledge with enough information, so that the μ_0-values could be calculated from the data are those of Fr. Schaffernak, in Vienna, Austria (1915), Erik G. W. Lindquist, M. Am. Soc. C. E., in Stockholm, Sweden (1926), and the Swiss Government Department of Hydraulics (1926). All these gaugings were made with the greatest care, but with different equipment and different rating methods.

Schaffernak published* the results of seventeen measurements for a weir 1 m. long and 0.56 m. high for mean heads lying between 0.0288 m. and 0.3082 m. In these tests only one ventilator pipe with a cross-sectional area of about 5 sq. cm. was provided for aerating the space under the jet. This pipe certainly could not have provided sufficient air for heads greater than 0.2 m. Therefore, only the data for heads less than 0.2 m. may be considered to be correct. The results of these eight tests are shown in Table 63.

The maximum difference between the μ_0-values calculated from Formula (12) and those observed by Schaffernak for heads between 0.0288 m. and 0.187 m., is only 0.0027, or 0.43 per cent. The mean absolute percentage differences of observed and computed values, according to Formula (12), is 0.16.

Lindquist's experiments,† in Stockholm, were made on a weir, 0.50 m. in height, for heads that ranged between 0.124 m. and 0.452 m. (Table 64).

The maximum difference between observed μ_0-values and those of the writer's formula is 0.0042, or 0.64 per cent. The mean of all percentage differences is 0.28.

† Sent to the writer by letter of April 3, 1926.

The measurements of the Swiss Department of Hydraulics, in Berne,* agree equally well with the results of Formula (12). These measurements were made on a sharp-crested weir, 0.8 m. high, at the Amsteg Power Plant, in Switzerland, and the data were given to the Swiss Society of Engineers and Architects to be used in preparing standard specifications for weir measurements.

Mean discrepancy	.....	.....	.....	0.00185	0.28

The mean discrepancy between observed and computed values of μ_0 is 0.25 per cent. The coefficients of discharge reported by the Swiss Department of Hydraulics agree still more closely with the values of μ_0 computed by the writer's earlier formula (1911)†:

$$\mu_0 = 0.605 + \frac{1}{1\,100\,h_0} + \frac{h_0}{12\,p} \qquad (19)$$

* Mitteilungen des Eidgenössischen Amtes für Wasserwirtschaft, herausgegeben unter Leitung von Dr. Mutzner, 1926, No. 18.

† *Zeitschrift* des Verbandes deutscher Architekten- und Ingenieur Vereine, 1, Jahrgang No. 1, 6 Januar, 1912.

The greatest discrepancy between the observations and the results of Formula (19) do not in any case exceed 0.0024, and the mean discrepancy between all observed and computed values is only 0.0009, or 0.14 per cent. A comparison of the μ_0-values of these observations and those of Lindquist with the writer's μ_0-lines for the same heights of weir, is shown in Fig. 65.

A comparison of the coefficients of discharge determined experimentally in Vienna, Stockholm, and Amsteg for different testing layouts, with the corresponding coefficients calculated by Formula (12), shows a maximum discrepancy of 0.64 per cent. The mean discrepancy for the entire thirty-three measurements is only 0.24 per cent.

Referring to the form of the μ_0-lines in Fig. 65, it is noteworthy that the writer, in setting up Formulas (12) and (19), took into consideration only observations for weirs 0.5 m. or less in height and for heads up to 0.18 m. in magnitude for the latter and up to 0.231 m. for the former.

Even if the μ_0-values for larger weir and overflow heights were obtained only by consideration of the law of similitude as a basis, they show a variation of less than 0.25% from the μ_0-values later obtained by the Swiss Department of Hydraulics on weir and overflow heights of 0.80 m.

Experiments were also conducted in the Hydraulic Laboratory at Dresden for the purpose of checking Formula (12), but the details of these tests were not published. A letter from H. Engels, Director of this Laboratory, stated, however, that the agreement of the formula with the experimental results was most satisfactory.

M. Carstanjen* shows discharge curves for two series of experiments made by the late A. Koch in Darmstadt and the corresponding discharge curves according to Formula (12). The experimental and calculated curves lie near together, but the data are not presented in sufficient detail, so that a numerical comparison of the μ_0-values can be made.

In addition to these more recent experimental verifications in the various hydraulic laboratories of Europe, the writer has also a report from Dr. Hahn, of the J. M. Voith Company, in Heidenheim, Germany, that Formula (12) agreed very well with experimental results obtained in the Voith Turbine Laboratory.

The extensive gaugings of the flow over sharp-crested weirs made in recent years by the Swiss Society of Engineers and Architects have not yet been published and, therefore, could not be included in the comparisons which are presented herewith.

The experiments† by Floyd A. Nagler, M. Am. Soc. C. E., for a weir 1.124 m. high, gives μ_0-values still higher than those of Bazin and from 3.6 to 4.9% higher than those of Formula (12). These results show that the hydro-chemical method is not reliable for verifying weir measurements.

Weir Gaugings by Schoder and Turner.—The authors' paper, presenting the results of 2 438 gaugings, is the most comprehensive compilation of the records of gauging of sharp-crested suppressed weirs that has come to the writer's attention. It includes the results of experiments on weirs of different heights, under wide ranges of heads, and is a source of information of inestimable value to the hydraulic experimenter.

After a detailed study of the 1 017 measurements in Series D to P (Table 1), the writer has come to the conclusion that these measurements for weirs of normal height (0.5 ft. to 4 ft.) under normal heads between 1 in. and 2 ft. were made with a particularly high degree of accuracy. For heads less than 1 in. (0.025 m.), the data are somewhat erratic, but this is considered unavoidable because measurements of heads could only be made by means of the float-gauge without a vernier scale and, therefore, could not reach a very great precision.

The accuracy of the data for the weirs, 5.5 and 7.5 ft. in height, is open to some question. If the coefficients of discharge, μ_0, are plotted as abscissas and the corresponding heads, h_0, as ordinates for the weirs of different heights, p, it will be seen that the coefficient of discharge for a given head decreases regularly as a function of the height for weirs measuring 4 ft. or less. However, some of the coefficients of discharge for weirs 5.5 and 7.5 ft. high are greater than those for the weir 4 ft. high under the same heads. It is wholly unreasonable to think that, for a given head, h_0, the coefficient of discharge becomes greater when the weir height is increased because the velocity of approach must become increasingly slower.

The erratic behavior of the data for the weirs, 5.5 and 7.5 ft. in height, is at once traceable to the construction of the approach channel shown in Fig. 6.

* Koch-Carstanjen, "Von der Bewegung des Wassers und den dabei auftretenden Kräften", Berlin, 1926, Julius Springer Verlag, p. 156.

† "Verification of the Bazin Weir Formula by Hydro-Chemical Gaugings," *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 105.

The surface of the fixed bottom of the approach channel over the 30-in. supply pipe appears to be only about 5 ft. below the weir crest, while the movable bottom near the weir lies below this level during the tests of the two highest weirs. Undoubtedly, the disturbance arising from this type of construction changed the flow in such a way that the "effective" height of the weir was actually much less than the height measured from the crest to the bottom of the approach channel near the weir. The fact that the data for the 5.5 and 7.5-ft. weirs (Series D, K, L, M, and O, Table 1) are obviously unreliable is, however, of little importance, because sharp-crested weirs more than 4 ft. in height are almost never used in practice.

The writer also feels that the accuracy of the data for heads greater than 0.5 to 0.6 m. (1⅔ to 2 ft., and more) is also questionable. There are disturbances in the law of similarity at low heads, but these are barely perceptible if the head on the weir is about 0.3 m. (1 ft.), and they disappear almost entirely at higher heads. If the μ_0-values of Schoder and Turner for high heads were correct some new disturbance must occur which makes the coefficients of discharge increase suddenly if the head is greater than about 2 ft. This is hardly to be expected and is not borne out by the experiments of the Swiss Government Department of Hydraulics which have been summarized in Table 65 and Fig. 65.

The most common cause of such abrupt changes in the discharge coefficient-head relation at the higher heads is insufficient ventilation of the space between the jet and the weir plate. Whether the sudden divergence of the authors' measurements from the $\mu_0 h$-curve, which is nearly straight, is chargeable to insufficient ventilation, or to some other cause, cannot be stated definitely without having at hand more detailed information concerning the arrangement of the testing layout.

If the measurements for heads greater than 0.6 m. (2 ft.) are neglected and the formulas are applied only to heads less than 2 ft., as Bazin and Frese have recommended, the comparison still covers nearly the entire practical range of heads, which is generally used for sharp-crested weirs.

The coefficient of discharge, μ_0, in Formula (7) was calculated for each of the Schoder and Turner gaugings for all heads between 0.01 m. and 0.60 m. These μ_0-values are compared with the corresponding μ_0-values determined by Formulas (9) to (12), inclusive. Figs. 66 to 71 show graphically the comparison of the observations for weirs ¾, 1, 1½, 2, 3, and 4 ft. high, respectively, as found by Formulas (9), (10), (11), and (12). (See, also, Fig. 64.) The limits of the formulas, as given by their respective authors, are shown by black points. Beyond these limits the curve of the formula is shown only by lighter lines.

These diagrams show that, in all cases, Formula (9) gives much higher values of discharge for a given head than the Schoder and Turner tests indicate. Formula (10) shows a somewhat better agreement, but all the values are still too high. Formula (12) shows the best agreement with the results of the authors' experiments. Formula (11) also agrees quite well with the

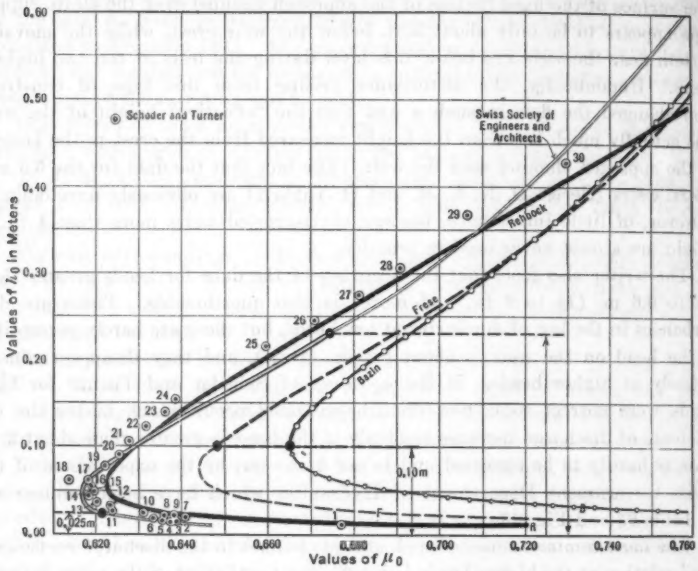

FIG. 66.—μ_0-VALUES FOR WEIRS 0.75 FOOT HIGH.

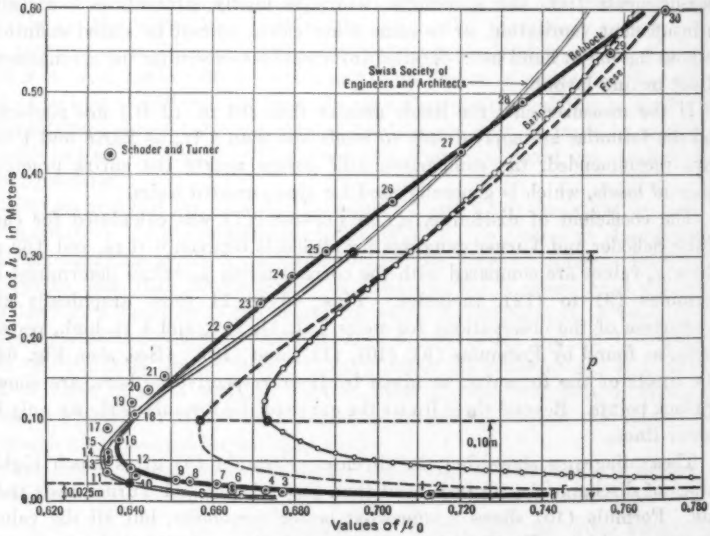

FIG. 67.—μ_0-VALUES FOR WEIRS 1.0 FOOT HIGH.

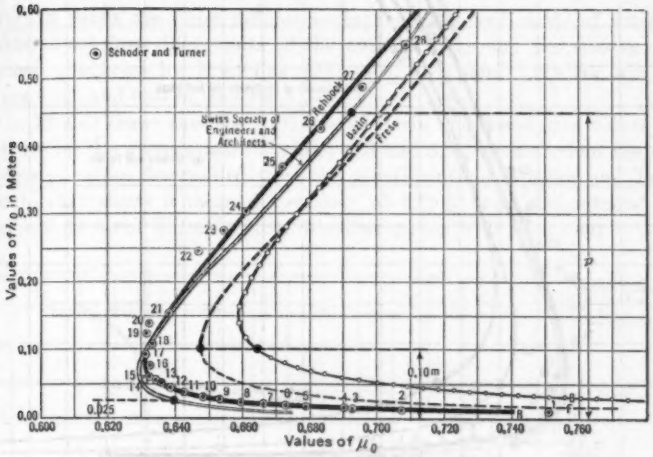

FIG 68.—μ_0-VALUES FOR WEIRS 1.5 FEET HIGH.

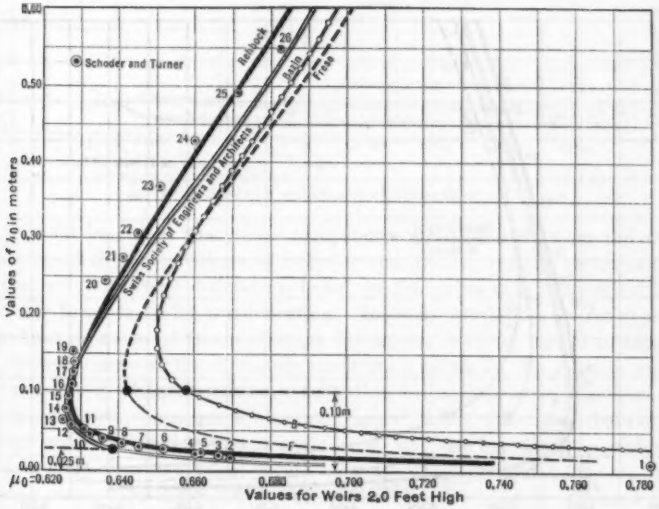

FIG. 69.—μ_0-VALUES FOR WEIRS 2.0 FEET HIGH.

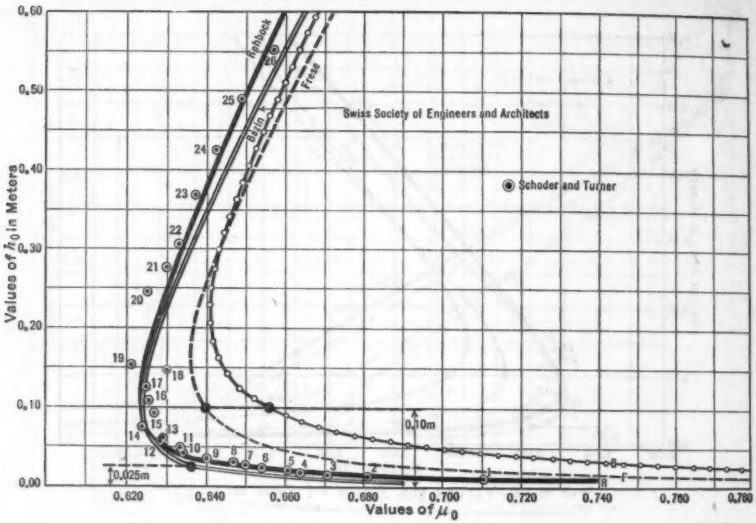

FIG. 70.—μ_0-VALUES FOR WEIRS 3.0 FEET HIGH.

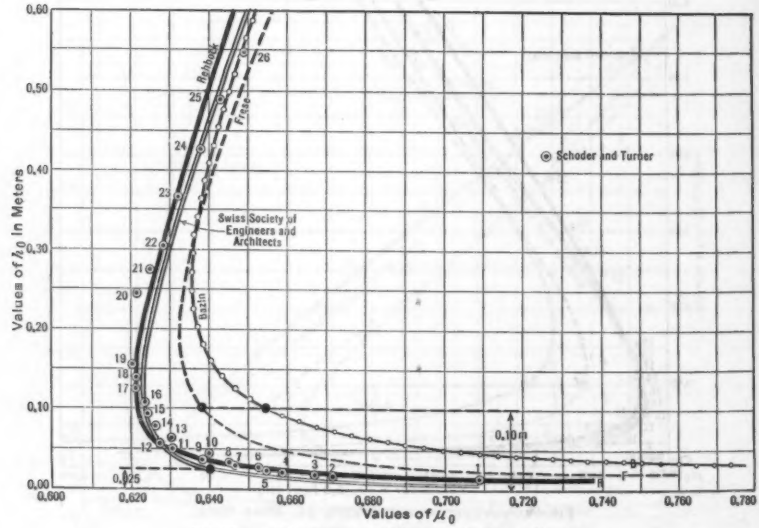

FIG. 71.—μ_0-VALUES FOR WEIRS 4.0 FEET HIGH.

experimental results, but shows mean differences nearly twice as large as those from the writer's Formula (12).

Fig. 72 shows the mean differences between the coefficients of discharge, μ_0, determined from the results of the authors' tests and the corresponding μ_0-values calculated by Formulas (9), (10), (11) and (12) for all heads between 0.025 and 0.60 m. and for $h_0 < 2\,p$.

Fig. 72 also shows that the formulas of Bazin and Frese give values of μ_0 which are on the average approximately 6.3 and 3.2% greater than the corresponding μ_0-values determined from the experiments of Schoder and Turner. Formula (11) shows a mean discrepancy of 0.70% from the authors' tests, while, in the case of Formula (12), this discrepancy is 0.38 per cent.

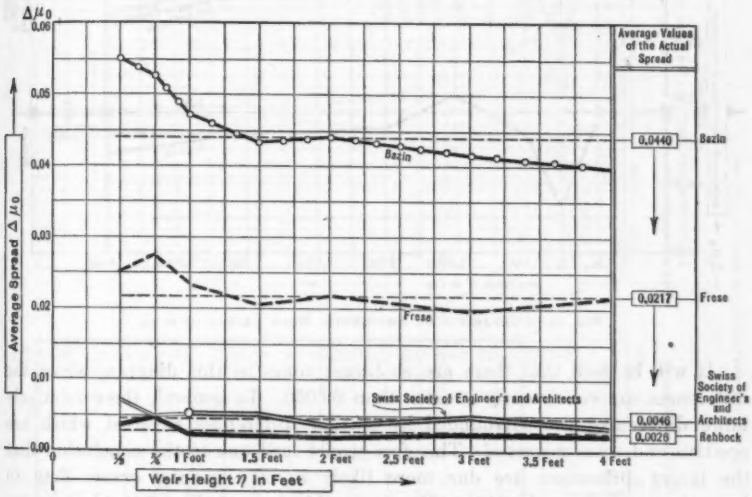

FIG. 72.—COMPARISON OF AVERAGE VALUES OF Δ μ_0.

It should be stated that the discrepancies mentioned between the several formulas and the observations of Schoder and Turner are the mean values of the absolute percentage differences based on the value of μ_0 according to the particular formula under consideration. In other words the figures represent the arithmetic mean of the percentage deviations, without regard to algebraic sign, between each of the discharge coefficients given by the authors and the corresponding discharge coefficients according to the respective formulas.

Fig. 73 shows the average absolute values of the differences between the observations of Schoder and Turner and the corresponding μ_0-values of Formula (12) for very small heads between 0.015 m. and 0.025 m. on the different weirs. The difference for these small heads of nearly the same height is the arithmetic average of the μ_0-values. These differences are small and reach only 0.0023, or 0.33 per cent.

Fig. 74(*a*) shows the differences between the coefficients of discharge determined from the test data of Schoder and Turner, Schaffernak, Lindquist,

and the Swiss Department of Hydraulics and the corresponding coefficients calculated by Formula (12). The magnitude of the differences is indicated by the symbols shown in the legend (Fig. 74(*d*)). It is noteworthy that nearly 50% of all the differences are less than 0.0025 and that more than 75% are less than 0.0050. With one exception the differences which exceed 0.010 are only for heads less than 0.02 m.

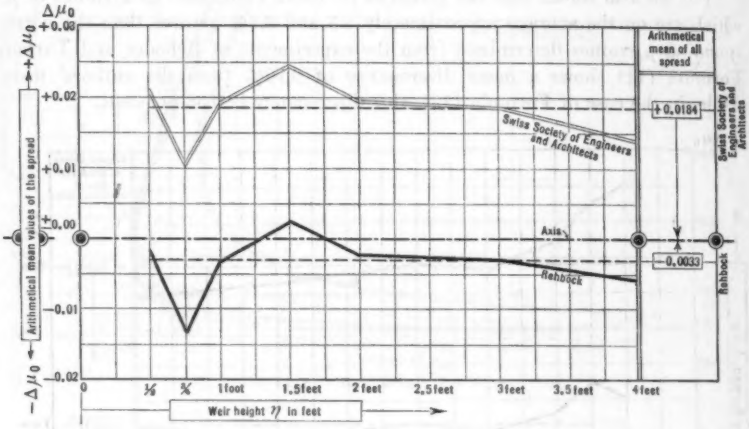

FIG. 73.—COMPARISON OF ARITHMETIC MEAN VALUES OF Δ μ_0

It will be seen that there are no larger zones in this diagram where the differences are consistently greater than 0.0050. In general, these relatively large differences are surrounded by smaller differences some of which are positive and some negative. This fact would lead one to the conclusion that the larger differences are due more likely to experimental errors than to inexactness of Formula (12). The heavy black line (Fig. 74(*a*)) indicates the field usually covered by weir measurements.

From Fig. 74(*b*) it is possible to determine the effect of an error of 0.0001 m. in measuring the value of the head, h_0, on the corresponding value of μ_0.

Slight irregularities in the magnitude of the velocity of approach to the weir as they occur in a normal channel do not have a material influence on the coefficient of discharge as long as the cross-section of the approach channel is the same throughout its entire length and as long as the flow is in an axial direction. Schaffernak conducted two series of experiments on weirs, one with and the other without screens in the approach channel and found that, although the velocity distribution was quite different in the two cases, the coefficients of discharge differed not more than by 0.2 per cent. The close agreement between coefficients of discharge as determined from the tests made in Amsteg, Karlsruhe, Ithaca, N. Y., Stockholm, and Vienna, each with different testing installations, would seem to indicate also that slight irregularities in the velocity of approach have little effect on the results. Large

FIG. 74.—COMPARISON OF THE μ_0-VALUES.

variations in the magnitude of velocity and the direction of flow in the approach channel, however, as they can be produced by baffles which are improperly placed, or by abrupt changes in the section of the approach channel, may have an appreciable effect on the accuracy of the results, as the Schoder and Turner tests with baffles showed. Such installations should be avoided.

Soon after presenting Formula (12) in 1912,* the writer stated,† that this formula might be expected to give reliable values of the discharge coefficient, μ_0, for sharp-crested, suppressed weirs "within 0.005 of the correct value for heads down to 0.02 m. and perhaps even to 0.015 m.", and that this limit of 0.005 "will not be exceeded for heads up to 0.5 m. to 0.6 m. and probably not even for larger heads if the nappe is beyond question fully ventilated and not affected by back-water."

The expectations of the writer thus expressed in January, 1913, seem to have been justified by the experiments of Schoder and Turner and by those of the other experimenters referred to in this discussion. If the observations of Schoder and Turner, of Schaffernak, of Lindquist, and of the Swiss Governmental Department of Hydraulics are correct, the mean discrepancies between the discharge computed by Formula (12) and the actual discharge will hardly exceed 0.2 to 0.3 per cent.

Formula (12) has the advantage, over the other formulas in use, of agreeing more closely with experimental results, of being simpler to use mathematically, and of having practically no limits to its applicability.

While the writer has attempted to show in the foregoing that his formula for flow over sharp-crested weirs is in substantial agreement with the results of precise measurements and that rates of discharge may be calculated with ample accuracy from properly measured heads, he does not intend to convey the idea that the errors in discharge measurements with sharp-crested weirs will always or even generally lie between 0.2 to 0.3 per cent. These limiting accuracies can be attained in general only under the most favorable laboratory conditions, with excellent apparatus, and by an experienced observer. In general, the limits of error may lie between 0.5 and 1 per cent. These bounds should not be exceeded under reasonably favorable conditions.

In presenting the results of their comprehensive series of experiments on the flow of water over sharp-crested weirs the authors have rendered the Engineering Profession a most valuable service. They are deserving of the gratitude of all who are working in the field of hydraulic engineering. The data on their own experiments, together with the data of numerous other experimenters at Cornell University, are most valuable contributions to the literature on the subject of weir measurements.

The writer wishes to express his thanks to F. Theodore Mavis, Assoc. M. Am. Soc. C. E., Kenneth C. Reynolds, of Cambridge, Mass., and Karl Grein and Th. Musterle, of Karlsruhe, for their assistance in calculating the coefficients of discharge from the Schoder and Turner data and from the four formulas quoted, and to Professor Mavis for his translation of this discussion from the German.

* Handbuch der Ingenieurwissenschaften, dritter Teil, 2. Band, 1. Abteilung, Leipzig 1912, p. 58.

† *Zeitschrift* des Verbandes Deutscher Arch. u. Ing. Vereine, 1913, Nr. 1.

ERIK G. W. LINDQUIST,* M. AM. SOC. C. E. (by letter).—This interesting and valuable paper shows that the distribution of velocity in the channel on the up-stream side of a sharp-crested weir has a great influence on the discharge. On the basis of their experiments, the authors have derived a formula,

$$Q = 3.33\ L \left[\left(h + \frac{v_a^2}{2g} \right)^{\frac{3}{2}} + \frac{h}{3.33} \times \frac{v_b^2}{2g} \right]$$

(*D*), the application of which requires a knowledge of the distribution of velocity in the approach channel.

This formula does not seem to have a correct theoretical basis. The first term in the parenthesis is of the dimension, $L^{\frac{3}{2}}$, while the second has the dimension, L^2, and is not "of the nature of a volume", since the coefficient, 3.33, has the dimension, $L^{\frac{1}{2}}$. Such dimensionally incorrect formulas should be avoided as they can only express the result obtained with a particular experimental arrangement, which usually cannot be duplicated by other experimenters. In spite of the fact that, in most cases, the Schoder and Turner tests show a very irregular distribution of velocity, a theoretical treatment of them shows to some extent the influence of the factors involved.

Consider, first, a perfect fluid (frictionless and not affected by molecular forces, such as surface tension) under the influence of gravity and flowing over an infinitely high, vertical weir, with a horizontal and sharp crest. Since no other forces are considered as acting, the stream lines are parallel and have the same energy content. The factors determining the discharge are the acceleration of gravity and the head above the crest.

The ratio, $\frac{Q}{L}$, can be found, with the aid of dimensional analysis, to be,

$$\frac{Q}{L} = \phi \sqrt{2g}\, h^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

Combining this with the formula,

$$Q = \frac{2}{3} \mu L \sqrt{2g}\, h^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

which is derived by the usual method of integrating the elementary discharges of the sheet, the value of ϕ is found to be,

$$\phi = \frac{2}{3} \mu \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

For a sharp crest, the coefficient, ϕ, can be shown to be mathematically equal to 0.407. The discharge coefficient, μ, is thus 0.611.

Under these assumptions, μ has a constant value for all heads. If the weir is not infinitely high, μ can no longer be constant, but must vary with the height of the weir and the head. Indicating the height of the weir as w, the head as h, and the velocity head as k, μ must be a function of the ratios, $\frac{h}{w}$, $\frac{k}{h}$, or $\frac{h}{h+w}$. Theoretically, μ must be a constant when $w = \infty$, and

* Research Engr., Hydr. Structures Laboratory, Royal Tech. Univ., Stockholm, Sweden.

equal to 1 when $h = \infty$, or when $w = 0$. From these considerations it is evident that it is not sufficient to assume that,

$$\mu = m + n\frac{h}{w} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

since μ would then become ∞ when the height of the weir is very small in comparison with the head. The expression, $\frac{h}{h+w}$, satisfies the theoretical conditions.

For a perfect fluid, the velocity head is,

$$k = \frac{v^2}{2g} = \frac{Q^2}{L^2 (h+w)^2 2g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

and combining Equation (24) with Equations (20) and (21), the resulting ratio is,

$$\frac{k}{h} = \phi^2 \left(\frac{h}{h+w}\right)^2 = \frac{4}{9}\mu^2 \left(\frac{h}{h+w}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Therefore,

$$\mu = f_1\left(\frac{k}{h}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Considering now a real fluid (viscous, adhesive, and having a certain surface tension) flowing over a weir of finite height, the energy content of the different stream lines is not the same, due to the viscosity. For this reason, two weirs having the same value of $\frac{h}{h+w}$ will show the same value of μ only when the distribution of velocity is the same at the sections at which the head is measured. If these distributions are determined by the viscosity alone, they can be similar only when the values of the Reynolds' number are the same. This criterion of similarity is the product of the mean velocity in the section, a length characterizing the section, and the reciprocal of the kinematic viscosity.

Thus,

$$E = \frac{v\ l}{\nu} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

The length can be chosen as the hydraulic radius, $R = \frac{A}{P}$, giving,

$$E = \frac{1}{\nu}\frac{Q}{A}\frac{A}{P} = \frac{1}{\nu}\frac{Q}{P} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

In this case, P, the wetted perimeter, is, $L + 2(h+w)$. Hence,

$$E = \frac{1}{\nu}\frac{Q}{L + 2(h+w)} = \frac{1}{\nu}\frac{Q}{L}\frac{1}{1 + 2\left(\frac{h+w}{L}\right)}$$

Among other things, the Reynolds' number is dependent on the width and height of the weir and the operating head. Consequently, μ must be a function of E and the complete expression is

$$\mu = F\left\{\frac{k}{h}, E\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

Experiments to determine the loss of head in smooth pipes and the resistance of thin smooth plates, towed through still water, have shown that the Reynolds' number enters the resulting equation as $f\left(\frac{1}{E}\right)$ rather than as $f(E)$, showing that at high speeds or large dimensions the viscosity does not affect the magnitude of these quantities. Hence, for practical cases, where L and w are usually large, the influence of the viscosity can be neglected. However, it must be stated that this conclusion only holds true when the type of flow is turbulent. For very low heads on high weirs, laminar flow may occur, causing a change in the conditions.

In most cases met in practice, the distribution of velocity in the cross-section at which the head is measured, is determined chiefly by other forces or arrangements than the viscosity and is not governed by any known mechanical law. To take into account the influence of the distribution of velocity on the discharge, the relation between the velocity heads as computed from the mean velocity may be compared with the mean kinetic energy of the individual stream lines or mass elements.

Considering a mass element, $d\,m$, flowing through a cross-sectional area, $d\,A$, with a velocity, v_y,

$$d\,m = \rho\,d\,A\,v_y \quad \ldots\ldots (30)$$

the velocity head is,

$$d\,k = \frac{\rho\,d\,A\,v_y\,v_y^2}{2\,g} \quad \ldots\ldots (31)$$

and for the whole cross-section, the kinetic energy is,

$$\frac{\rho}{2\,g}\int_0^A v_y^3\,d\,A \quad \ldots\ldots (32)$$

The mean velocity at the section is,

$$v_m = \frac{\int_0^A v_y\,d\,A}{A} \quad \ldots\ldots (33)$$

and the total mass flowing through the section is,

$$m = \rho\int_0^A v_y\,d\,A \quad \ldots\ldots (34)$$

Hence, the mean velocity head is,

$$k_m = \frac{\rho}{2\,g}\,\frac{\left[\int_0^A v_y\,d\,A\right]^3}{A^2} \quad \ldots\ldots (35)$$

The ratio between these differently computed velocity heads is,

$$\delta = \frac{A^2\int_0^A v_y^3\,d\,A}{\left[\int_0^A v_y\,d\,A\right]^3} \quad \ldots\ldots (36)$$

As δ is not a constant, but varies from case to case, a further condition arises, namely, that,

$$\mu = \phi\,\{\delta\} \quad \ldots\ldots (37)$$

Neglecting the influence of purely viscous flow, the relation thus far discovered is,

$$\mu = \psi\left[\frac{k}{h}, \delta\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38)$$

When the distribution of velocity is determined by the viscosity alone, δ must be a function of E.

In the Schoder and Turner experiments, the value of δ, computed on the basis of the curves for the vertical element at mid-stream, varies as follows:

Series	E, Run 53 to 57	1.07
"	I, Run 54 to 58	1.08
"	I, Fence 1	1.60
"	I, Fence 3	2.08
"	D, Run 101 to 105	1.80
"	D, L, M (Fig. 46)	2.0

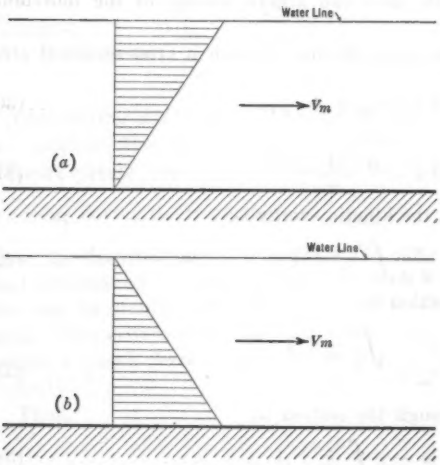

FIG. 75.

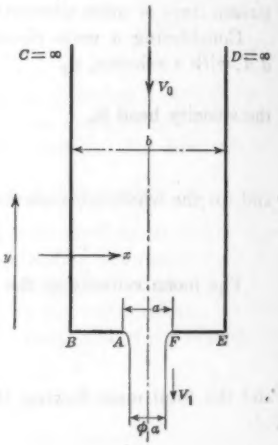

FIG. 76.

However, the question arises as to whether δ completely determines the influence of the velocity distribution on μ. Imagine, for instance, two distribution curves with the same value of δ and with the same mean velocity, but with different surface and bottom velocities, as shown in Fig. 75. It seems possible that the μ-values will differ. In order to find other factors determining the μ, consider another problem capable of being treated mathematically, namely, the discharge of a fluid through a very long rectangular orifice in the bottom of an infinitely high basin (Fig. 76).

Assume that the flow is the result of an external pressure, p_0, on the surface instead of the force of gravity. Under the assumption that viscosity is not affecting the flow, the stream lines are parallel at infinity and have the same energy content.

From Bernouilli's theorem,

$$p_0 + \rho \frac{v_0^2}{2} = p + \rho \frac{v^2}{2} \quad \ldots\ldots (39)$$

in which, p and v are the pressure and velocity at any point and ρ is the density of the fluid. At some point beyond the orifice, the stream lines are parallel and have the same velocity, v_1, which the outer stream lines have had since leaving the orifice, because the surface of the jet is under constant pressure. Hence,

$$p_0 + \rho \frac{v_0^2}{2} = \rho \frac{v_1^2}{2} \quad \ldots\ldots (40)$$

If q is the discharge per unit length and ϕ is the coefficient of contraction (see Fig. 76),

$$q = v_0 b = \phi a v_1 \quad \ldots\ldots (41)$$

In order to find an expression for computing ϕ apply the law according to which the change in momentum between the initial and final sections is equal to the forces acting. The change in momentum is $\rho q (v_1 - v_0)$, and the forces are due to the pressures, p_0, and the pressures on the walls. These latter pressures may be denoted by $\int p \, dx$ and $\int p \, dy$. The integration is to be made over the entire boundaries and the differentials have the following values:

		dx.	dy.
Stretch	A-B	—	0
"	B-C	0	+
"	D-E	0	—
"	E-F	—	0

Hence, from symmetry,

$$\rho q (v_1 - v_0) = p_0 b + \int_A^F p \, dx \quad \ldots\ldots (42)$$

Combining Equation (42) with Equations (39), (40), and (41), and simplifying, the result is,

$$\phi = \frac{1}{1 + \sqrt{1 - \frac{a}{b} + \frac{a}{q^2} \int_A^F v^2 \, dx}} \quad \ldots\ldots (43)$$

From Equation (43), it seems that the contraction coefficient depends on the velocity of flow along the walls approaching the orifice. The pressure on this face will decrease as the velocity increases. If the value of the integral is known it is possible to compute the value of the coefficient.

This analysis has been made by assuming an ideal fluid not acted upon by gravity. According to experiment, with gravity acting, the fluid filaments are sensibly parallel a short distance outside the orifice and, hence, this factor has only a slight effect on the path of flow. As for the motion of the fluid within the basin, it is immaterial whether the flow is assumed to take place under the action of gravity or a constant pressure.

The presence of fluid friction in a real fluid does not materially change any of the conclusions drawn from Equation (43).

If a vertical weir in an open channel is assumed to be one-half the basin just considered, with the height, $\frac{b-a}{2}$, and the head, $\frac{a}{2}$, it is necessary to measure the pressure on the face of the weir to determine the total effect of the velocity distribution on the value of μ. As such measurements have not previously been made in connection with measurements of the coefficient it is not possible to fix the total influence of the distribution.

The molecular forces may affect the discharge of a sharp-crested weir in one of three ways: First, either by adhesion, causing the nappe to cling to the crest, and giving the effect of its being rounded; second, by the surface tension acting on the surfaces of the sheet and giving a force in the same direction as the force of gravity, thereby causing an increase in the vertical acceleration of the discharge; and, third, by a combination of the other two.

If the rounding of the crest may be considered as constant for all heads, its influence will be greater at lower than at higher heads and the relation may be written,

$$\mu = f\left(\frac{\varepsilon}{h}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

in which, ε is the radius of the crest caused by the adhesion. The effect of the surface tension may be taken into account by using the expression,

$$\mu = \chi\left(\frac{T}{\rho\, g\, h^2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

in which, T is the surface tension and $\rho\, g$ is the weight per unit volume. This function can be found by the aid of dimensional analysis.

The influence of the molecular forces may be illustrated by Figs. 77 and 78, which show the same discharge over a sharp-crested weir, 700 mm. high, made of brass. The writer's experiments have shown that there will be no discharge over such a weir when $h = 0.0026$ m. When $h = 0.0028$ m., the discharge begins. If this is slowly increased, the sheet will cling to the face until the head is 0.059 to 0.062 m., when it will become free. By touching the sheet, or by introducing air below it, it can be freed when $h > 0.0105$.

Within this range it is possible to make the sheet cling by means of a board, etc. By slowly lowering the head, the sheet will remain free until $h = 0.010$. It will begin to cling at some point below this head and is always clinging at $h = 0.0088$ m. At heads greater than 0.062 m., the sheet will be free. These values are for a water temperature of 11° cent.

The writer's studies have shown that the coefficient of discharge, μ, is a function of the dimensionless quantities, $\frac{k}{h}$, δ, $\frac{\varepsilon}{h}$, and $\frac{T}{\rho\, g\, h^2}$, and that it will have the same value when each of the ratios is the same simultaneously.

With respect to the conditions expressed in Equation (38) the writer has studied the function and the value of δ by plotting known experimental values in a diagram, with μ as the ordinates and $\left[\mu\frac{h}{h+w}\right]^2$ as the abscissas. For

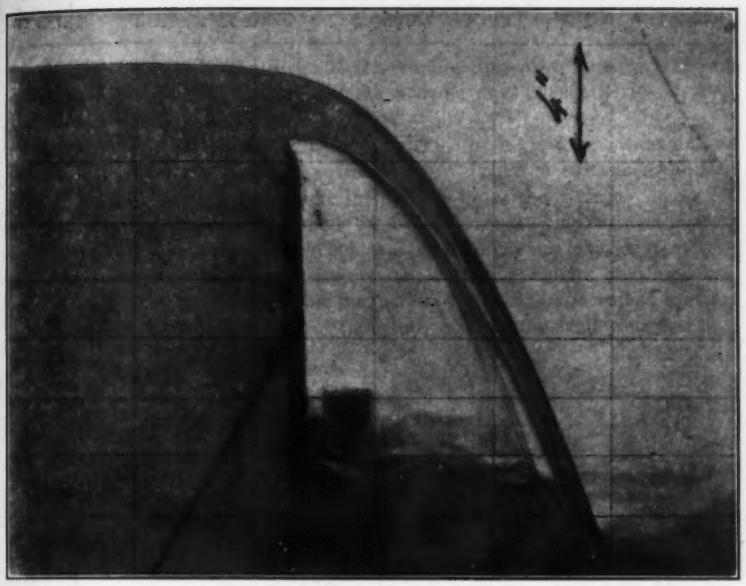

FIG. 77.—DISCHARGE OVER SHARP-CRESTED WEIR, $h > 0.0105$.

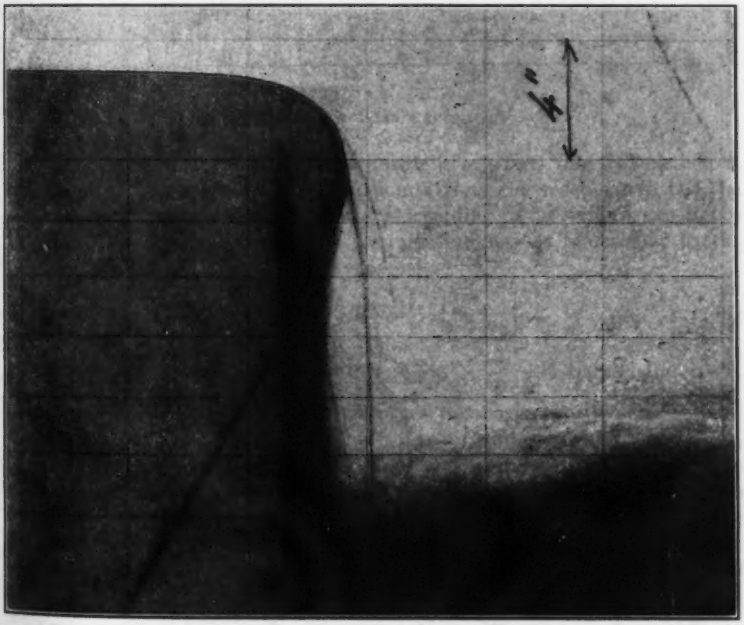

FIG. 78.—DISCHARGE OVER SHARP-CRESTED WEIR, $h < 0.0105$.

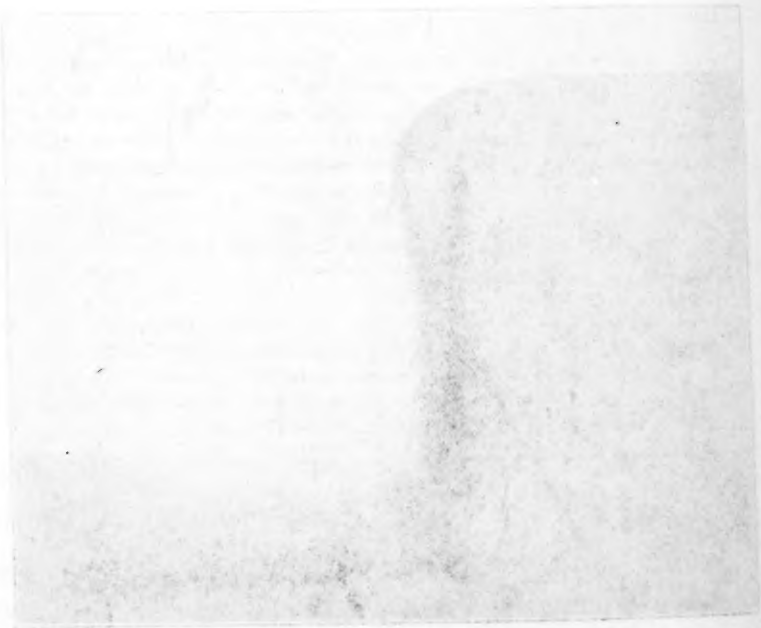

this purpose the tests by the Swiss Hydrographic Bureau at Amsteg,* Bazin's experiments Nos. 5, 7, 9, and 10, and the Schoder and Turner Series D to O, have been chosen.

In the experiments at Amsteg the weir was 0.8 m. high, 3.0 m. wide, and its distance from the draft-tube of the Amsteg plant was 23 m. Between the weir and the turbines thirteen racks were installed to quiet the surface.

The Bazin experiments were made in a channel 2 m. wide, using the same weir crest. The channel of approach was 44 and 95 m. long, respectively, measured below a calibrated, sharp-crested weir, the height of which was 1.135 m. The known fact that the Bazin tests give discharge values that are too high, does not affect the value of this study because the same weir was used as an indicator of the discharge.

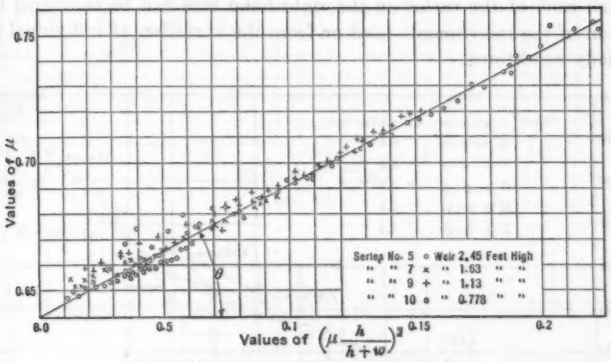

FIG. 79.—BAZIN'S WEIR EXPERIMENTS.

Fig. 79 shows that the Bazin experiments give points that fall close to a straight line. The divergence of the points from the mean curve may be attributed to the experimental error, which according to the writer's experience affects the third decimal place. The average line may be represented by the formula,

$$\mu = 0.640 + 0.515 \left[\mu \frac{h}{h + w}\right]^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (46)$$

The computed value of δ is, therefore, $0.515 \times \frac{9}{4} = 1.16$. These results show that the distribution of velocity has been regular and fairly similar in all the experiments.

Before studying the Schoder and Turner tests in the same manner as those of Bazin, it is first necessary to examine the experiments on high weirs (Table 1), particularly the Series D, J, K, L, M, and O, respectively, as to the relation between values of μ, the head, and the distribution of velocity. Fig. 80 shows that these series give the same value of μ within the limits of the probable experimental error.

* Communications du Service des Eaux, No. 18, "Contribution à l'étude des méthodes de jaugeage".

The authors do not indicate the probable errors of the experiments in spite of the great assistance that such a computation gives for judging the reliability of experimental results. The formula for determining the error is obtained by taking the partial differential of Equation (21) which gives,

$$\frac{\delta Q}{Q} = \frac{\delta \mu}{\mu} + \frac{\delta L}{L} + \frac{3}{2}\frac{\delta h}{h} \quad \ldots\ldots\ldots\ldots\ldots\ldots (47)$$

Since,

$$Q = \frac{\text{Volume}}{\text{Time}} = \frac{V}{T}$$

the error is given by,

$$\pm \frac{\delta \mu}{\mu} = \pm \frac{\delta V}{V} \mp \frac{\delta T}{T} \mp \frac{\delta L}{L} \mp \frac{3}{2}\frac{\delta h}{h} \quad \ldots\ldots\ldots\ldots (48)$$

in which each of the ratios on the right-hand side can be estimated from the precision of the instruments used or from the variation of individual readings for steady conditions.

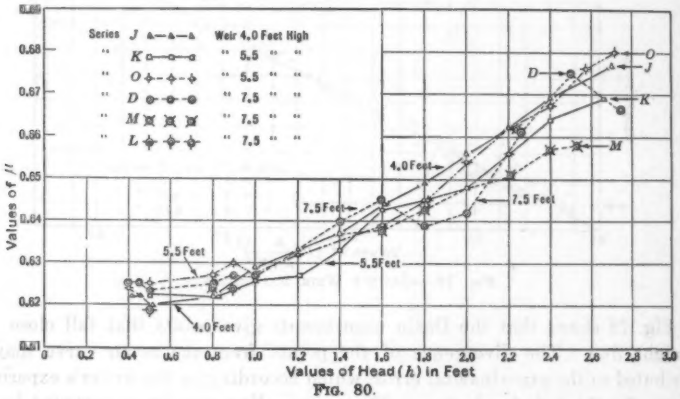

FIG. 80.

Comparing the distribution diagrams for the Series D, K, L, M, and O with those for Series J, it is found that, upward from a point 4 ft. below the crest, the diagrams are fairly similar and that below this point the depth has very little effect on the currents. From these experiments, it seems to the writer to be quite impossible to make a decision as to the applicability of any formula, since the results are so greatly influenced by the experimental arrangements used by the authors.

The Schoder and Turner Series E, F, and N are shown in Fig. 81. It will be noted that the points can be represented by a straight line, the slope of which is θ. In the lower range of the abscissas, the points diverge from this line by increasing amounts as the abscissas decrease. The three series of experiments give the formulas:

Series E and F,

$$\mu = 0.621 + 0.57\left[\mu \frac{h}{h+w}\right]^2; \ \delta = 1.28 \quad \ldots\ldots\ldots (49)$$

Series N,

$$\mu = 0.621 + 0.54\left[\mu\frac{h}{h+w}\right]^2;\ \delta = 1.21 \quad \text{.....(50)}$$

and the mean curve is,

$$\mu = 0.621 + 0.56\left[\mu\frac{h}{h+w}\right]^2$$

The greater the angle, θ, for any series, the larger will be the value of δ. This is illustrated in Fig. 82, representing the Schoder and Turner Series G, H, I, and K, and the experiments of the Swiss Hydrographic Bureau at Amsteg.

The Schoder and Turner Series G, H, and I can be represented fairly well by the formula,

$$\mu = 0.621 + 0.61\left[\mu\frac{h}{h+w}\right]^2;\ \delta = 1.37 \quad \text{.....(51)}$$

and the Swiss series can be as represented by Equation (50).

In this discussion it has been assumed that the experimental values can be represented by the formula,

$$\mu = 0.621 + \theta\left[\mu\frac{h}{h+w}\right]^2 \quad \text{.....(52)}$$

Equation (52) will give $\mu = 1$ for $w = 0$, only when $\theta = 0.379$; and it is, therefore, limited in its application. As there are no experiments on low weirs under very high heads, it is necessary to find the proper form of the equation in another manner.

TABLE 66.—Comparison of Coefficients of Contraction.

Ratios, $\frac{a}{b}$, corresponding to $\frac{h}{h+w}$	Values of ϕ According to:	
	Mises' computations.	Writer's formula, Equation (53).
0.0	0.611	0.611
0.1	0.612	0.612
0.2	0.616	0.616
0.3	0.622	0.622
0.4	0.633	0.633
0.5	0.644	0.645
0.6	0.662	0.663
0.7	0.687	0.687
0.8	0.722	0.721
0.9	0.781	0.774
1.0	1.000	0.941

For the ideal flow through an orifice, such as discussed herein, Professor Mises, of Berlin, Germany, has computed the values of the coefficient of contraction by means of conformal transformations. His values (see Table 66) can be closely represented by the empirical formula,

$$\phi = 0.611 + 0.33\left[\phi\frac{a}{b}\right]^2 \quad \text{.....(53)}$$

The agreement between the values found by Mises and those given by Equation (53) (which was derived on the assumption that the relation between ϕ and $\left[\phi \frac{a}{b}\right]^2$ is a straight line) shows, that under ideal conditions this type of formula is applicable if the highest values of ϕ near the limit, $\phi = 1$, are not considered.

On account of this agreement and the foregoing results the writer believes that the type of formula, Equation (52), for sharp-crested weirs, fits its purpose well.

The influence of the molecular forces is expressed by the relation,

$$\mu = \phi \left\{ \frac{\varepsilon}{h}, \frac{T}{\rho g h^2} \right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (54)$$

The form of the function is not known. As the μ diverges from the straight line representing the formula for higher heads, the effect of the molecular forces may be determined by subtracting the μ given by Equation (52) from the observed value.

$$\mu_{\text{Remainder}} = \mu - 0 \left[\mu \frac{h}{h + w}\right]^2 - 0.621$$

Plotting these values against the head gives, in foot-pounds,

$$\mu_{\text{Remainder}} = \frac{0.0007}{h^{\frac{3}{2}}}$$

which represents the results of Schoder and Turner Series E, F, G, H, J, and N (see Fig. 83).

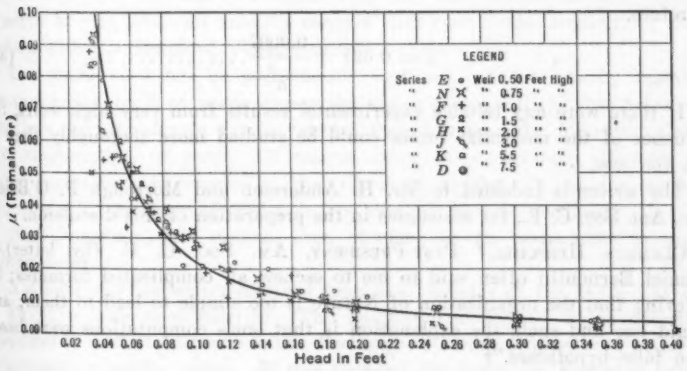

FIG. 83.

Since μ is a number, the numerator, 0.0007, has the dimensions, $l^{\frac{3}{2}}$, including the surface tension, T, which, in common with other factors, depends on the temperature.

On the basis of the Swiss, Bazin, and the Schoder and Turner tests, the formula for computing the discharge coefficient for a sharp-crested weir is,

$$\mu = 0.621 + \theta \left[\mu \frac{h}{h + w}\right]^2 + \frac{0.0007}{h^{\frac{3}{2}}} \quad \ldots\ldots\ldots\ldots\ldots (55)$$

or

$$\mu = \frac{1}{2\,\theta}\left(\frac{h + w}{h}\right)^2 \left\{1 - \sqrt{1 - 4\,\theta\left(0.621 + \frac{0.0007}{h^{\frac{3}{2}}}\right)\left(\frac{h}{h + w}\right)^2}\right\} \quad \ldots (56)$$

in which, θ has the following values,

Schoder and Turner Series E and F	0.57
" " " " N	0.54
" " " " G, H, and J	0.61
Swiss Series, Amsteg	0.54
(Bazin's Series Nos. 5, 7, 9, and 10	0.515)

The formula is rather complicated, but for practical use it can be represented graphically.

When the head on the weir is low, the velocity of approach has very little influence on the μ-value. Assuming, then, 0.001 as an upper limit for the error, ignoring the velocity head term and making $\theta = 0.55$ and $\mu = 0.62$, the resulting relation between the head and the height of the weir, at which the velocity of approach can be neglected, is:

$$\theta \left[\mu \frac{h}{h + w}\right]^2 < 0.001 \quad \ldots\ldots\ldots\ldots\ldots\ldots (57)$$

Hence,

$$\frac{h}{w} < 0.07$$

The formula for computing the μ-value at low heads, less than 0.07 w, is, therefore,

$$\mu = 0.621 + \frac{0.0007}{h^{\frac{3}{2}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

If there were any reliable experimental results from very high weirs, the influence of the molecular forces could be studied more thoroughly than is now the case.

The writer is indebted to Mr. H. Andersson and Morrough P. O'Brien, Jun. Am. Soc. C. E., for assistance in the preparation of this discussion.

CLEMENS HERSCHEL,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—"Daniel Bernouilli often said to me to eschew all complicated formulas; he believing that the organization of Nature is too simple to lead to them; and should one find such, the explanation is that one's computations were based upon false hypotheses."†

"These things are beyond all use,
And I do fear them."‡

* Hydr. Engr., New York, N. Y.

† R. Wolf, "Biographies Relating to the History of Civilization in Switzerland," 1860, Vol. III, p. 176 (in French).

‡ Shakespeare, "Julius Caesar," Act II, Scene 2.

In reading the paper, and the learned discussions upon it, the question is likely to arise in the mind of a thoughtful hydraulic engineer:

"What is to be the outcome of so much labor, toward serving the profession in its work? Is there any use in it all? What is or should be a weir? Should it be the tool of an engineer, or is it a laboratory instrument, on which to found experiments and computations, and diagrams, and the laborious setting up of formulas to encompass these experiments? Should not an engineer, of all professions, constantly keep utility in view? And, surely, is not simplicity a measure of utility?"

Of course, every one knows the argument that science can not be fettered by considerations of utility; that science must be pursued for science's sake, and motives of utility must be rigorously banished; leading, as a possibly fine example, to the work of the German professor who spent a life time in translating the Latin classics into ancient Greek. But are such considerations properly presentable to engineers? Are not in these days, as many and more inventions and discoveries made by those who directly and specifically seek them, as by those who blindly grope and experiment, even though they do happen occasionally to lay the foundation for the utilitarian work of others?

Consider then, that a notable part of the work of a hydraulic engineer is to measure the flow of water, as he meets with it in his practice. This will include the flow of water in pipes, and in natural channels of a much larger size, such as rivers; and but little else. For the case of pipes a meter has been in existence since 1887, applicable alike to pipes ¼ in., or an unlimited number of feet (17 ft. actually in use) in diameter, the discharge formula of which is expressed in the simplest of terms, and is usually made to record its results automatically. The writer has lately seen a ponderous diagram proving once again that its record is correct, and in this particular case, that it coincides with the results found by the "salt velocity method"; or, as it might be put, "the salt velocity method" has been found accurate by comparison with the Standard Venturi meter.

The meter need not be permanently installed. A temporarily installed Venturi meter, built of wood, except the throat-piece, will in most cases cost less than the long drawn out operations made necessary by following almost any other method of work. Of course, there are exceptions, although not many, generally to be covered by the Gibson, or by the salt velocity method; but, as a rule, the sharp-crested weir has long ago become needlessly laborious in itself; needless, and useless, even obsolete, as an instrument to meter flowing water.

Not long ago the writer received from the Director of the Delta Barrage, in Egypt, a little book entitled, "The Discharge of Pipes", which described experiments made to determine the discharge of forms of pipe used in Egypt to measure irrigation water. It was founded, no doubt, on Egyptian habits, apparently in vogue since the time of the Pharaohs; but this little book, to the mind of the writer, is a good parallel to present-day dissertations on weirs and weir formulas. Their use seems to him to be as much out of date for metering water, as that of the forms of pipe used presumably for thousands of years past in Egypt, for the same purpose.

This is the age of machinery and mechanisms, as compared with ages of manual and mental work in the past. Offices are already filled with computing machines, typewriters, dictaphones, cameras, and what not besides; similarly, much mechanical work of the hydraulic engineer in the field can be replaced by the work of meters and their recording mechanisms. Take the case of the operation of the Aquedotto Pugliese, in Italy, which in its work of keeping what was nigh a desert, a flourishing district, uses 400 Venturi meters; or take New York's main water supply, that has three 17-ft. meters and more than seventy of smaller size.

To resume the consideration of weir formulas: Let any one look at the collection of such in the paper:

$$\mu_0 = 0.605 + \frac{1}{1\,020\,h_0 - 3} + 0.08\,\frac{h_0}{d_0}$$

for the value of one term to be used in computing according to the formula that contains it; and ask himself the question: Whether this is not the case of "a poor sport that is not worth the candle".

The defects of all weir gaugings are not new matters for the consideration of hydraulic engineers; and it is both startling and discouraging to find how the present paper and discussion have completely ignored what was said on the subject by Floyd A. Nagler, M. Am. Soc. C. E., in 1918* and by the writer in 1920,† and the reader will wonder at the dilatoriness with which progress is made in the practical advance of the art of the hydraulic engineer.

As regards the paper† last referred to, it must be remembered that the experiments were made in an hydraulic laboratory, whose use, including installation of apparatus and its removal, of necessity counted only twenty-three days. They consisted of devising a more rational form of weir than the classic sharp-edged weir; together with an attempt to measure "head on the weir" with "correction for velocity of approach" automatically compensated for; and resulted in finding a weir the formula of discharge of which was:

$$Q = 5.50d \text{ (English measures)}$$
$$Q = 1.675d \text{ (metric measures)}$$

The exactitude of this result has been questioned by a group of students in the University of California; but merely to have made an approach to such a result, is already a great advance in the art. Naturally, the apparatus used, the first of its kind, is capable of palpable improvements; and should meet with them at the hands of the next experimenters on the "hollow crest weir". This has been since May, 1920, repeatedly expressed to inquiring friends, and for future possible service an extract from one such letter follows:

"I have learned of the very great importance of having the piezometer holes in the crest tube bored precisely at a right, or a proposed angle to the '2:1 slope'.‡ And I regret to state that this direction of bore was not done

‡ *Transactions*, Am. Soc. Mech. Engrs., Vol. 42 (1920), No. 36, p. 205.

with a mechanical direction of the boring instrument, but made only with direction guided by hand and eye, in case of the weir I built in Boston. There were also too many of these piezometer holes, so that one cannot now tell which hole or holes prevailed, and the precise angle at which it or they were bored.

"I believe, were I in position to repeat the experiments, I would follow the 'original intention'* and have only one piezometer hole—certainly not more than three. This would surely lead to a hollow crest weir, having a straight line formula. Whether it would also prove the same, to have the piezometer hole, or holes, at right angles to the 2:1 slope, I cannot now affirm.

"Another point: Referring to Figs. 4 and 5,† you will notice the lack of any and all test, in the true sense of the word, of an idea; the idea being, to correct mechanically—by the way the observations are taken—for 'velocity of approach'. I still think this apparatus is good, and that the idea has value."

To summarize:

(1) As the late Frederic P. Stearns, Past-President, Am. Soc. C. E., expressed it,‡ "in the present state of the art the weir is not an accurate instrument for the measurement of water"; and no improvement in its use has been made, since that was written.

(2) The weir, and especially the sharp-crested weir, is, or should be, grossly obsolete so far as cost, convenience, and time-saving in its use to meter water are considered.

(3) Experiments upon its discharge, and setting up of involved formulas to portray with more or less precision their results will not remove these defects; nor are they of use to the practicing hydraulic engineer.

Ernest W. Schoder,§ M. Am. Soc. C. E. (by letter).—The discussions supply a kind of international symposium of opinion on the sharp-crested weir as a precise measuring device. The Engineering Profession is particularly indebted to those who have discussed the paper, have contributed valuable additional experimental data, have made original analyses of the data given in the paper, or who have made searching comparisons of old and new data. The discussions merit much intensive study and consideration, and the writer feels certain that due credit will be forthcoming as soon as the engineering public has had the opportunity of weighing the various arguments advanced.

It seems unfortunate that about 1890 a combination of circumstances started the idea that a precision for estimated weir discharge within 1% of the truth was readily obtainable. This idea has persisted to a surprising extent, due largely to the tendency of human nature to focus attention on and remember vividly the occasional close agreements while relegating to the "scrap pile of unexplained divergences" the numerous more scattered results, although the latter are often quite consistent among themselves. The writer heartily approves Mr. Parshall's comment that "much work remains to be done". Although the paper with the discussions is a contribution toward the desired end, the second conclusion‡ of the late Frederic P. Stearns, Past-

§ Prof. of Experimental Hydraulics, Cornell Univ., Ithaca, N. Y.

President, Am. Soc. C. E., to which Professor King has called attention, may well serve as a guide: "That the art should be developed so that the causes of the variation in results may be discovered and eliminated". Both Mr. Herschel and Professor King quote also the first conclusion* of Mr. Stearns: "That in the present state of the art the weir is not an accurate instrument for the measurement of water."

It will not be amiss to invite every one making use of weir measurements to study carefully some curves presented by Mr. Stearns† in discussing another paper. In his remarks he calls attention to the wide divergences between the results of the several experimenters, amounting to fully 5% at 0.5-ft. head. Figs. 27, 28, and 29, and Fig. 49, of the paper give similar information.

If the data by Professor Pardoe had been available to Mr. Stearns, or to the writers, an even wider range of results would be indicated. For all ten heights of weir, from $y = 0.1$ to $y = 2.3$ ft. (see Fig. 59), Professor Pardoe's experimental coefficients are markedly lower than those found by Rehbock's formula (which is itself the lowest on Mr. Stearns' Fig. 25†); for instance, at 0.2-ft. head the coefficients are from 10.9 to 1.4% lower, and at 0.7-ft. head, from 8.0 to 1.3% lower. (See Table 67.) The writers and the discussors have explained several causes of differences, but it still seems necessary to seek the full explanation. No single authority has enough data at his command to enable him to classify definitely the reasons for all these departures. It is time that some international co-operative researches are undertaken.

* See Fig. 59.

Professor Rehbock shows by Figs. 64 to 74 that his formula fits very closely nearly all the "regular" runs (those with fairly uniform distribution of velocities in the approach channel) of the writers' Series D to P on weirs 4 ft. and less in height and for heads of not more than 2 ft.; and that this is the case also for several other sets of data of more limited extent. Professor Rehbock has stated that:

"Slight irregularities in the magnitude of the velocity of approach to the weir as they occur in a normal channel do not have a material influence on the

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 172.
† *Loc. cit.*, p. 170.

coefficient of discharge as long as the cross-section of the approach channel is the same throughout its length and as long as the flow is in an axial direction."

This conclusion seems to be justified. Two important questions, however, are involved: (1) What magnitudes of irregularities are permissible for particular limits of precision? and (2), how can one be certain of approximately "normal" distribution without measuring the velocities?

True, in many laboratories, permanent fixed baffles can be set by trial so as to give satisfactorily uniform distributions of velocities throughout a considerable range of heads. For such conditions an easily applied formula like Rehbock's (after being thoroughly tested) is obviously preferable to one involving additional measurements and more extended computations, such as in the writers' Formula (*D*). However, there is something to be said against an idolatrous acceptance of formulas of the rigid type like those of Bazin and Rehbock. Even in a laboratory, if the discharge through carefully adjusted baffles is increased beyond the ordinary operating range (and what experienced experimenter has not desired and striven at times to extend the usual limit?), the nature of the distribution of velocities in the approach channel is likely to change more or less abruptly. Then, one must either undertake re-adjustment of the baffles to secure, by laborious trials, a proper distribution for the new higher heads, or one must abandon the non-conforming formula for one more adaptable.

Moreover, the principles involved are not limited to a refined laboratory weir. In some cases for temporary weirs used in field or plant tests, and usually for dams in rivers, it may be out of the question to exercise much control over the channel of approach. If the bottom of the channel is sloping or otherwise irregular; if the pond becomes filled with gravel, sand, or silt; if the contractor has left (as is quite common) part of his coffer-dam to be submerged and forgotten (except by the approaching water); if a water-logged boat or any sort of jetsam prevents normal bottom velocities; if an ice cover or high winds up streamward retard normal surface velocities; if a flood of unprecedented magnitude appears on the scene; in such cases, the engineer, who desires the most accurate estimates possible, will make all the necessary measurements to portray conditions as they are, and then will select or devise a formula to suit. The writer grants that, for the utmost precision, it is desirable to control the alignment of the sides and bottom up stream and that it is necessary to prevent major cross-currents. Nevertheless, there arise many cases in which expediency demands that the conditions be accepted considerably short of the ideal. If doubt exists as to the distribution of velocities, measurements must be made and, when made, the data for Formulas (*B*) or (*D*) are available, practically irrespective of any extremes that may be found.

An interesting illustration is at hand. Professor Rehbock comments on the irregularity of the coefficients for the writers' 5.5 and 7.5-ft. weirs, in that the coefficients in instances are higher for the same head than for the 4-ft. weir. Then, after agreeing with the writers in the explanation that the obstruction caused by the deflector hood over the 30-in. supply pipe retards the velocities that would occur near the bottom of a normal channel, thus reducing the

"effective" height of the weir to a figure less than the apparent height, Professor Rehbock characterizes the data for the 5.5 and 7.5-ft. weirs (Series D, K, L, M, and O, Table 1) as "obviously unreliable". Of course, he means "unreliable" for a formula involving the height of the weir. The writer wonders what Professor Rehbock would do if forced to deal with cases in which the effective height is less or greater than the measured height. As for the statement that sharp-crested weirs more than 4 ft. in height are almost never used in practice, that certainly does not apply to many cases on record in engineering literature. At Cornell University sharp-crested weirs that are much higher have been and are being used.

Next, Professor Rehbock questions the accuracy of the data for heads greater than $1\frac{3}{4}$ ft. because there are disturbances to the law of similarity, in that the coefficients of discharge increase rather suddenly if the head is greater than about 2 ft. It requires only a short examination of the distributions of velocities as shown in Figs. 39, 40, 44, and 45, for one to become convinced that the ratio of the velocity above the crest level to the mean velocity was greater for the highest heads than for the medium heads. In short, the law of similarity required some modification to suit the facts of the case. The explanation ventured by Professor Rehbock that possibly the ventilation under the overfalling nappe was insufficient, does not apply to the writers' apparatus. The atmosphere had free access to the space beneath the nappe.

It seems to the writer that the real reason why a formula, such as Equation (14), may have to be limited to heads less than 2 ft. and heights of weir less than 4 ft. lies in the probable insufficient length of channel of approach for cases outside these dimensions. The law of similarity, in its simplest geometric demands, would require a much longer channel for high heads than for low heads (for a fixed height of weir); and, also, a longer channel for a high weir than for a low weir (for a fixed head). Strictly, the requirements of axial flow and of fairly normal distribution of velocities should be met at a cross-section far up stream from the weir, as, for example, a distance of about six to ten times the total depth of water. For a head of 2 ft. on a weir 4 ft. high, making a total depth of 6 ft., perhaps a length of 36 ft. would satisfy most requirements; but a head of 4 ft. on a weir 6 ft. high would then require a length of 60 ft., subject to a sufficiently effective system of baffles for the greater velocities.

The apparatus used by the writers obviously falls short of such requirements, but the data are not, therefore, lacking either in accuracy or reliability. The measurements of heads and discharges apply, not to idealized conditions, but to the particular velocity conditions placed on record in the paper. The writers purposely went to extremes in the matter of causing abnormally high and low velocities both near the surface and near the bottom. None of the discussors has questioned the marked effect of these abnormally non-uniform distributions, and, apparently, the writers' conclusion still stands, that "no visual inspection could distinguish between discharges that differ as much as 4 or 5% at the same head due solely to different distributions of velocities in the channel of approach."

The experiments described by the writers receive the approval of Mr. Streiff. Comparing them with those of Professor Rehbock, he states:

"Professor Rehbock's experiments should be placed in a different class. These [Rehbock's] are 'indoor' experiments, conducted on such a small scale that this latter circumstance may easily introduce results that are 1% or 2% too small".

In this connection it is interesting to abstract parts of a communication received from Professor Rehbock in April, 1928. He stated that the latest measurements made by the writers, as well as by the Swiss Government Department of Hydraulics and by Professor Lindquist, do not support any contention that the discharges computed by the Rehbock formula are 1% or 2% too small.

Professor Lindquist made 10 measurements which, on the average, were only 0.01% greater than that computed by Equation (14), and, for 15 Swiss measurements, the average was 0.2% greater. Furthermore, he states that the average for the 137 measurements made by the writers for normal approach, for heights of weir between 0.5 ft. and 4 ft. and for overflow heights between 0.8 in. and 2 ft., gives a value that is 0.16% less than the average as determined by Equation (14). Therefore, the values determined by use of this Rehbock equation are considered to be slightly greater than the average of measurements made by the writers rather than 1% or 2% less; that is, for weirs of "ordinary heights". According to Professor Rehbock, values for such unusual weir heights as 5.5 ft. or 7.5 ft. must be eliminated from the comparison because the crest of the weir was only about 5 ft. above the floor which was formed by the top of the deflector hood about 13 ft. up stream from the place where the head was measured in the writers' experiments. The use of such relatively great weir heights, according to Professor Rehbock, gave discharge values by Equation (14) that were much too small. He has been led to conclude from the latest measurements, previously mentioned, that his Equation (12) gives values for μ that are correct within a few thousandths.

Mr. Streiff states further that Table 59 "shows the tendency of the Rehbock formula to be on the small side and the Swiss 'S. I. A. V.' ('Schweizerische Ingenieur und Architekten Verein'), formula is shown to check more closely than that of Rehbock". In his letter, Professor Rehbock agrees that the measurements made at Amsteg are greater, but only by a very small amount which averages 0.2% more than the values determined by Equation (14). He states, however, that values computed by Equation (14) agree better with the Amsteg measurements than those computed by the formula of the Swiss Society of Engineers and Architects. He submits Table 68 to support this statement. It shows that the Rehbock differences in Column (8) are less than the S. I. A. V. differences (Column (6)), in twelve of the fifteen cases listed. In the mean value of the deviations listed, the S. I. A. V. mean is 1.7 times as great as the Rehbock mean.

From these and other observations, Professor Rehbock concludes that, despite occasional statements to the contrary, the weir is a well-qualified instrument for measuring the flow of water accurately. This view, he states, has been corroborated by numerous recent calibrations of sharp-crested weirs,

especially those of Professor H. Engels, at Dresden, Germany, J. M. Voith, at Heidenheim, Germany, Professor Lindquist, at Stockholm, Sweden, Professor Schaffernack, at Vienna, Austria, The Swiss Federal Department of Hydraulics, at Berne, Switzerland, Engineer J. Th. Thysse, at Delft, Holland, and the experiments conducted by the writers at Ithaca, N. Y. Experiments by all these authorities give results which Professor Rehbock declares check within a few thousandths of the values computed by Equation (12). In brief, Professor Rehbock states that,

"All these newer measurements show convincingly that sharp-crested suppressed weirs, with aerated jets, are exceedingly accurate devices for measuring flowing water, if only a sufficient aeration of the jet is allowed, if the free approach of the water is not disturbed by built-in structures, if the overflow height is determined with sufficient accuracy, and if an accurate formula for computing the discharge from the width of weir and height of overflow, is used."

It seems to the writer that this statement of the chief features of a high-class measuring weir leaves too much uncertainty as to what is meant by the terms, "free approach" and "sharp-crested", and that it falls short in failing to mention the proved effect of variations in the roughness of the up-stream face of the weir near the crest.

It is obvious that Professor Rehbock depends on strict geometric and hydraulic similarity when he extends the formula derived from his small-scale measurements to much greater heights of weir and heads, expecting estimates of discharge within less than 1 per cent. Consequently, for such pre-

cision, it seems highly important to the writer that every influence known to affect the discharge even a small fraction of 1% should be pointed out clearly.

Any engineer called upon to make a precise estimate of discharge by weir measurement (having first to construct his weir), should recognize the magnitude of the percentage effects corresponding with various departures as, for example, from strict smoothness of the up-stream face of the weir plate, strict sharpness of the square up-stream edge of the crest, and from "normal" distribution of velocities in the channel of approach. To illustrate, if the head is 1 ft., and use is made of a formula like that of Professor Rehbock which assumes a fairly uniform distribution of velocities with, say, 2.1 ft. per sec. for mean velocity above the crest level, when actually it is 2.0 ft. per sec., then an error of almost 1% in estimated discharge will result.

Professor Rehbock exhibits a remarkably close agreement with his formula by several experimenters. By inference it would seem to be true that good systems of baffles (in rectangular channels with fairly smooth sides and bottom) cause nearly similar distributions of velocities. Nevertheless, the writer thinks that engineers will not be freed entirely from scruples until ample direct evidence of similarity of velocity conditions is submitted. It is pertinent to point out again that Professor Rehbock omitted the data of the writer's highest heads in making his comparisons. The writer feels that Mr. Streiff is justified (even if not because of the extension from small-scale experiments to large-scale predictions) in his feeling that some "circumstance may easily introduce results that are 1% to 2% too small" (or too large). In brief, it must be known positively that both the construction of the weir and the condition of the approaching water are similar before one can expect agreements within 1 per cent.

Professor Nagler presents experimental evidence in Table 58 to the effect that the ratio of ϵ to h was the same (0.108), for his own sharp crest and for Bazin's corresponding weir (by interpolation). No evidence is presented showing the effects on this ratio of various degrees of rounding the edge of the crest, but the effect of increasing the roughness of the up-stream face of the weir is shown to decrease the ratio. It does not seem at all conclusive to the writer that the agreement in ratios proves that Bazin's crest piece had a strictly sharp edge, or that the up-stream face was similar in smoothness to the "standard sharp crest" used by Professor Nagler. The question of the distribution of velocities arises, whether it was the same in Bazin's "standard weir", 3.72 ft. high, and in his comparison weir, 1.15 ft. high, located in his down-stream canal. The value of 0.112 for $\frac{\varepsilon}{h}$ was obtained from the weir 3.72 ft. high and the value of 0.099 from the weir 1.15 ft. high. Obviously, the matter of height of weir is a factor, and if there was a different distribution of velocities in the two cases the corresponding same-basis "effective heights" would not agree with the actual heights. Moreover, there does not seem to be any proved basis for using arithmetical interpolation to obtain the ratio for a weir 3 ft. high. The velocity conditions for Professor Nagler's 3-ft. weir, in fact the discharge itself, may have been sensibly different than for the cor-

responding height under Bazin's conditions. Everything considered, it would seem that many more data are needed to make this ingenious argument valid.

It is interesting to note that Professor Nagler has found increases in discharge due to roughening the up-stream face of the weir plate. Direct comparisons with Barr's data on V-notches and Weber's data with the roughening caused by grooving the weir plate are difficult to make, but the main fact seems to be well established. Coating the up-stream face with sand doubtless causes a condition like that of tuberculation on iron or lime deposits on brass; and grooving somewhat resembles pitting. In January, 1929, the writer made careful measurements of the up-stream water level and of the discharge over a crest piece made of a steel angle that had become badly tuberculated both on the up-stream face and on top. Without disturbing the inflow, the tuberculation was then cleaned off. It was a matter of considerable surprise to find that the up-stream water level did not change perceptibly, but it was reasoned that Nature had caused a balance. With the rust on top removed the same water level meant a greater head, but with the up-stream face cleaned this head was necessary to offset the increased contraction due to removal of the roughening of the up-stream face and the accompanying rounding of the up-stream top edge.

Inasmuch as Professor Nagler's hydro-chemical measurements have been mentioned in several of the discussions, and because Professor Rehbock has shown that his formula fits the writers' data very closely for reasonably uniform distributions of velocity in the channel of approach, Fig. 84 has been prepared* to show the distribution of velocities in mid-channel 25 ft. up-stream from Professor Nagler's weir. The surface velocities are low probably because of the stilling-raft floating on the surface a few feet up stream. Assuming that this represents also the distribution 16.35 ft. from the weir (where the head was measured), the mean values of $\frac{v_a^2}{2g}$ and $\frac{v_b^2}{2g}$ are obtainable for use in Formula (D), which gives (after adjusting v_a and v_b to agree with the first approximation to Q): for $h = 2.97$ ft., $Q = 18.315$ cu. ft. per sec. per ft., or 120.1 cu. ft. per sec. for the 2-m. (6.556-ft.) length. Rehbock's formula,

$$Q = \left[0.605 + \frac{1}{320\,h - 3} + \frac{0.08\,h}{d_0}\right] \frac{2}{3}\, L\, h \sqrt{2\,g\,h}$$

with $h = 2.97$ and $d_0 = 3.72$ ft., gives $Q = 18.307$ cu. ft. per sec. per ft., which differs only 0.13% from the value obtained by Formula (D). There is no other record now available to the writer for the distributions of velocities in Professor Nagler's channel of approach during his hydro-chemical gaugings, and, therefore, Formula (D) cannot be used for other heads.

Fig. 85 shows the lines from Professor Nagler's Fig. 24† with indicated discharges for heads of 2, 2.97, and 4 ft. by the formulas of Fteley and Stearns, Rehbock, and the writers' Formula (D), the latter for 2.97 ft. only. It appears that the hydro-chemical gaugings show fully 1% greater discharge than Rehbock's formula at 2, 3, and 4 ft.; they show the same as compared with

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 125, Fig. 11.
† *Loc. cit.*, p. 152.

the writers' Formula (D) at 2.97 ft.; and about 1% greater than the mean of Bazin's experiments at 2-ft. head. The latter coincides practically with the Fteley and Stearns formula,

$$Q = L\left[3.31\left(h + 1.5\,\frac{v^2}{2g}\right)^{\frac{3}{2}} + 0.007\right]$$

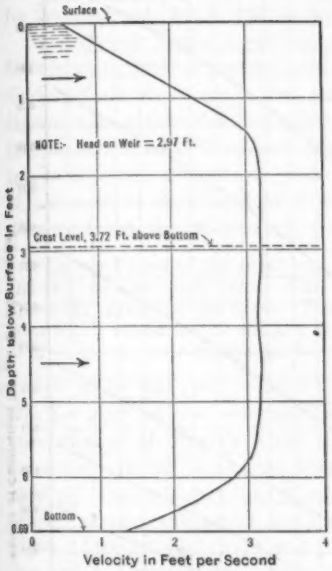

FIG. 84.

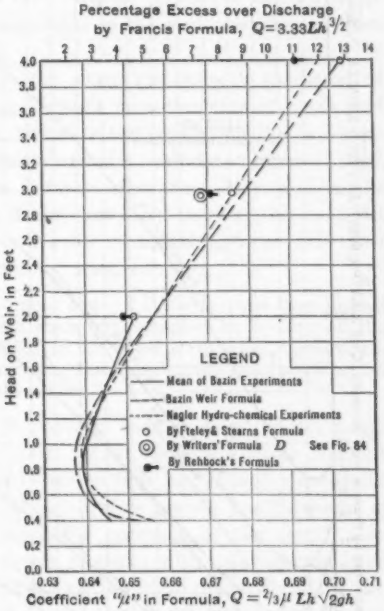

FIG. 85.

Concerning the cross-over trend of the values by the latter formula, it may be pointed out that Fig. 14 indicates the tendency of this formula at the greater heads to over-estimate discharges for weirs more than 3 ft. high, with velocity distributions as shown in Figs. 39 and 40, which distributions resemble approximately those made by Fteley and Stearns. These distributions are of the average type for flow in open channels, with near-surface velocities greatest, but only slightly greater than mid-depth velocities, and with near-bottom velocities least. Evidently, for a case with distribution more nearly uniform, as shown in Fig. 84, the discharge would be less, and Fteley and Stearns' formula would over-estimate to a greater extent. The 3.31 instead of the Francis 3.33 tends to keep the discharges low at the lower heads, but the 1.5 multiplier for the added term more than offsets this as the heads increase.

Bazin himself was very careful to state that the table of coefficients obtained from the averaging lines for his experiments was his own preference. The extension of his approximating formula far beyond the range of his experiments was never sanctioned by him, as far as the writer is aware. In order to show clearly what liberties have been taken with the so-called Bazin

"formula", Fig. 86 has been prepared. This diagram includes only the range of heads covered in the writers in Series A to P. The location, curvature, and slopes of lines should be compared with those in Fig. 9. It is true that

FORMULA: $\left(Q=\left(0.405+\frac{0.00984}{h}\right)\left[1+0.55\left(\frac{h}{p+h}\right)^2\right]Lh\sqrt{2gh}.\right)$

heights and heads considerably beyond the range of Bazin's experiments are shown for the "formula", but a table* that has had wide circulation gives dis-

* *Water Supply and Irrigation Paper No. 200*, U. S. Geological Survey, pp. 187–189, Table 9.

charges computed according to the Bazin formula for heads up to 10 ft., with heights of weir from 2 to 30 ft. It is clearly seen that Bazin's approximating weir formula is a poor fit for his experiments, even within their range. For heads greater than the heights of weir the formula lines are concave downward, whereas the experimental data lines are concave upward throughout. The percentage extent of departures of the "formula" from the indications of Bazin's experimental data must be considerable in the region where the lines for the same weir are diverging rapidly.

If Professor Nagler's opinion as to the sharp and smooth condition of Bazin's weir plates is correct, and if the latter's measurements of heads and discharges are also correct, then one is forced to the conclusion that a future experimenter will be able to duplicate Bazin's results. All data presented since 1912, except those of Professor Nagler, indicate otherwise. Moreover, in the translated words of M. Hegly, who was Bazin's assistant, there are no clean-cut phrases such as those used by Professor Nagler in describing* the weir crest piece used with the Michigan hydro-chemical tests, namely,

"The back face of the plate and the upper edge of the brass was then planed and finished absolutely true. This left a sharp right-angled knife-edge on the up-stream corner of the crest. The object of the brass strip was to produce a crest which would not be subject to corrosion, thus preventing the introduction of error in the weir discharge from this source."

The writer has been assured that the words, "bien dressée" do not imply that the plate of iron was machine-planed. If, to quote Professor Nagler's translation of M. Hegly's letter: "From time to time he [Bazin] cleaned the top and up-stream face of the weir plate in order to remove small deposits of algæ and rust which might have affected the accuracy of the crest", then Bazin did what the writer has done scores of times with iron or steel crest pieces. Algæ intensify rust, and rust means pitting of an originally plane surface and dulling of an originally sharp, square corner. A few weeks of intermittent submergence in warm weather has a decided effect on ordinary rolled iron or steel.

Attention is called to the fact that for the runs with the very highest heads the writers found so much leakage into the stand-pipe through the hinge of the diverter that a perceptible volume of water was in mid-air, descending in the stand-pipe which was used as a measuring tank, and, therefore, did not appear on the float-gauge reading for the initial levels. The vertical distance between the initial and final levels in the tank was about 40 to 45 ft. Auxiliary tests, made to determine the rate at which this leakage water fell down the empty stand-pipe, and the lag (if any) in response by the float-gauge at "nearly full" and "nearly empty" levels, supplied the necessary data for estimating the effect. This condition was ignored in the computations leading to Tables 9 to 24, and, therefore, the tabulated discharges for heads greater than 2 ft. should be decreased by about 0.1% for a head of 2.25 ft., and 0.2% for a head of 2.5 ft. The effect on the lines at the right end of Fig. 18 is scarcely noticeable.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 114.

The writer believes that he fully appreciates the comments that Mr. Herschel makes in discussing this paper. Whether the writers have done much toward finding the perfect weir may well be questioned. They had to meet a practical situation in which sharp-crested weirs, or what passed for such, met their immediate need. The research described in the paper was an offshoot from their main undertaking. Mr. Herschel was assured by the writer in correspondence of 1904 that other forms of weirs and other means of measuring the head difference were prominent features in his program for future experiments. That is still true, but the words of Edward Gibbon in his preface to the first volume of "The Decline and Fall of the Roman Empire" seem to apply: "The execution of the extensive plan * * * would require many years of health, of leisure, and of perseverance". To do profound investigation (in a field as complex as is the flow of water in open channels) in one's spare time presents a dilemma. Many an experimenter has wondered why the purse-strings of otherwise generous affluence are not loosened for practical engineering research.

It is with regret that the writer closes the discussion without giving fuller evidence of having carefully read all the valuable contributions. Probably the discussions and the wealth of hydraulic engineering literature in the numerous references furnish as nearly an up-to-date view of the subject as is practically possible.

Paper No. 1712

ANALYSIS OF ARCH DAMS BY THE TRIAL LOAD METHOD

By C. H. Howell,* M. Am. Soc. C. E., and the Late A. C. Jaquith,† Esq.

With Discussion by Messrs. B. F. Jakobsen, George R. Rich, C. A. P. Turner, F. H. Constant, F. W. Hanna, L. J. Mensch, William Cain, Fred A. Noetzli, Fredrik Vogt, J. L. Savage and Ivan E. Houk, A. Floris, and C. H. Howell.

Synopsis

This paper presents a method of arch dam analysis that has been gradually developed in the Designing Office of the United States Bureau of Reclamation. It has also been used by the Salt River Valley Water Users Association, the Middle Rio Grande Conservancy District, and by one of the writers for a high arch dam in Mexico. It is based on the assumption that an arch dam is composed of systems of horizontal arches and vertical cantilevers, that each system carries a proportion of the total load, and that the deflections of the two systems are equal.

The method consists in applying a series of assumed proportional loads to each system and computing their deflections. When a proportionate loading has been found that gives equal deflections at all points for both systems, the stresses are computed and are considered to be those which will obtain in the dam.

The mathematical treatment of the problem has been gradually developed and improved. The final form is given in the Appendix. If applied to the earlier designs, the numerical results would be slightly different, but the stresses and the shape of the loads would not be greatly changed.

† Asst. to Chf. Engr., J. G. White Corporation, S. en C., City of Mexico, Mexico. Mr. Jaquith died September 23, 1927.

It is now generally conceded that the cylinder formula does not give correct results when applied to arch dams. It makes no allowance for temperature changes, rib-shortening, or the effect of cantilever action. The theory is wrong and the resultant designs are uneconomical. The lack of economy increases very rapidly as the size of the dam is increased.

No dam, designed as a cylinder, has failed as far as is known to the writers. However, it is probable that some of them are stressed nearly to the safe limit. Existing dams designed as cylinders are of moderate height, and the maximum allowable stresses assumed in their designs are relatively low. These facts probably account for the lack of failures.

Many arch dams of great height are now under consideration. Consequently, the development of a complete theory of design is greatly needed. This paper is not presented as a complete solution of the problem, but as a step toward it.

A somewhat generally accepted method of investigating arch dams is to consider that the water load is carried by two systems of elements. One system is vertical and is considered as a series of cantilevers. The other system is horizontal and is considered as a series of arches. The two systems have equal deflections at all points and carry proportional parts of the load. It is probable that they are not exactly at right angles to each other, especially near the abutments. This complicates the problem. The amount of error caused by assuming the systems normal to each other is not known.

Several methods have been proposed for determining the distribution of the load between the arches and the cantilevers. These methods generally have been based on the relative rigidity of the arches and the cantilever at the crown. Each arch element is assumed to carry a uniform load such that, when the remainder of the unit water load is placed on the crown cantilever, the computed arch deflections at the crown will equal the computed crown cantilever deflections. It is believed that such a procedure is entirely inadequate.

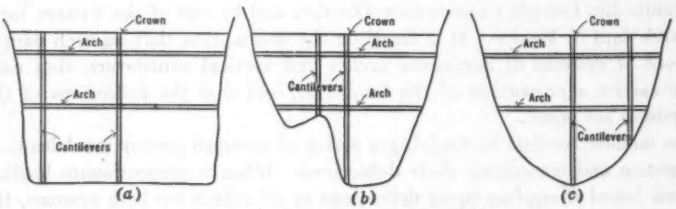

FIG. 1.—TYPICAL CANYON SECTIONS.

Consider a canyon section, as in Fig. 1 (*a*). The cantilevers at the crown and near the abutments, being of the same height and cross-section (assuming arch elements of uniform thickness), will theoretically deflect the same amounts under equal loads. Under a uniform load, the arch deflection at the crown will be much greater than that near the abutments. Hence, if the crown deflection of the arch equals the cantilever deflection at that point, it cannot be equal to that of the cantilevers at other points. Therefore, no uniform divi-

sion of load between the two systems can produce equal deflections at all points.

Consider a canyon section as in Fig. 1 (*b*). The cantilever at the hump, due to its greater stiffness, will clearly carry more of the load than the cantilever at the crown or maximum section. Therefore, the arch will carry less at the hump than at other points. In fact, the arch will undoubtedly be subject to a negative load at such a point. Some dams exist that have approximately this profile. Even in regular profiles similar to Fig. 1 (*c*) the arch loads were not found uniform in any of the detailed studies made by this method. All computations made thus far have indicated that uniform arch loads can obtain only under the most specialized conditions. It follows, therefore, that a general expression for the proportional loads on the two systems of elements must take into account the shape of the canyon. Such an expression has not yet been developed.

Computing the deflections and proportional loads at the crown alone, or at any other one section, therefore, means little in the study as a whole. The deflections and proportionate loads must be obtained at numerous points in each system in order to obtain even an approximate solution.

If the assumption that all the load is carried by the horizontal and vertical elements is accepted, there is certainly some definite division of the load that will give equal deflections for both systems at all points. This division can be found approximately by applying a series of trial proportionate loads to each system. If enough trials be made, equal deflections for arch and cantilever elements at all points will finally be found for any assumed temperature change. The computed stresses due to these final loads, when modified by Poisson's ratio, will probably be as close to the true stresses as those computed in gravity dams. It is believed they will be more nearly correct than stresses obtained by any method that ignores the effect of the cantilever elements or computes the cantilever effect at one section only.

This method has been in development for some time and is not yet considered as entirely complete. It is believed, however, that it has reached a stage where a description of it will be found interesting. A number of dams have been analyzed and designed by this system, and the results obtained for four of them are shown in the accompanying diagrams and tables. Unfortunately, no two of them are strictly comparable because of the gradual evolution and improvement of the mathematical treatment. When the plan was first evolved it was considered impracticable to do more than roughly approximate the actual conditions. For example, in the first analysis attempted, the stresses were computed on the assumption that reinforcing steel would have to be used to resist tension in the concrete and transmit tensile stresses across construction joints. As the methods of computation were improved during further studies it was found possible to go a step farther and eliminate computation of tension in the arch elements. This was done by varying the thickness of the arch and by assuming definite interior arches of regular shape at elevations where the first computations indicated tension. These interior arches are completely enclosed within the constructed arches and are entirely

in compression. The largest possible interior arch that could be drawn without showing tension, was used in the final analysis. Later, it was found possible to consider the arch action to be confined entirely to the irregular shape, whatever it might be, of the uncracked concrete that forms the actual interior arch. The load is assumed as applied to the constructed arch but entirely carried by the interior one. This method is now in use and the mathematics,

TABLE 1.—ARCH DATA, DAM NO. I.

Elevation in feet.	Thickness, in feet.	Angle.	Up-stream radius, in feet.	Down-stream radius, in feet.
4 830.0	5.00	141° 0′	197.08	192.08
4 845.4	5.00	141° 0′	197.08	192.08
4 815	7.84	108°12′	193.02	185.18
4 805	9.66	95°30′	189.15	179.49
4 795	11.48	83°00′	183.49	172.01
4 785	13.30	79°16′	177.10	163.80
4 775	15.12	77°30′	170.28	155.16
4 765	16.94	74°48′	162.80	145.86
4 755	18.75	72°08′	154.63	135.88

as given in the Appendix, has been adopted for the analysis of these irregularly shaped arches. The part of the base of the cantilever not in compression is likewise excluded in computing stability. No tensile stresses are now assumed in either cantilever or arches. This is believed to be essential for a correct analysis as it is practically impossible to secure an adequate anchorage for reinforcing steel in the arch abutments or in the bases of the cantilevers.

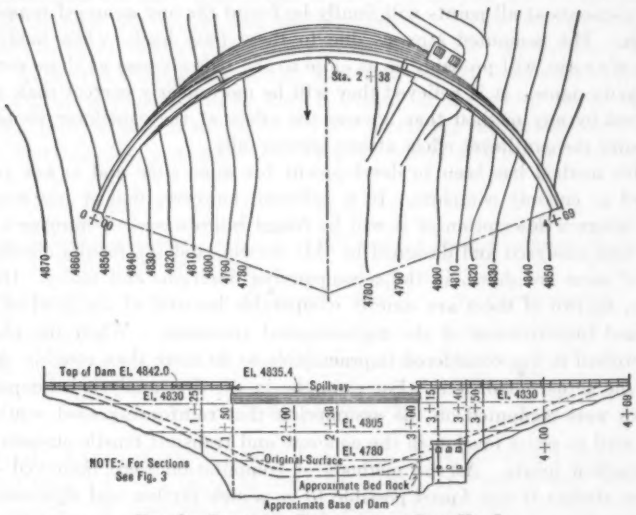

FIG. 2.—PLAN AND ELEVATION OF DAM NO. I.

Fig. 2 shows the layout and profile of Dam No. I, and Table 1 contains the arch data. This is a small dam designed and built in accordance with the cylinder formula for a stress of 25 tons per sq. ft. It is the first dam to be

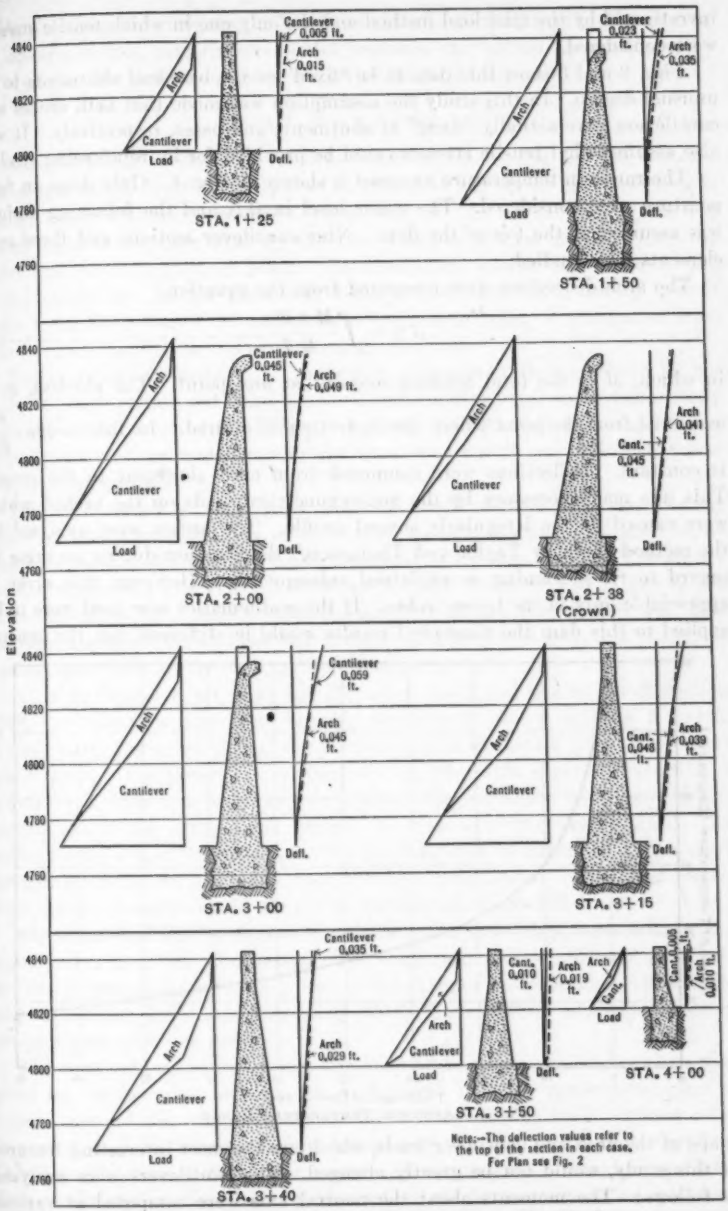

FIG. 3.—LOADS, SECTIONS, AND DEFLECTIONS OF DAM NO. I.

investigated by the trial load method and the only one in which tensile stresses were considered.

Figs. 2 and 3 show this dam to be "fixed" at the base and abutments to an unusual degree. In this study the assumption was made that both arches and cantilevers were actually "fixed" at abutments and bases, respectively. It was also assumed that tensile stresses could be provided for by reinforcing steel.

The range in temperature assumed is shown on Fig. 4. Only drops in temperature were considered. The water level in this and the following designs was assumed at the top of the dam. Nine cantilever sections and three arch elements were studied.

The arch deflections were computed from the equation,

$$\Delta y = \int \frac{M x \, d s}{E I} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which, M is the total bending moment at any point. The abscissa, x, is measured from the point where the deflection is desired. In this design, $\frac{d s}{E I}$ is constant. Deflections were computed from each abutment to the crown. This was made necessary by the non-symmetrical loads on the arches, which were caused by the irregularly shaped profile. The arches were analyzed by the method given by Taylor and Thompson,* thereby introducing an error in regard to rib-shortening as explained subsequently. However, this error is appreciable only in the lower arches. If the mathematics now used were to be applied to this dam the numerical results would be different, but the general

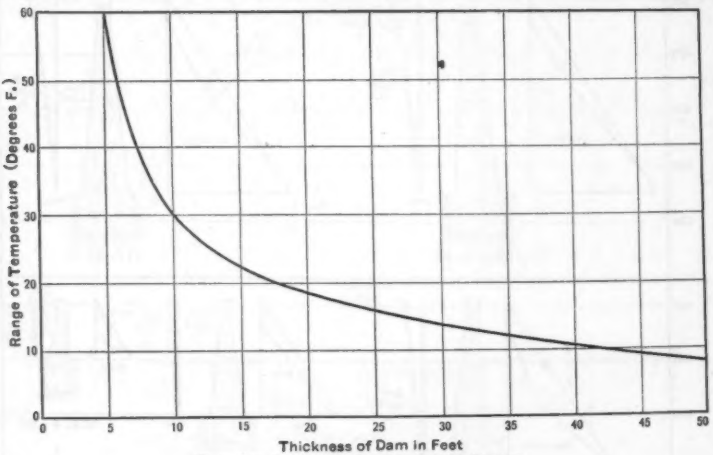

FIG. 4.—ASSUMED TEMPERATURE RANGE.

shape of the arch and cantilever loads, which are the most interesting features of this study, would not be greatly changed. The cantilevers were analyzed as follows: The moments about the neutral axis were computed at various

* In "Concrete Plain and Reinforced."

heights, loading the structure with the weight of concrete, weight of water on the up-stream face, and the horizontal pressure due to the assumed proportional load. The deflections were computed from the formula,

$$y = \int\int \frac{M}{E\,I}\, d\,x\, d\,x$$

Deflections due to shear are also included in studies for the latest dams. The computations for the cantilevers in this dam are somewhat more simple than in a dam without an overflow spillway notch. In the latter type, the top arches throw a negative load on the top of the cantilever because they are under little or no hydraulic head. The cantilevers, conversely, throw a load on the top arches. In this dam, with water at Elevation 4 842, the top arch is under a head of about 7 ft. and deflects correspondingly. No negative load, therefore, was applied to the cantilevers in this dam.

The modulus of elasticity, E, was taken as constant at 288 000 000 lb. per sq. ft. for both arches and cantilevers. There is, of course, much uncertainty as to the actual value of E. This uncertainty applies to all problems in concrete design and the usual assumption of a constant E was followed, therefore, in these studies.

Fig. 5 (*a*) and Fig. 5 (*b*) show two trial loads and the final load for the arches at Elevation 4 830. It is interesting to note the effect of the canyon profile on the shape of the arch loads, especially at Station 3 + 50. The abrupt change in the load line between Voussoir VI and Voussoir VII is due to the sudden break in the profile between Station 3 + 40 and Station 3 + 50. The diagrams also show the extreme sensitiveness of a long thin arch to a change of loading, especially if the loading is non-uniform.

After numerous trials, four for Elevation 4 805 and twelve for Elevation 4 830, the deflection lines were brought together as shown in Figs. 3 and 5. It was clearly indicated that if the process were continued a closer agreement would result. The poorest is at Station 3 + 50. This short stiff cantilever is only 10 ft. from one of maximum height. The deflection of the two under approximately the same loads cannot be even approximately equal. The arches cannot adjust themselves well to the difference in deflection in the short distance of 10 ft. At this point there will be a complicated condition of stress. Such abrupt changes should always be eliminated if possible.

The greatest difficulty found in adjusting the trial arch loads was in the upper arches near the abutments. The long thin arches are very sensitive, and slight changes of loads gave very great changes in deflections. Relatively large up-stream deflections frequently result from slightly excessive loads at the haunches, and *vice versa*.

The computed maximum stress was very high, very much higher than that given by the cylinder formula. It is believed that the constructed dam is stressed beyond the computed maximum, because it was built without reinforcement and, as tension is not taken care of, the arches have cracked. Therefore, they are resisting the compressive stresses on reduced dimensions. This condition is believed to be common to all dams designed as cylinders. On all the following designs it was found desirable to increase the arch thickness toward the abutments in order to obtain lower stresses.

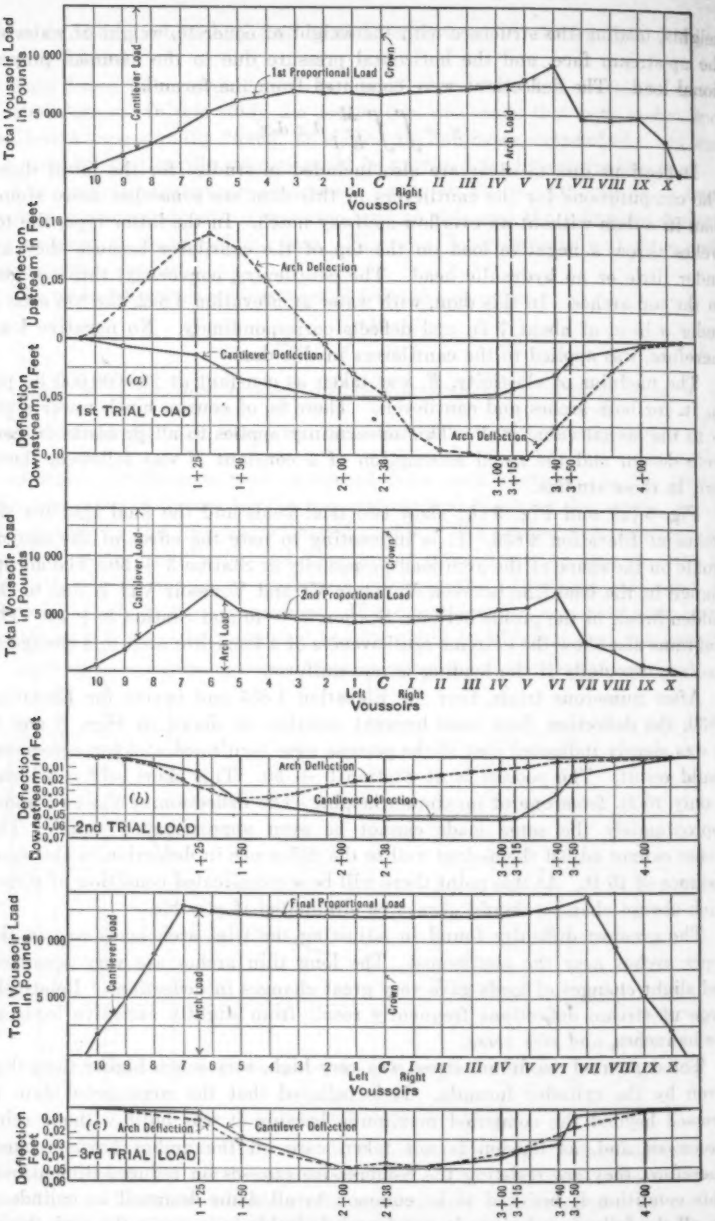

FIG. 5.—LOAD DEFLECTION DIAGRAM FOR DAM NO. I.

Dam No. II is a large arch dam, as yet (1927) in the preliminary design stage. It is interesting because of the very uniform V-shaped profile shown in Fig. 6. The arch data are arranged in Table 2. A dam designed by the cylinder formula was first proposed for this site. It was later analyzed by the trial load method, which showed that exceedingly high stresses would occur due to the faulty distribution of the concrete.

The design was then changed to that shown in Figs. 6 and 7. It was assumed that the profile would be made actually symmetrical by excavation and concrete footings, as shown in Fig. 6. This assumption reduced the work of analysis by one-half, as it was only necessary to compute the deflections of one-half the various arches and their respective cantilevers.

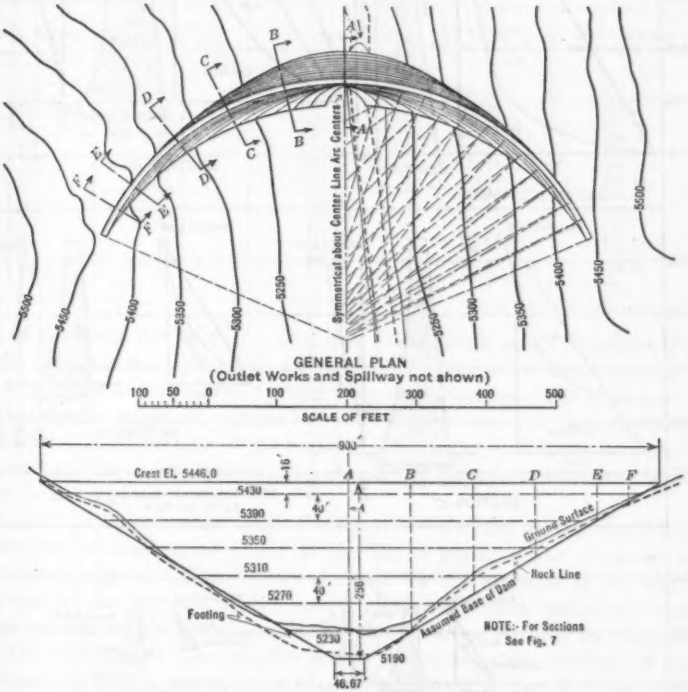

FIG. 6.—PLAN AND ELEVATION OF DAM NO. II.

The size of both systems of elements and the small depth of rock excavation precluded either system from being considered "fixed" in the sense that tension could be resisted by the grip of the rock on the concrete. Therefore, the arches were shaped so as to carry their loads entirely in compression. To accomplish this they were gradually thickened from crown to abutments, except at the top elevation. Both intrados and extrados are circular segments having different radii and centers. The cantilevers also were considered as incapable of resisting tension not only at their base but at any point. Unless reinforcing steel is used it is difficult to believe that tension could ever develop

in a dam due to the opening of the construction joints, even if it were considered that the concrete itself could resist tension. To simplify the calculations, the cantilevers for this and other dams were assumed to be 1 ft. thick

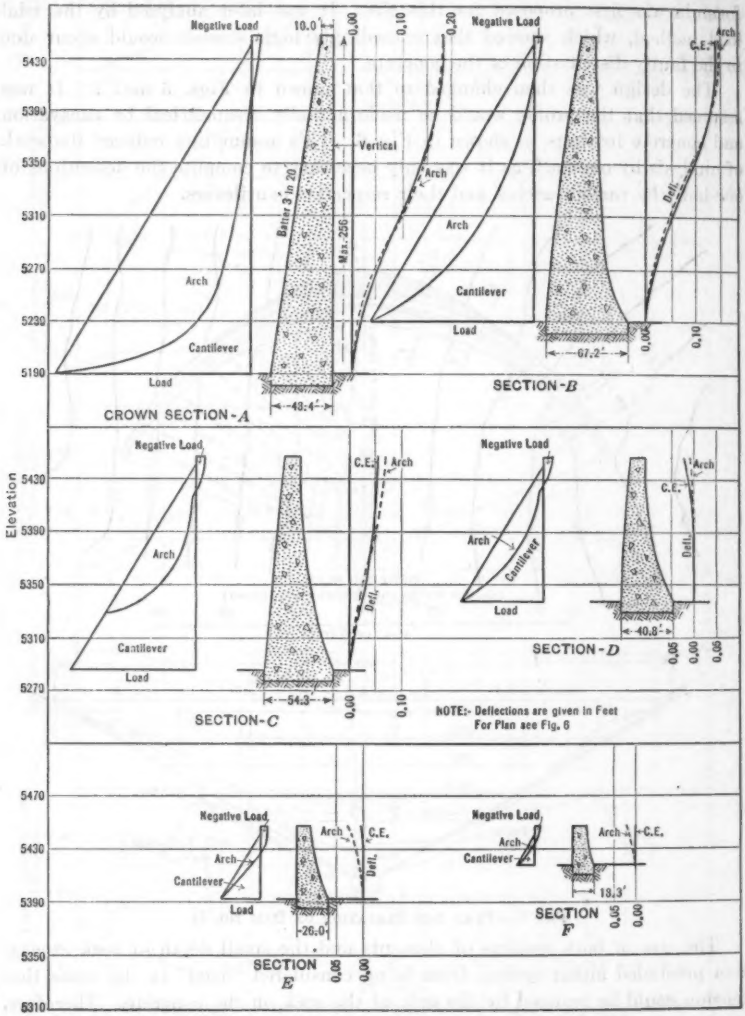

FIG. 7.—SECTIONS, LOADS, AND DEFLECTIONS, DAM NO. II.

throughout on lines radial to the crest of the dam. This is not strictly correct. The sections, except at the crown, are not exactly radial at the faces of the dam and the cantilevers are not of uniform thickness. The designs made thus far include whatever errors are due to the inaccurate assumptions mentioned.

The cantilever moments included the weight of concrete, water on the up-stream face, the negative load due to the unloaded arches at the top, and the assumed proportional part of the water load. These forces were taken as acting about the neutral axis of the sections at the various elevations considered. In cases where the resultant fell out of the middle third of the section, the moment of inertia was taken only for the portion of the section in compression, and the moments were considered as acting about the neutral axis of the compressed portion. The deflections were computed for each 20 ft. in height.

TABLE 2.—ARCH DATA, DAM NO. II.

Elevation, in feet.	Thickness of crown, in feet.	Angle.	Up-stream radius, in feet.	Down-stream radius, in feet.
5 446	10.0	132° 54′	388.00	378.00
5 430	12.4	126° 04′	386.45	369.28
5 410	15.4	117° 32′	384.11	337.39
5 390	18.4	109° 00′	381.20	343.55
5 370	21.4	100° 27′	377.87	326.61
5 350	24.4	91° 54′	372.84	308.91
5 330	27.4	83° 27′	366.84	285.15
5 310	30.4	75° 00′	358.14	256.70
5 290	33.4	65° 56′	351.69	228.00
5 270	36.4	56° 52′	337.17	196.70
5 250	39.4	48° 40′	316.99	143.11
5 230	42.4	40° 28′	284.73	92.77
5 210	45.4	32° 00′	231.65	53.33
5 190	48.4	.....	.....	.....

As in the study for Dam No. I, it was found much easier to adjust the loads for the lower elevations than for the higher. The top arches being only about 10 ft. thick and about 900 ft. long were very sensitive. The high cantilevers having the resultants outside the middle third were also very unstable. Moreover, the long lever arm of the negative load on the cantilevers (produced by the unloaded top arch) caused large changes in deflections with very small changes in the negative loads.

In the three lower arches (Elevations 5 310, 5 270, and 5 230) the thickness required to avoid an overhang at the higher portions was too great to avoid tension entirely. This tension develops on the extrados at the abutments and on the intrados at the crown. Interior arches, therefore, were assumed to form within the constructed arch and to act entirely in compression. The deflection of these interior arches should coincide with that of the cantilevers. It was in the analysis of the thick lower arches that the error in the usual method of computing rib-shortening was discovered. This error consists in computing the rib-shortening thrust from the average thrusts due to loads and temperature, without including the rib-shortening itself. If the rib-shortening is not included in obtaining the average, there will be negative thrusts in short thick arches. This error was corrected by a modification of the rib-shortening formula and the remaining arch analyses were similar to those used for Dam No. I. The computed results are believed to be quite close to those which would be obtained by the present mathematical treatment.

UNIVERSITY OF MICHIGAN LIBRARIES

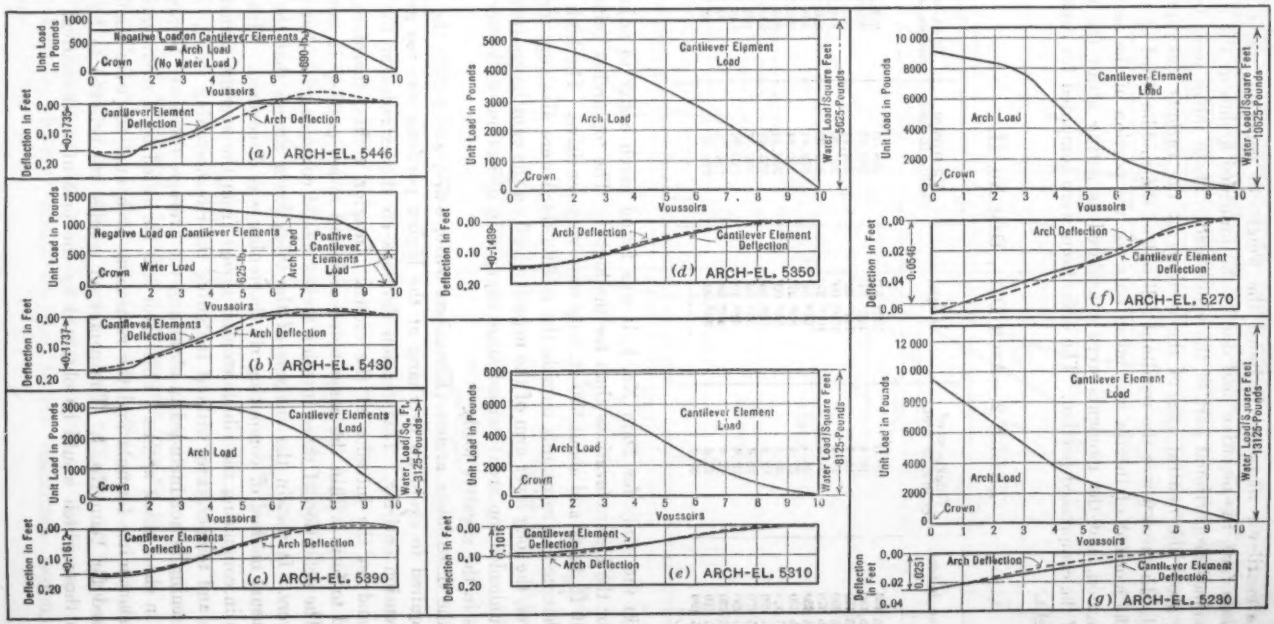

FIG. 8.—LOAD AND DEFLECTION CURVES, DAM NO. II.

Fig. 7 shows the vertical sections, the final proportionate water loads carried by each system, the negative load at the top, and the computed deflections. Fig. 8 (*a*) to Fig. 8 (*g*) shows the horizontal shape of the final arch loads and the deflections of the arches and cantilevers. Fig. 9 shows the developed elevation of the dam on which are drawn lines of equal deflections as computed for the arches. Fig. 10 shows the assumed interior arches for the three lowest elevations. They were found by removing from the original arches the parts in tension, and drawing symmetrical arches in the unarched portion. The reduced arches were then analyzed. This method is only approximate. It does not give definitely the largest interior arch that is free from tension.

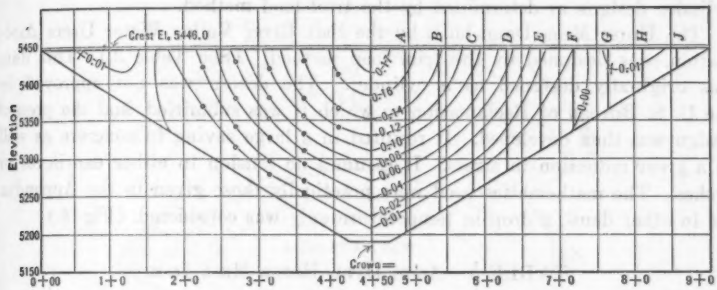

FIG. 9.—DEVELOPED ELEVATION OF DAM NO. II, SHOWING LINES OF EQUAL DEFLECTION (DEFLECTIONS, IN FEET).

At the time the studies of this dam were being made, it was considered too laborious to analyze the irregularly shaped interior arches. In the succeeding designs, however, this was done.

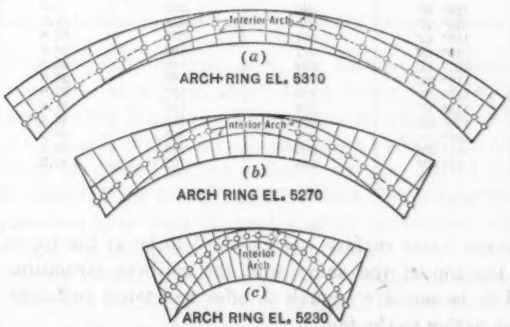

FIG. 10.—ASSUMED INTERIOR ARCHES, DAM NO. II.

The formation of the interior arches has been well stated by L. J. Mensch,* M. Am. Soc. C. E., William Cain,† M. Am. Soc. C. E., and also by B. F. Jakobsen,‡ M. Am. Soc. C. E.

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 308.
† *Loc. cit.*, p. 310.
‡ *Loc. cit.*, Vol. 90 (June, 1927), p. 475.

The greatest discrepancy between the cantilever and arch deflections is shown in Fig. 8 (*a*) and Fig. 8 (*b*) for Elevations 5 446 and 5 430. This is also shown in Fig. 7 for Cantilevers *D*, *E*, and *F*. These lines could have been brought more closely together by further trials. However, those already made, ten or more for each arch, showed relatively great variation in deflection and small changes in stress. Therefore, the further effort was not considered worth while.

As stated before, this design is a preliminary one only. It was made as an attempt to improve the original cylinder design. The saving in concrete amounts to 25%, and the stresses are less than one-half those in the cylinder designs as determined by the trial load method.

The Horse Mesa Dam, built by the Salt River Valley Water Users Association, was designed by the trial load method. (See Table 3.) This dam was originally designed as a cylinder. The design was not approved by the U. S. Bureau of Reclamation to which it was submitted, and the present design was then developed. It resulted in a large saving in concrete as well as a great reduction in stress. It assumes no tension in either cantilever or arches. The mathematics used were practically those given in the Appendix. As in other dams, a drop in temperature only was considered. (Fig. 4.)

TABLE 3.—ARCH DATA, HORSE MESA DAM.

Elevation of crest.	Central angle.	Up-stream radius, in feet.	Down-stream radius, in feet.	ARCH THICKNESS, IN FEET.	
				Crown.	Springing line.
1 921	112° 30′	240	232	8.0	8.0
1 897	114° 47′	235	218	11.6	14.4
1 875	116° 45′	231	206	14.8	20.1
1 850	119° 18′	227	198	18.6	26.8
1 825	121° 11′	224	181	22.3	33.4
1 800	118° 26′	220	168	26.0	40.9
1 775	117° 17′	216	157	29.0	46.0
1 750	116° 57′	213	146	31.8	51.5
1 725	118° 32′	210	136	34.8	56.5
1 700	106° 11′	207	123	36.5	61.0
1 675	91° 31′	202	113	38.5	59.8
1 650	76° 45′	195	102	40.2	57.3

The maximum water surface was assumed to be at the top of the parapet (5 ft. above the top of the dam), and the spillway structures at the ends were assumed to be massive enough to offer resistance sufficient for the dam to develop arch action to the top.

This design proved to be well proportioned, the average compression in the arches being 286 lb. per sq. in., and in the cantilevers, 222 lb. per sq. in. The difference in the maximum compression of the two elements was only 12 lb. The profile of this dam is irregular as was the case with Dam No. I, and again this irregularity is strikingly reflected by the shape of the arch loads.

On account of the thin section at the crown practically no load is taken by the cantilever. This condition exists at the abutments where, on account

of the almost perpendicular sides, the cantilevers cannot deflect; between these points the cantilevers carry a fair proportion at the bottom, but practically nothing at the top, of the dam.

In the analysis of this dam the effective section of the arches was considered to be only that portion in compression. Where tension developed, it was eliminated by assuming reduced sections until one was found that had practically a zero stress along the lines of the discarded areas. This condition occurred only in the lower portion of the dam where the arches are relatively thick. These reduced sections are shown in Fig. 11 and are not symmetrical, due to the unsymmetrical loading of the arches.

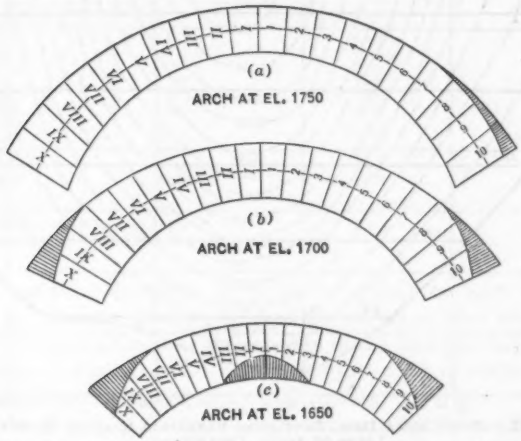

FIG. 11.—PLANS OF ARCHES AS ASSUMED TO ELIMINATE TENSION, HORSE MESA DAM.

Analysis discloses that, in this case, the maximum deflection does not occur at the crest, but at a point about 45 ft. below the crest and near the crown of the arch. (See Fig. 12.) This was to be expected as the only load on the arch at the top is that due to the negative load on the cantilevers. A similar condition of deflection was deduced by Mr. Alfred Stucky in his analysis of the Jogne Dam, Switzerland.* Since the designs described were made, the dimensions have been changed slightly to conform with conditions that have developed in the process of construction.

Table 4 gives the results of the analysis of the Gibson Dam on Sun River, Montana, which is now (1927) being built by the U. S. Bureau of Reclamation. This site has been under consideration for a long time, but hitherto only for a gravity dam. The shape of the profile does not clearly indicate the suitability of an arch dam. However, by taking advantage of the effect of the cantilever action in reducing water loads, as determined by the trial load method, the present design is responsible for a saving of more than 41 000 cu. yd. of concrete over the gravity design. In contrast to the three foregoing dams, the Gibson Creek Dam has a vertical up-stream face and a constant up-stream

* "Study of Arched Dams," *Bulletin technique de la Suisse Romande*, 1922.

radius. The previously considered designs are of the variable radius type. Because of the wide flat-bottomed profile (Fig. 13), a large proportion of the cantilevers are of approximately maximum height. In a variable radius design the crown cantilever has a vertical down-stream face and an inclined up-stream one. The adjacent sections approximate this shape. They are very inefficient in resisting thrusts on the up-stream face. The same area

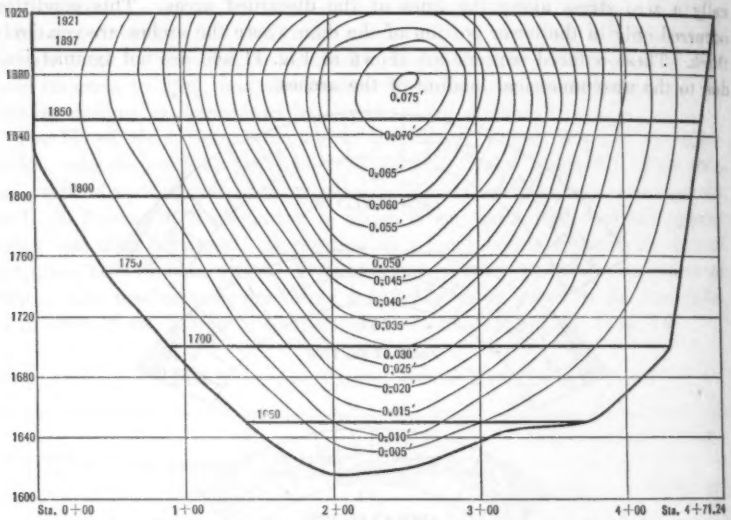

FIG. 12.—HORSE MESA DAM: DEVELOPED ELEVATION LOOKING UP STREAM, LINES OF EQUAL DEFLECTION.

with vertical up-stream and inclined down-stream faces is much stiffer. Therefore, if cantilever action is to be considered in profiles similar to that of the Gibson Dam, it will usually be found that the vertical up-stream face, or constant-radius type, is the most economical. This is not true, however, with narrow V-shaped profiles where the bottom arches are short and relatively more efficient, and the maximum height obtains for only a small proportion of the profile.

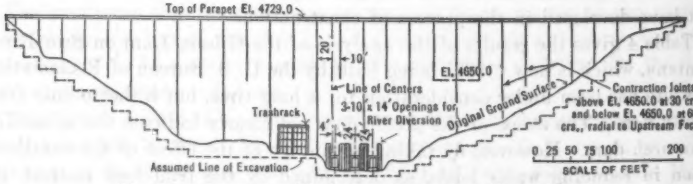

FIG. 13.—DEVELOPED UP-STREAM ELEVATION, GIBSON DAM.

The mathematics used are those given in the Appendix and represent the latest development. The maximum computed stress is 600 lb. per sq. in. and occurs at Elevation 4 550. The maximum arch stress is 300 lb. per sq. in.

and occurs at the crown at Elevations 4 675 and 4 650. Several arches at the lower elevation were analyzed with their full water load. These computations showed a maximum stress of approximately 1 000 lb. per sq. in. The computed stresses on this dam are believed to be the most accurately determined of all those studied thus far.

In all the dams described, provision was made to leave openings for closing plugs. These plugs are poured in the coldest weather practicable, and as long a time as possible after the concrete in the dam has been placed so as to compensate, to some degree, for the shrinkage of the concrete. Other than this no consideration has been given to shrinkage.

In this design, due to the large relative importance of the cantilever action as compared to the arches, an arbitrary assumption for uplift was made. It was considered that the full head at the up-stream face diminished to zero or tail-water elevation at the down-stream face and acted over one-half the base of the section. In addition, a drainage system was provided.

No attempt was made in any of these studies to consider foundation deformation or swelling of the concrete due to water soakage. Both these actions undoubtedly modify deflections and stresses to some degree. The writers believe that an attempt to include foundation deformation would be unwarranted from a practical standpoint because of the indeterminate and, in many cases, the variable bearing power of the rock itself.

At present, so little is actually known about the changes in volume of concrete due to water soakage that the writers have not tried to include its effect in this method. If, however, one should desire to provide for the effect of water soakage there is no reason why the additional assumption could not be incorporated in the trial load method.

The action of gravity, however, is definitely known. The resistance offered by the cantilevers can be determined probably more accurately than that of the arches. The writers believe that action of cantilevers should not be neglected in designing arch dams. They certainly carry a part of the load and just as certainly modify the arch loads; and this fact should be recognized

in designing the arches. The trial load method offers a practical means of doing this.

Conclusions

In conclusion, the writers desire to repeat that this paper is not offered as a rigid and complete solution of the problem of arch dam design, but as a step toward it.

It is believed, however, that four conclusions are indicated:

(1) If the cantilevers act the arch elements are not under uniform loads.

(2) Computing proportional loads and deflections for each system at the crown, or at any other one point, means little or nothing in the solution of the problem as a whole.

(3) Rational formulas for a complete solution must include terms that express the shape of the canyon.

(4) An approximately accurate analysis can be made by the use of the method herein proposed.

The designs and studies of all the dams described were made under the direction of J. L. Savage, M. Am. Soc. C. E., Designing Engineer, U. S. Bureau of Reclamation. Julian Hinds, M. Am. Soc. C. E., as Assistant Designing Engineer, developed the final form of the mathematics and assisted throughout in perfecting this method. Ivan E. Houk and J. J. Doland, Members, Am. Soc. C. E., and Mr. R. E. Glover, Engineers, U. S. Bureau of Reclamation, assisted in the designs of the Gibson Dam.

APPENDIX

The following discussion involves the application of the elastic theory to arches both symmetrical and unsymmetrical in form. The underlying principles are the same as those given in various textbooks on concrete. The formulas deduced in textbooks, however, are generally subjected to simplifications that limit their usefulness in the study of arched dams. An attempt is here made to develop the formulas in a perfectly general way. The resulting equations are rather forbidding in appearance, but are, in fact, comparatively simple to apply.

Fig. 14 represents one side of an arch, the influence of the other side upon it being replaced by the introduction of proper forces or reactions at the crown. A load, W, placed on the arch will cause the crown point of the arch axis to be displaced. The displacement will be due partly to the bending of the arch ring, and partly to a change in the length of the center line of the arch.

In general, a load placed on the arch will produce a moment at every point along the ring. These moments cause the arch ring to bend.

The arch may be considered as made up of a series of short sections, or voussoirs. The bending of any short length, such as that having its center at D, will cause an angular displacement of the part ring, $A\ C$, and a displace-

ment, in space, of the crown point at C. The movement at C will be equal to $E\,C\,\Delta\,\theta$, plus the actual displacement of the point, E, $\Delta\,\theta$ being the change in angle between the two end faces of the voussoir. If the voussoirs are short, the movement is approximately $D\,C\,\Delta\,\theta$. From mechanics:

$$\Delta\,\theta = \frac{M\,s}{E\,I} \qquad (1)$$

in which, M is the bending moment, s is the length of the voussoir, E is the modulus of elasticity, and I is the moment of inertia of the arch ring. Equation (1) is strictly accurate only when M and I are constant throughout the voussoir, or when the length, s, is infinitesimal. However, it is assumed to serve with sufficient accuracy in practical cases if average values of M and I are taken for each voussoir. A further simplification is often made by assuming that M and I computed at the middle of the voussoir are equivalent to the average values for the voussoir.

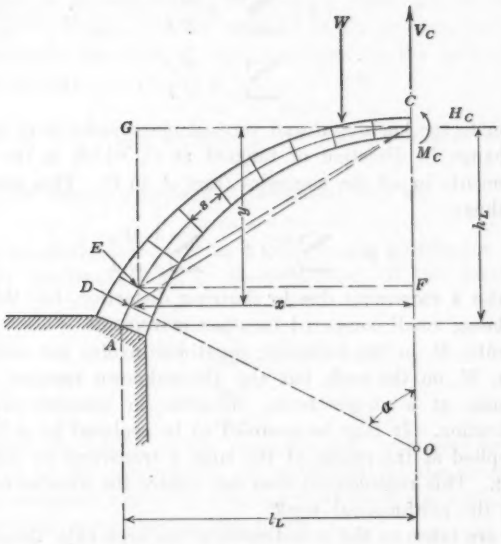

FIG. 14.

The angular movement, $\Delta\,\theta$, will be considered positive in a contra-clockwise direction, and M will be positive when the resulting tension is on the intrados side of the arch ring.

The path of motion at C will be determined by the direction of the line, $D\,C$. The use of angles is avoided by considering the vertical and horizontal motions separately. The vertical motion of the point, C, will be approximately equal to that of the point, F, or

$$\Delta\,y = x\,\Delta\,\theta = x\,\frac{M\,s}{E\,I} \qquad (2)$$

in which, Δy is the vertical movement of C, considered positive when upward; and x is the horizontal distance from C to D, considered positive regardless of direction of measurement.

The horizontal movement of C will be approximately equal to that of the point, G, or

$$\Delta x = -y\,\Delta\theta = -y\,\frac{M\,s}{E\,I} \quad \ldots\ldots(3)$$

in which, Δx is the horizontal movement of C, considered positive to the right, and y is the vertical distance from D to C, considered positive in all cases. The terms, horizontal and vertical, are used for convenience, although in arched dams the ordinate, y, is never vertical.

If Equations (2) and (3) are applied successively to each voussoir from A to C and the results added algebraically, the total movement of the point, C, due to bending, will be determined. The process may be expressed as follows:

$$\Delta y = \sum_{C}^{A} x\,\frac{M\,s}{E\,I} \quad \ldots\ldots(4)$$

$$\Delta x = -\sum_{C}^{A} y\,\frac{M\,s}{E\,I} \quad \ldots\ldots(5)$$

In addition to the horizontal and vertical movements there is an angular motion, or change in direction of tangent at C, which is the sum of the angular movements in all the voussoirs from A to C. This movement may be expressed thus:

$$\Delta\phi = \sum_{C}^{A} \Delta\theta = \sum_{C}^{A} \frac{M\,s}{E\,I} \quad \ldots\ldots(6)$$

There is also a movement due to shearing distortion, but this is usually neglected as being small compared to other movements.

The moments, M, in the foregoing equations involve not only the known external loads, W, on the arch, but also the unknown reaction at C. This reaction consists of a single force, unknown in amount, direction, and point of application. It may be assumed to be replaced by a horizontal or axial force applied at the center of the ring, a transverse or shearing force, and a moment. This replacement does not reduce the number of unknowns, but simplifies the arithmetical work.

If x and y are taken as the co-ordinates of the arch axis, then the moment of all forces about any given point between A and C (Fig. 14) will be:

$$M = M_C + H_C\,y + V_C\,x - M_L \quad \ldots\ldots(7)$$

in which, M_C, H_C, and V_C are, respectively, the moment, thrust, and shear at the crown, and M_L is the moment, about the point in question, of all external loads, W, between the crown and the point. All factors are considered positive when acting as shown in Fig. 14. The use of the minus sign before M_L in this case is not strictly mathematical, but conforms to usual practice. Actually, M_L is added algebraically, but, since it is in all usual cases a negative quantity, it is customarily computed without regard to algebraic sign and then subtracted.

Substituting this value for M in Equations (4), (5), and (6), yields three equations, as follows:

Change in y at crown,

$$\Delta y = \sum_C^A \frac{x\,s}{E\,I}(M_C + H_C\,y + V_C\,x - M_L) \quad \ldots\ldots (8)$$

Change in x at crown,

$$\Delta x = -\sum_C^A \frac{y\,s}{E\,I}(M_C + H_C\,y + V_C\,x - M_L) \quad \ldots\ldots (9)$$

Change in direction at crown,

$$\Delta \phi = \sum_C^A \frac{s}{E\,I}(M_C + H_C\,y + V_C\,x - M_L) \quad \ldots\ldots (10)$$

Equations (8), (9), and (10) give the movement at C produced by bending only, the length of the center line being assumed to be constant. If this length changes, as it always does in practice, there will be an additional movement. If the length, $A\ E$, is changed by an amount, Δs, other things remaining constant, the point, E, and, consequently, the point, C, will move vertically an amount:

$$\Delta y = \Delta s \sin \alpha \quad \ldots\ldots (11)$$

in which, α is the angle that a radius to the point, D, makes with the crown radius.

Likewise, the resulting horizontal movement will be,

$$\Delta x = \Delta s \cos \alpha \quad \ldots\ldots (12)$$

The total resulting movement at C will be the summation of the movements due to the lengthening or shortening of all the voussoirs between A and C, or,

$$\Delta y = \sum_C^A \Delta s \sin \alpha \quad \ldots\ldots (13)$$

$$\Delta x = \sum_C^A \Delta s \cos \alpha \quad \ldots\ldots (14)$$

A change in the length of the voussoirs may be caused by a change in temperature or by the compression (or extension) of the fibers by an axial thrust. The movement caused by a temperature change is readily determined. The total vertical movement at the crown is,

$$\Delta y = h_L\,c\,t \quad \ldots\ldots (15)$$

in which, h_L is the rise of the arch, c is the coefficient of temperature expansion, and t is the temperature change.

Likewise, if l_L is the length of the half span, the horizontal movement at the crown is,

$$\Delta x = l_L\,c\,t \quad \ldots\ldots (16)$$

The change in length in any voussoir due to thrust is:

$$\Delta s = -\frac{H s}{E\,T} \quad \ldots\ldots (17)$$

in which, H is the average axial thrust throughout the voussoir, and T is the average radial thickness of the arch ring, the thickness normal to the

plane of the paper in Fig. 14 being unity. The minus sign is required if both a compressive thrust and a lengthening of the fibers are considered positive. The value of H at any point is the combination of the components of H_C, V_C, and the external loads between the crown and the point, acting in the direction of the axis at the point. If H_L be chosen to represent the sum of the components of all external forces between the point and the crown, parallel to the axis at a given point, the thrust at that point is:

$$H = H_C \cos \alpha - V_C \sin \alpha + H_L \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

Equation (17), therefore, may be written thus:

$$\Delta s = - \frac{s}{E\,T} (H_C \cos \alpha - V_C \sin \alpha + H_L) \ldots\ldots\ldots\ldots (19)$$

Inserting this value for Δs in Equations (13) and (14), the total movement of C due to elastic change in length of center line of arch may be expressed thus:

$$\Delta y = - \sum_C^A \frac{s \sin \alpha}{E\,T} (H_C \cos \alpha - V_C \sin \alpha + H_L) \ldots\ldots\ldots (20)$$

$$\Delta x = - \sum_C^A \frac{s \cos \alpha}{E\,T} (H_C \cos \alpha - V_C \sin \alpha + H_L) \ldots\ldots\ldots (21)$$

Adding Equations (8), (15), and (20), the total vertical movement at C is found to be:

$$\Delta y = \sum_C^A \frac{x\,s}{E\,I} (M_C\, H_C\, y + V_C\, x - M_L) + h_L\, c\, t$$

$$- \sum_C^A \frac{s \sin \alpha}{E\,T} (H_C \cos \alpha - V_C \sin \alpha + H_L) \ldots\ldots\ldots\ldots (22)$$

The total horizontal movement, found by adding Equations (9), (16), and (21), is:

$$\Delta x = - \sum_C^A \frac{y\,s}{E\,I} (M_C\, H_C\, y + V_C\, x - M_L) + l_L\, c\, t$$

$$- \sum_C^A \frac{s \cos \alpha}{E\,T} (H_C \cos \alpha - V_C \sin \alpha + H_L) \ldots\ldots\ldots\ldots (23)$$

Equations (10), (22), and (23) are independent, but cannot be solved since they contain the six unknowns, Δx, Δy, $\Delta \phi$, H_C, V_C, and M_C. However, the right-hand half of the arch may be treated in the same manner and three similar equations obtained involving the same six unknowns, thereby making it posssible to determine the reaction at the crown.

The equations for the right-hand part of the arch will be identical with those just developed for the left-hand part, except as to certain signs. A positive moment on the right will cause rotation in a clockwise, or negative, direction. For this reason, $\Delta \theta$ in Equation (1) and $\Delta \phi$ in Equations (6) and (10) become negative. Since distances and co-ordinates are considered positive regardless of direction, the sign of Δy will not change in any equation. A positive moment will produce a Δx-movement toward the right. Therefore, the negative sign will be dropped in Equations (3), (5), and (9). Since a positive shear is assumed to re-act upward on the left-hand part of the

arch, it must re-act downward on the right-hand half. It will produce, therefore, a negative bending moment, and the term, $V_C x$, in Equation (7) will become negative. Likewise, the effect on the thrust will be reversed and the V_C sin α-term in Equation (18) will become positive. The effect of Δs on Δx will be reversed, and a reversal of sign is required in Equations (12), (14), and (16). When these changes have been made and carried through the derived equations, a new set of equations applicable to the right side of the arch are obtained.

Equations (10), (22), and (23), on the left side, and the similar equations, (10), (22), and (23), on the right side, are independent, and contain only six unknowns. They are, therefore, capable of simultaneous solution. The crown movements, Δy, Δx, and $\Delta \phi$, are necessarily equal for the two sides of the arch. They may be eliminated at once by equating Equations (10) left, and (10) right, (22) left, and (22) right, and (23) left, and (23) right. The resulting equations are as follows:

$$\sum_C^A \frac{s}{E\,I}(M_C + H_C\,y + V_C\,x - M_L) = -\sum_C^B \frac{s}{E\,I}(M_C + H_C\,y - V_C\,x - M_R) \quad \ldots\ldots(24)$$

$$\sum_C^A \frac{x\,s}{E\,I}(M_C + H_C\,y + V_C\,x - M_L) + h_L\,c\,t - \sum_C^A \frac{s \sin\alpha}{E\,T}(H_C \cos\alpha - V_C \sin\alpha + H_L) = \sum_C^B \frac{x\,s}{E\,I}(M_C + H_C\,y - V_C\,x - M_R) + h_R\,c\,t - \sum_C^B \frac{s \sin\alpha}{E\,T}(H_C \cos\alpha + V_C \sin\alpha + H_R) \quad \ldots\ldots(25)$$

$$-\sum_C^A \frac{y\,s}{E\,I}\left(M_C + H_C\,y + V_C\,x - M_L\right) + l_L\,c\,t - \sum_C^A \frac{s \cos\alpha}{E\,T}\left(H_C \cos\alpha - V_C \sin\alpha + H_L\right) = \sum_C^B \frac{y\,s}{E\,I}\left(M_C + H_C\,y - V_C\,x - M_R\right) - l_R\,c\,t + \sum_C^B \frac{s \cos\alpha}{E\,T}\left(H_C \cos\alpha + V_C \sin\alpha + H_R\right) \quad \ldots\ldots(26)$$

If $\sum_C^A$ and $\sum_C^B$ are designated, respectively, by $\sum_L$ and $\sum_R$, Equations (24), (25), and (26) simplify as follows:

$$M_C\left(\sum_L \frac{s}{I} + \sum_R \frac{s}{I}\right) + H_C\left(\sum_L \frac{s\,y}{I} + \sum_R \frac{s\,y}{I}\right) + V_C\left(\sum_L \frac{s\,x}{I} - \sum_R \frac{s\,x}{I}\right) = \sum_L \frac{M_L\,s}{I} + \sum_R \frac{M_R\,s}{I} \quad \ldots\ldots(27)$$

$$M_C\left(\sum_L \frac{x\,s}{I} - \sum_R \frac{x\,s}{I}\right) + H_C\left(\sum_L \frac{x\,y\,s}{I} - \sum_L \frac{s \sin\alpha \cos\alpha}{T} - \sum_R \frac{x\,y\,s}{I} + \sum_R \frac{s \sin\alpha \cos\alpha}{T}\right) + V_C\left(\sum_L \frac{x^2\,s}{I} + \sum_R \frac{x^2\,s}{I} + \sum_L \frac{s \sin^2\alpha}{T} + \sum_R \frac{s \sin^2\alpha}{T}\right) = \sum_L \frac{M_L\,x\,s}{I} - \sum_R \frac{M_R\,x\,s}{I} + \sum_L \frac{H_L\,s \sin\alpha}{T} - \sum_R \frac{H_R\,s \sin\alpha}{T} - c\,t\,E\,(h_L - h_R) \quad \ldots\ldots(28)$$

$$M_C\left(\sum_L \frac{y\,s}{I} + \sum_R \frac{y\,s}{I}\right) + H_C\left(\sum_L \frac{y^2\,s}{I} + \sum_R \frac{y^2\,s}{I} + \sum_L \frac{s \cos^2\alpha}{T} + \sum_R \frac{s \cos^2\alpha}{T}\right) + V_C\left(\sum_L \frac{x\,y\,s}{I} - \sum_R \frac{x\,y\,s}{I} - \sum_L \frac{s \sin\alpha \cos\alpha}{T} + \sum_R \frac{s \sin\alpha \cos\alpha}{T}\right) = \sum_L \frac{M_L\,y\,s}{I} + \sum_R \frac{M_R\,y\,s}{I} - \sum_L \frac{H_L\,s \cos\alpha}{T} - \sum_R \frac{H_R\,s \cos\alpha}{T} + c\,t\,E\,(l_L + l_R) \quad \ldots\ldots(29)$$

After the constant terms and the constant coefficients of M_C, H_C, and V_C are found, Equations (27), (28), and (29) are readily solved. If desired, the solution may be made in the general form, and expressions obtained from which the unknowns can be calculated directly, but the work is not expedited by this procedure.

After M_C, H_C, and V_C are found, the moments, thrusts, and shears at other points may be computed from Equations (7) left, (7) right, (18) left, and (18) right.

The horizontal and vertical components of the crown deflection are given by Equations (22) left, and (23) left, or by Equations (22) right, and (23) right. These formulas can be used for computing the deflection at points other than the crown, by carrying the summations from the abutment up only to the point at which the deflection is desired. The modulus of elasticity, E, is assumed as a constant, and may be placed outside the summation sign wherever convenient.

The deflections at intermediate points can be determined with less labor, however, by computing the movement within each voussoir separately, and taking the summation from the abutment toward the crown. The angular movement of any division, such as the one having its center at F, Fig. 14, is found by the summation of Equation (1), from A to F, thus:

$$\Delta\,\theta_F = \sum_F^A \frac{M\,s}{E\,I} \quad \ldots\ldots(30)$$

The actual linear movement of the upper end of the voussoir, due to this angular movement, is:

$$\Delta\,d_F = s \sum_F^A \frac{M\,s}{E\,I} \quad \ldots\ldots(31)$$

The movement, $\Delta\,d_F$, in Equation (31) is, practically, at right angles to the chord of the voussoir; that is, parallel to the radius through the center

of the voussoir. These movements for the various voussoirs are not in one direction, and cannot be added algebraically, as they stand. They may be combined graphically, or resolved into horizontal and vertical components, and then added. The components are obtained by multiplying Equation (31) by the cosine and sine of the angle to the center of the voussoir. Performing these multiplications and taking the summation from the abutment up, the total component movements of the upper end of the voussoir, F, are found to be:

$$\Delta x_F = \sum_F^A \left(s \cos \alpha \sum_F^A \frac{M s}{E I} \right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

$$\Delta y_F = \sum_F^A \left(s \sin \alpha \sum_F^A \frac{M s}{E I} \right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

Equations (30) to (33), inclusive, refer to movements due to bending only. The movements caused by change in length of the center line, due to thrust and temperature change, are parallel to the various chords. They are, therefore, normal to the movements due to bending and must be resolved separately. After the individual components for both bending and shortening have been found, they may be added separately, and then combined, or combined and then added. Where the work is done on a computing machine it is advantageous to determine the summation separately. The total movement in any voussoir from temperature and thrust, is,

$$\Delta s = s c t - \frac{H s}{E T} \quad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

Taking components and summating, the total horizontal and vertical movements at the upper end of the voussoir, F, due to temperature and rib-shortening, are

$$\Delta x_F = \sum_F^A \cos \alpha \left(s c t - \frac{H s}{E T} \right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

$$\Delta y_F = \sum_F^A \sin \alpha \left(s c t - \frac{H s}{E T} \right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

Equations (32) and (35) and Equations (33) and (36) may be combined if desired.

All the formulas deduced have been left in the general form. If the factor, s, is made constant for the entire arch, or for each side, it may be removed from the summation, or both s and I may be so removed if $\frac{s}{I}$ is constant. The modulus of elasticity, E, is presumably a constant, and may be placed outside the summation sign wherever convenient.

These equations do not differ essentially from those ordinarily given for the elastic arch, except in regard to the allowance for the elastic shortening of the arch rib. In the analysis of concrete bridge arches it is customary to base the rib-shortening stresses on the average thrust exclusive of the rib-shortening thrust. In long flexible arches this plan is sufficiently accurate for all practicable purposes. With short stiff arches, such as those encountered at the bottom of an arched dam, the magnitude of the rib-shortening thrust

becomes appreciable, and failure to make proper allowance in computing the average thrust is likely to lead to serious error. This approximation is eliminated from the equations herein deduced.

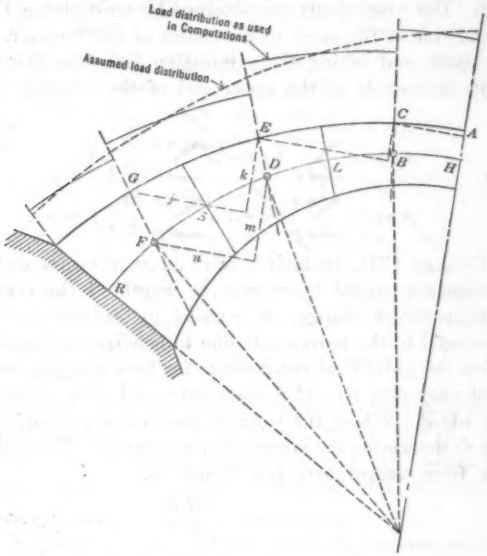

FIG. 15.

Applying this rule to Fig. 15, and considering the horizontal and vertical forces separately, the moment at F is, evidently,

$$M_F = M_D + n \sum_D^H p\ X + m \sum_D^H p\ Y + \frac{1}{2}\ n\ p\ j + \frac{1}{2}\ n\ p\ k \ldots (37)$$

In Equation (37), M_D is the total moment at D. $\sum_D^H p\ X$ is the vertical shear at D, $\sum_P^H p\ Y$ is the horizontal shear at D, X is the vertical load increment between D and F, and $p\ Y$ is the corresponding horizontal load increment. In Table 5, j and k are represented by X and Y, respectively, and n and m by Δx and Δy.

Accordingly, Equation (37) may be revised as follows:

$$M_F = M_D + \Delta x \left(\frac{1}{2}\ p\ X + \sum_D^H p\ X\right) + \Delta y \left(\frac{1}{2}\ p\ Y + \sum_D^H p\ Y\right). \quad (38)$$

Evidently, $\frac{1}{2}\ p\ X + \sum_D^H p\ X$ and $\frac{1}{2}\ p\ Y + \sum_D^H p\ Y$ are, respectively, the vertical and horizontal shear at S, and the moment equation may be further revised to read,

$$M_F = M_D + \Delta x \sum_S^H p\ X + \Delta y \sum_S^H p\ Y \ldots\ldots\ldots (39)$$

To facilitate the application of these formulas a computation form has been devised, as shown in Table 5. The arch used as an example is at Elevation 4 625 of the Gibson Dam, on the Sun River Project. (See, also, Table 4.)

In Table 5, Columns (1) and (4) represent basic data, taken from the drawing of the arch to be analyzed, T being the average thickness of the voussoirs, and α the radial angle from the crown to the center of the various voussoirs. Column (2) is used only in the derivation of the reciprocal of the moment of inertia, Column (3).

Column (5) is used for determining values of x and the vertical components of forces and movements. Column (6) is used for the computation of horizontal components of forces and deflections. Column (7) is for use in the computation of Column (12). Columns (8) and (9) are for use in the production of other columns containing these functions, and for insertion in the equations for determining the crown forces. The co-ordinates, x and y, Columns (10) and (12), are, respectively, the horizontal and vertical distances from the crown to the center of the voussoirs, as indicated in Fig. 14.

For a simple circular center line, x is equal to radius times sine α and y is equal to the radius times vers. α. The values of Δx and Δy, Columns (11) and (13), Table 5, may be obtained by taking the differences of consecutive values in Columns (10) and (12), respectively. For a non-circular, or compound arch center line, the values of the co-ordinates and their differences cannot be computed by the method outlined, and suitable changes in column designations and in the method of procedure will be required. Columns (14) and (15) are used in the preparation of other columns, and their sums are used in the determination of the crown forces.

The load co-ordinates, X and Y, Columns (16) and (17), Table 5, correspond to the differential co-ordinates, Δx and Δy, Columns (11) and (13), except that they are measured, or computed to the up-stream face of the dam. Where the water face and the center line of the arch are not concentric, the computations of these co-ordinates are complicated. They usually may be scaled with sufficient accuracy. The method of laying these co-ordinates out is shown on Fig. 15. The points, B, D, and F, are at the mid-points of the center lines of their respective voussoirs, and the lines, BC, DE, and FG, are radial to the water face of the dam. Obviously, the water load coming on the chord, FD, is included between the points, G and E, and similarly for the other chord lengths.

In Table 5, Column (18) contains one-half the average unit water loads for Divisions AC, CE, etc. The loads may be measured at the two ends of the divisions and averaged; or the measured, or computed, load at the center of each division may be taken as the average. Columns (19) and (20) show, respectively, one-half the vertical and horizontal loads on the voussoirs. Summations of the load components, from the crown toward the abutment, shown in Columns (21) and (22), are used to compute the water-load moments, M_L, and the water load thrusts, H_L, shown in Columns (23) and (24). A description of the method of computing these moments and thrusts will bring out the reasons for using half loads in Columns (18), (19), and (20).

In order that the moments at the various points of diversion may be computed progressively, use is made of the rule that the moment at any point is equal to the moment at a preceding point, plus the shear at the preceding point, times the distance between the two points, plus the moment of any intervening loads.

If only the moments were desired the load co-ordinates might be measured, therefore, between the ends, rather than the centers of the voussoirs, and the full water loads used. However, the water thrusts are functions of the shears at the centers of the voussoirs. For this reason the water loads are calculated and summed by halves, giving the load summations at both the centers and the ends of the voussoirs. Additional columns might be provided between Columns (22) and (23), in which to record and combine $\Delta x \Sigma p X$ and $\Delta y \Sigma p Y$ before summing. Table 5, as shown, is designed for use in connection with a computing machine, and no advantage results from recording intermediate steps. The only disadvantage in this plan is that it causes some confusion as to where the computed sums shall be recorded. It will be noted that two horizontal lines are provided in Table 5 for each voussoir. Functions that apply at the centers of the voussoirs are recorded opposite the numerals 1, 2, 3, etc., in the "point" column. These numerals represent the numbers of the voussoirs. Functions pertaining to the joints between voussoirs are recorded in the intermediate horizontal lines. The increment in moment to any voussoir center is obtained by multiplying the shear at the preceding voussoir end by the preceding value of Δx or Δy, and, if recorded, would be set down in the horizontal line intermediate between the two points to which it applies. However, when summated, these differences become the moments at the points, and, for clearness, should be dropped a half space when recorded in Column (23). The first moment recorded in Column (23), which comes at the center of the first voussoir, is obtained as follows:

$$18\,620 \times 14.58 + 490 \times 0.30 = 271\,627$$

The second moment, which is at the center of the second voussoir, is obtained by adding

$$73\,078 \times 29.08 + 3\,683 \times 2.35$$

to the previous moment; and the remainder are computed in a similar manner to the center of the last voussoir. Column (23), therefore, may be produced by multiplying, successively, in horizontal pairs, the voussoir joint values in Columns (21) and (22) by the corresponding values in Columns (11) and (13), recording a half space down, in Column (13), the sum of the products after the completion of each pair of multiplications. The computing machine must not be cleared between multiplications.

The thrusts, H_L, in Column (24) are obtained from the figures in Columns (21) and (22), as indicated, without continuous summation, the values being recorded opposite the numbers from which they are derived.

The derivation of Columns (25) to (27), inclusive, is evident. The summations of these columns complete the data required for the determination of the crown forces, from Equations (27), (28), and (29). A convenient form for use in the computation of the constants in these equations is arranged at

the end of Table 3. Space is also provided in which the computations for M_C, H_C, and V_C may be made.

Having obtained the crown forces, the moments and thrusts at intermediate points are readily computed, as shown in Columns (28) to (31), inclusive.

The remaining columns of Table 5 are useful in the determination of deflections and stresses. The method of computing the deflections may be explained by reference to Fig. 16. Because of the bending in the voussoir, AC, the tangent to the center line at C will be deflected from its original direction through a small angle, the value of which is,

$$\Delta \beta_B = \sum_C^A \Delta s \frac{M}{E I} \quad \ldots\ldots (40)$$

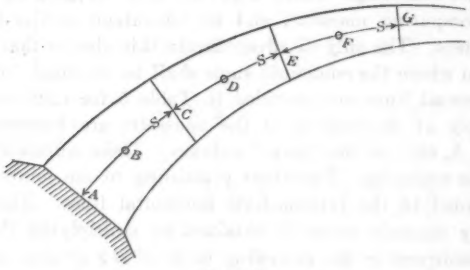

FIG. 16.

If the values of M and I as computed in Table 5 for the point, B, are taken as the average values for the voussoirs, Equation (40) may be written thus:

$$\Delta \beta_B = s \frac{M_B}{E I_B} \quad \ldots\ldots (41)$$

This bending will continue through the succeeding voussoirs, the increments for the voussoirs with centers at D and F being, respectively,

$$\Delta \beta_B = s \frac{M_D}{E I_D} \quad \ldots\ldots (42)$$

$$\Delta \beta_F = s \frac{M_F}{E I_F} \quad \ldots\ldots (43)$$

The total angular movement at E, the upper end of Voussoir D, is, therefore,

$$\beta_E = s \frac{M_B}{E I_B} + s \frac{M_D}{E I_D} = \sum_E^A s \frac{M}{E I} \quad \ldots\ldots (44)$$

The movement at G is, likewise,

$$\beta_E = s \frac{M_B}{E I_B} + s \frac{M_D}{E I_D} + s \frac{M_F}{E I_F} = \sum_F^A s \frac{M}{E I} \quad \ldots\ldots (45)$$

The average angular movement for any voussoir may be taken as the angular movement at its center. Therefore, in Fig. 16, the summations should

be made to the points, B, D, F, etc., if the average angles are desired. In each case, such a summation will include only one-half the last $\Delta\beta$. For this reason half values of $\frac{M}{I}$, Column (33), is obtained by adding each half value in Column (32) twice, reading the summation between the first and last additions of each half value. The factor, s, is omitted from Column (33), to be introduced later, in Column (34). This is possible only when s is constant throughout the length over which the summation is made. The modulus of elasticity, E, is likewise omitted from this column.

These angular movements cause the points along the arch center to be displaced in space. The point, C, will move with reference to A, a distance,

$$\delta_C = \frac{1}{2}\, s\, \beta_C = \frac{1}{2}\, s^2\, \frac{M_B}{E\, I_B} \qquad (46)$$

The direction of motion will be approximately parallel to the radius at B.

The point, E, will move with reference to C, approximately parallel to the radius at D, a distance,

$$\delta_E = s\, \beta_C + \frac{1}{2}\, s\, \Delta\beta_D = \sum_D^A s^2\, \frac{M}{E\, I} \qquad (47)$$

It should be noted that δ_E is the movement of E with reference to C. The movement of E with respect to A will be the geometric sum of δ_C and δ_E. This sum can be most readily obtained by resolving δ_C and δ_E into horizontal and vertical components and adding the components. In the example, Table 5, the individual moments are shown in Column (34). The vertical components of these individual movements are obtained by multiplying each term in Column (34) by the corresponding value of cos α, as recorded in Column (6). The individual components are not recorded in Table 5. The summed products are shown in Column (35); the multiplications are made successively, beginning at the bottom of the column, without clearing the computing machine; and the total is recorded after each operation a half space above the last factors used. The values shown in Column (35) are the vertical deflections of the upper ends of the voussoirs, due to bending only. The horizontal deflections, due to bending, shown in Column (40) are computed in the same way, substituting — sin α for cos α. The minus sign is required in Column (40) for the left half of the arch because of the negative horizontal movement.

In addition to the deflections caused by bending, points on the arch center line are displaced due to changes in length of the voussoirs. The amount that each voussoir will shorten, due to thrust, is shown in Column (36) and the net shortening due to thrust and temperature is shown in Column (37). The values in Column (37) multiplied by — sin α and summed, from the abutment toward the crown, as shown in Column (38), give the vertical deflections due to change in length of the arch center line. In the same way, using — cos α, the horizontal deflections are derived, as shown in Column (41). The negative cosines are required because a positive thrust and a negative temperature change produce negative horizontal and vertical deflections for the left half of the arch.

The total y-deflections, obtained by adding Columns (35) and (38), are shown in Column (39); and the total x-movements, the sum of Columns (40) and (41), are shown in Column (42). These component deflections give the complete computed displacement, in space, of points at the ends of the voussoirs, as C, E, and G, Fig. 16. The resultant radial deflections may be obtained as indicated in Column (43).

The eccentricity, Column (44), is obtained by dividing the moment by the thrust, and is required only when the line of pressure is to be platted, or the portion of the section subject to tension determined. Columns (45) and (46) show, respectively, the average direct pressure and the unit fiber stress due to moment. Both columns are divided by 144 to convert the stresses into pounds per square inch.

The final maximum and minimum fiber stresses are shown in the two columns, which are derived from Columns (45) and (46) as indicated. This numerical example refers to a symmetrical case. Table 5 may be extended to unsymmetrical arch dams by inserting the following columns: (7a), $\frac{\sin \alpha}{T}$; (8a), $\frac{\sin^2 \alpha}{T}$; (9a), $\frac{\sin \alpha \cos \alpha}{T}$; (13$a$), $\frac{x}{I}$; (14a), $\frac{x^2}{I}$; (15a), $\frac{x\,y}{I}$; (25a), $\frac{M_L\, x}{I}$; (26a), $\frac{H_L \sin \alpha}{T}$; (28$a$), $V_C\, x$; and (30a), $V_C \sin \alpha$.

The constants required in the computations may be determined as shown in Table 6, the subscripts, L, denoting the left half of the arch, and R, denoting the right half. Use arch data values, as follows: For the left half: $s = 29.176785$ ft.; $l = 260.992$ ft.; R (up stream) $= 405.00$ ft.; and $t = -6°$. For the right half: $s = 29.176785$ ft.; $l = 260.992$ ft.; R (crown) $= 360.8$ ft.; $c = 0.0000056$; and $E = 288\,000\,000$. Then,

$$c\,t\,E = 0.0000056 \times 288\,000\,000 \times 6 = 9\,676.8$$

$$\frac{c\,t\,E\,l_L}{s} = \frac{0.0000056 \times 6 \times 288\,000\,000 \times 260.992}{29.176785} = -86\,560.87$$

$$\frac{s^2}{E} = \frac{29.176785^2}{288\,000\,000} = 0.0000029558$$

$$\frac{s}{E} = \frac{29.176785}{288\,000\,000} = 0.0000001013$$

$$c\,t\,s = 0.0000056 \times 6 \times 29.176785 = 0.00098$$

Use Table 6 to solve the following simplified equations:

$$A_1\, M_C + B_1\, H_C + C_1\, V_C = D_1 \quad \ldots\ldots (48)$$

$$C_1\, M_C + B_2\, H_C + C_2\, V_C = D_2 \quad \ldots\ldots (49)$$

$$B_1\, M_C + B_3\, H_C + B_2\, V_C = D_3 \quad \ldots\ldots (50)$$

Example.—

By Equation (48):

$$0.00184206\, M_C + 0.052223537\, H_C + 0 = 41\,457.477$$

By Equation (50):

$$0.052223537\, M_C + 3.30428902\, H_C + 0 = 2\,277\,028.44$$

Solving simultaneously and eliminating M_C,

$$H_C = 604\,086 \text{ lb.}$$

and,

$$M_C = 5\,379\,826 \text{ ft-lb.}$$

The constants given in Table 6 without arithmetical values will be needed in some of the problems encountered.

From Equation (51), the distribution of p can be calculated. The result is given in Table 7.

Equation (51) is not only valid for a load, p, applied very near the abutment, as p in Fig. 17(a), but it gives directly the ratio of the shear forces in two sections, one horizontal and the other vertical, through a point of the foundation. (See Fig. 17(b).) The shear transmitted to Point A by the cantilever, $A\,B$, and that transmitted to the same point by the arch, $A\,C$, that is, the total cantilever and arch shear, must be in the ratio prescribed by Equation (51), and independent of the elastic characteristics of the dam.

Alfred Stucky* has investigated the Jogne Arch Dam and has determined the division of the water load both with and without temperature variations. Fig. 17(c) shows a horizontal section through the dam at Elevation 790. Stucky determined the load distribution (no temperature variation) in the points marked O, I, II, III, and IV. Point O is the crown, and Point IV is practically at the abutment. In Fig. 17(d) the center line of the arch is developed and the load is divided in the same manner as in the authors' diagrams. The values as given by Stucky are shown in Table 8.

Point IV at the abutment, having a "50-50" division, corresponds to an angle, ϕ, of 45° (Fig. 17(a)).

At Elevation 770, Point II is practically at the abutment and there the arch takes only about 8% of the water load; at Elevation 760, Point I lies at the abutment and there the arch takes 66% of the water load. The load taken by the arch at the abutment is not constantly zero, as assumed by the authors, but varies between wide limits, depending on the slope at each particular point.

TABLE 7.—Distribution of p in Fig. 17(a), Between Arch and Cantilever.

Angle, ϕ, in degrees.	Percentage of Total Load, p.	
	Arch.	Cantilever.
0	0	100
30	36.6	63.4
45	50.0	50.0
60	63.4	36.6
90	100.0	0

The authors have made an attempt to deal with the secondary arch, see Figs. 10, 11, and 15. This leads to difficulties because, in Fig. 15, the angles, $G\,F\,R$, $E\,D\,S$, etc., are not right angles. The ordinary bending theory assumes the sections to be normal to the center line and leads to incorrect results when it is applied to oblique sections.† These uncertainties and inaccuracies may have a considerable influence on the bending moments and deformations and involve the whole calculation in serious difficulties, especially in thick arches where the assistance of the cantilever would be appreciable.

The mathematics seem somewhat laborious, but each individual will no doubt work out his own methods of computations along his own particular lines. The fact that the authors have dropped the usual assumption, that the arch is symmetrical, materially complicates the work. Of course, this assumption is, strictly speaking, always incorrect, but it does materially simplify the calculations. Judging from Fig. 5, in which the section is not particularly symmetrical and the loading is practically so, the assumption that the arches are loaded symmetrically does not lead one far astray, except perhaps in unusual cases.

GEORGE R. RICH,* ASSOC. M. AM. SOC. C. E. (by letter).—This excellent paper contributes materially toward a satisfactory evaluation of the many pertinent factors affecting the stresses in an arched dam that has been carefully pressure-grouted near the time of minimum temperature to insure the permanent simultaneous action of both horizontal and vertical elements.

For the short thick arches in the lower sections of the dam, the writer believes that the deflections caused by shearing stresses should not be neglected. He has attempted to show in the following analysis that this effect may be readily included with very little additional labor.

The original notation of the authors has been preserved, with one addition:

Q = the sum of the components of all external forces between the point and the crown, perpendicular to the axis at a given point.

In the formulas given herewith, a subscript, L, refers to the left of the crown and a subscript, R, refers to the right. Table 9, which gives a classification of the various deflection components, is of assistance in writing the basic crown deformations. In this table, E is the modulus for direct stress in all cases. For a rectangular section with parabolic shear distribution, the shear deflection,

$$\Delta = \frac{6}{5} \int \frac{Q\, q\, d\, s}{E_s\, T}$$

in which E_s is the shear modulus. For concrete,

$$E_s = \frac{E}{2.4}, \text{ or } \Delta = 2.88 \int \frac{Q\, q\, d\, s}{E\, T}$$

The mathematics seem somewhat laborious, but each individual will no doubt work out his own methods of computations along his own particular lines. The fact that the authors have dropped the usual assumption, that the arch is symmetrical, materially complicates the work. Of course, this assumption is, strictly speaking, always incorrect, but it does materially simplify the calculations. Judging from Fig. 5, in which the section is not particularly symmetrical and the loading is practically so, the assumption that the arches are loaded symmetrically does not lead one far astray, except perhaps in unusual cases.

George R. Rich,* Assoc. M. Am. Soc. C. E. (by letter).—This excellent paper contributes materially toward a satisfactory evaluation of the many pertinent factors affecting the stresses in an arched dam that has been carefully pressure-grouted near the time of minimum temperature to insure the permanent simultaneous action of both horizontal and vertical elements.

For the short thick arches in the lower sections of the dam, the writer believes that the deflections caused by shearing stresses should not be neglected. He has attempted to show in the following analysis that this effect may be readily included with very little additional labor.

The original notation of the authors has been preserved, with one addition:

Q = the sum of the components of all external forces between the point and the crown, perpendicular to the axis at a given point.

In the formulas given herewith, a subscript, L, refers to the left of the crown and a subscript, R, refers to the right. Table 9, which gives a classification of the various deflection components, is of assistance in writing the basic crown deformations. In this table, E is the modulus for direct stress in all cases. For a rectangular section with parabolic shear distribution, the shear deflection,

$$\Delta = \frac{6}{5} \int \frac{Q\, q\, d\, s}{E_s\, T}$$

in which E_s is the shear modulus. For concrete,

$$E_s = \frac{E}{2.4}, \text{ or } \Delta = 2.88 \int \frac{Q\, q\, d\, s}{E\, T}$$

* Engr., Hydr. Div., Stone & Webster Eng. Corporation, Boston, Mass.

in which, q is the shear on the differential element, when a load of 1 lb. is applied to the structure at the point where, and in the direction which, the deflection is desired.*

TABLE 9.—CLASSIFICATION OF DEFLECTION FACTORS.

Bending.	Shear.	Direct stress.
$\Delta\phi = \sum \frac{M\,s}{E\,I}$	$\Delta\phi = 0$	$\Delta\phi = 0$
$\Delta h = \sum \frac{M\,y\,s}{E\,I}$	$\Delta h = 2.88 \sum \frac{Q\,s \sin\alpha}{E\,T}$	$\Delta h = \sum \frac{H\,s \cos\alpha}{E\,T}$
$\Delta v = \sum \frac{M\,x\,s}{E\,I}$	$\Delta v = 2.88 \sum \frac{Q\,s \cos\alpha}{E\,T}$	$\Delta v = \sum \frac{H\,s \sin\alpha}{E\,T}$

Referring to Fig. 14 and Table 9, the motion clockwise of the crown section, left half, equals the motion clockwise of the crown section, right half:

$$+\sum_L \frac{M_L\,s}{E\,I} - \sum_L \frac{V_C\,x\,s}{E\,I} - \sum_L \frac{H_C\,y\,s}{E\,I} - \sum_L \frac{M_C\,s}{E\,I} = -\sum_R \frac{M_R\,s}{E\,I} + \sum_R \frac{M_C\,s}{E\,I} - \sum_R \frac{V_C\,x\,s}{E\,I} + \sum_R \frac{H_C\,y\,s}{E\,I} \quad \ldots(52)$$

The downward motion of the crown section, left half, equals the downward motion of the crown section, right half:

$$\begin{aligned} &+\sum_L \frac{M_L\,x\,s}{E\,I} - \sum_L \frac{V_C\,x^2\,s}{E\,I} - \sum_L \frac{H_C\,x\,y\,s}{E\,I} - \sum_L \frac{M_C\,x\,s}{E\,I} \\ &+\sum_L \frac{H_L\,s \sin\alpha}{E\,T} - \sum_L \frac{V_C\,s \sin^2\alpha}{E\,T} + \sum_L \frac{H_C\,s \sin\alpha \cos\alpha}{E\,T} \\ &-h_L\,c\,t + 2.88 \sum_L \frac{Q_L\,s \cos\alpha}{E\,T} - 2.88 \sum_L \frac{V_C\,s \cos^2\alpha}{E\,T} \\ &-2.88 \sum_L \frac{H_C\,s \sin\alpha \cos\alpha}{E\,T} = +\sum_R \frac{M_R\,x\,s}{E\,I} + \sum_R \frac{V_C\,x^2\,s}{E\,I} \\ &-\sum_R \frac{H_C\,x\,y\,s}{E\,I} - \sum_R \frac{M_C\,x\,s}{E\,I} + \sum_R \frac{H_R\,s \sin\alpha}{E\,T} + \sum_R \frac{V_C\,s \sin^2\alpha}{E\,T} \\ &+\sum_R \frac{H_C\,s \sin\alpha \cos\alpha}{E\,T} - h_R\,c\,t + 2.88 \sum_R \frac{Q_R\,s \cos\alpha}{E\,T} \\ &+2.88 \sum_R \frac{V_C\,s \cos^2\alpha}{E\,T} - 2.88 \sum_R \frac{H_C\,s \sin\alpha \cos\alpha}{E\,T} \quad \ldots\ldots(53) \end{aligned}$$

The motion to the right of the crown section, left half, equals the motion to the right of the crown section, right half:

$$\begin{aligned} &+\sum_L \frac{M_L\,y\,s}{E\,I} - \sum_L \frac{V_C\,x\,y\,s}{E\,I} - \sum_L \frac{H_C\,y^2\,s}{E\,I} - \sum_L \frac{M_C\,y\,s}{E\,I} \\ &-\sum_L \frac{H_L\,s \cos\alpha}{E\,T} + \sum_L \frac{V_C\,s \sin\alpha \cos\alpha}{E\,T} - \sum_L \frac{H_C\,s \cos^2\alpha}{E\,T} \end{aligned}$$

* "Deflections and Statically Indeterminate Stresses," by C. W. Hudson, M. Am. Soc. C. E.

$$+ l_L c t + 2.88 \sum_L \frac{Q_L s \sin \alpha}{E T} - 2.88 \sum_L \frac{V_C s \sin \alpha \cos \alpha}{E T}$$
$$- 2.88 \sum_L \frac{H_C s \sin^2 \alpha}{E T} = - \sum_R \frac{M_R y s}{E I} - \sum_R \frac{V_C x y s}{E I}$$
$$+ \sum_R \frac{H_C y^2 s}{E I} + \sum_R \frac{M_C y s}{E I} + \sum_R \frac{H_R s \cos \alpha}{E T} + \sum_R \frac{V_C s \sin \alpha \cos \alpha}{E T}$$
$$+ \sum_R \frac{H_C s \cos^2 \alpha}{E T} - l_R c t - 2.88 \sum_R \frac{Q_R s \sin \alpha}{E T}$$
$$- 2.88 \sum_R \frac{V_C s \sin \alpha \cos \alpha}{E T} + 2.88 \sum_R \frac{H_C s \sin^2 \alpha}{E T} \ldots\ldots (54)$$

The terms involving shear deformations can be easily identified by the coefficient, 2.88. By transposing, the simultaneous equations for the crown forces are obtained. In setting up numerical equations, the terms involving $\sum \frac{s \sin \alpha \cos \alpha}{T}$ and $2.88 \sum \frac{s \sin \alpha \cos \alpha}{T}$, may be combined; in this derivation they have been left separate to show, by comparison with the authors' original, what terms represent shear deformations:

$$M_C \left(\sum_L \frac{s}{I} + \sum_R \frac{s}{I} \right) + H_C \left(\sum_L \frac{s y}{I} + \sum_R \frac{s y}{I} \right)$$
$$+ V_C \left(\sum_L \frac{s x}{I} - \sum_R \frac{s x}{I} \right) = \sum_L \frac{M_L s}{I} + \sum_R \frac{M_R s}{I} \ldots\ldots (55)$$

$$M_C \left(\sum_L \frac{x s}{I} - \sum_R \frac{x s}{I} \right) + H_C \left(\sum_L \frac{x y s}{I} - \sum_R \frac{x y s}{I} \right.$$
$$- \sum_L \frac{s \sin \alpha \cos \alpha}{T} + \sum_R \frac{s \sin \alpha \cos \alpha}{T} + 2.88 \sum_L \frac{s \sin \alpha \cos \alpha}{T}$$
$$\left. - 2.88 \sum_R \frac{s \sin \alpha \cos \alpha}{T} \right) + V_C \left(\sum_L \frac{x^2 s}{I} + \sum_R \frac{x^2 s}{I} + \sum_L \frac{s \sin^2 \alpha}{T} \right.$$
$$\left. + \sum_R \frac{s \sin^2 \alpha}{T} + 2.88 \sum_L \frac{s \cos^2 \alpha}{T} + 2.88 \sum_R \frac{s \cos^2 \alpha}{T} \right)$$
$$= \sum_L \frac{M_L x s}{I} - \sum_R \frac{M_R x s}{I} + \sum_L \frac{H_L s \sin \alpha}{T} - \sum_R \frac{H_R s \sin \alpha}{T}$$
$$+ 2.88 \sum_L \frac{Q_L s \cos \alpha}{T} - 2.88 \sum_R \frac{Q_R s \cos \alpha}{T} - c t E (h_L - h_R) \ldots (56)$$

$$M_C \left(\sum_L \frac{y s}{I} + \sum_R \frac{y s}{I} \right) + H_C \left(\sum_L \frac{y^2 s}{I} + \sum_R \frac{y^2 s}{I} \right.$$
$$+ \sum_L \frac{s \cos^2 \alpha}{T} + \sum_R \frac{s \cos^2 \alpha}{T} + 2.88 \sum_L \frac{s \sin^2 \alpha}{T}$$
$$\left. + 2.88 \sum_R \frac{s \sin^2 \alpha}{T} \right) + V_C \left(\sum_L \frac{x y s}{I} - \sum_R \frac{x y s}{I} \right.$$
$$- \sum_L \frac{s \sin \alpha \cos \alpha}{T} + \sum_R \frac{s \sin \alpha \cos \alpha}{T} + 2.88 \sum_L \frac{s \sin \alpha \cos \alpha}{T}$$
$$\left. - 2.88 \sum_R \frac{s \sin \alpha \cos \alpha}{T} \right) = \sum_L \frac{M_L y s}{I} + \sum_R \frac{M_R y s}{I}$$

$$-\sum_L \frac{H_L\, s \cos \alpha}{T} - \sum_R \frac{H_R\, s \cos \alpha}{T} + 2.88 \sum_L \frac{Q_L\, s \sin \alpha}{T}$$
$$+ 2.88 \sum_R \frac{Q_R\, s \sin \alpha}{T} + c\, t\, E\, (l_L + l_R) \ldots\ldots\ldots\ldots (57)$$

It can be readily seen that these equations are identical with those of the authors, with the exception of the terms added for shear movements.

After working through the various differential deflections, the writer has some appreciation of the difficulty of avoiding errors in algebraic sign in spite of careful checking. For this reason he would ask that Mr. Howell verify these additions to Equations (27), (28), and (29), and then compute the division of load for a thick, short-radius arch (such as the Gibson Dam at Elevation 4 530), first, considering shear deflections, and, second, neglecting shear deflections so that a comparison may be available to the profession.

In computing the movements of thick cantilever elements, the same attention should be given to each of the deflection groups: For bending, $\int \frac{M\, m\, d\, s}{E\, I}$; and for shear, $\frac{6}{5} \int \frac{Q\, q\, d\, s}{E_s\, A}$, in which, m and q are the moment and shear, respectively, on the differential element caused by a load of 1 lb. acting on the structure at the point where, and in the direction which, the deflection is desired. M and Q are the general expressions for moment and shear, respectively, on any differential element due to the external loads. The writer would feel indebted to Mr. Howell for incorporating this deformation in the numerical example requested.

The writer hopes that the final closure of the dam by pressure-grouting will eventually disclose great latent possibilities for fixing the limiting stresses in the arches under the assumed range of temperature. This case appears somewhat analogous to the erection of a spandrel-braced steel arch bridge. After starting erection by cantilevering from back-stays, the bottom chord of the bridge is closed at the crown as a three-hinged arch for dead load; then hydraulic jacks are inserted into the top chord; stresses are induced corresponding to the two-hinged condition for dead and live load, and the final riveting is done under the two-hinged condition. A prohibitive length of time is required for the total dissipation of the chemical heat liberated by the setting of large masses of concrete in an arch dam; in addition, a fast construction schedule may make a closure in the summer months imperative. Under such conditions, it would still be at least theoretically possible to preclude vertical shrinkage cracks by inducing compressive stresses of magnitude sufficient to cancel the tensions caused later by shrinkage. The effect of a rise in temperature in raising compressive stresses would also have to be carefully anticipated; but the compressive stresses seldom reach their limiting values, and a given increase in unit compressive stress is much more readily accommodated than the occurrence of a tension of equal magnitude.

The adequate drainage both of the dam proper and the foundation rock, and also the insertion of grout pipes in the bed-rock near the heel, prime requirements of every modern design, amply warrant the uplift assumption

used by the authors for the cantilever elements, namely, full head-water pressure at the heel diminishing to zero at the toe, and acting over one-half the base section.

The present indications are that foundation deformations do have an appreciable effect on the division of load between arches and cantilevers. Similarly, when the phenomena of water-soakage are more clearly defined, commensurate refinements can be applied to this valuable method of attack.

The writer is thoroughly sympathetic with the author's "Conclusions". It is to be hoped that ultimately a rational theory embracing all the really pertinent elements can be made available in the form of curves; in the pursuit of this ultimate object, the paper deserves careful study.

C. A. P. TURNER,* M. AM. SOC. C. E. (by letter).—The authors are entitled to appreciation of the profession for their laborious effort to place the design of curved dams on a more rational basis. The increase in strength and economy of the curved vertical dam over that of the straight gravity type is little appreciated because of a fundamental misconception regarding its mode of resistance. In elementary mechanics the student is taught that the applied moment of an external force is the product of that force times its lever arm. Applied moment is an abstract quantity, balanced either by internal bending or twisting resistance, depending on the manner of support, restraint, and the form of the resisting section.

In many cases the internal resistance of the member considered is entirely bending resistance. In others, such as the shaft, the internal resistance is almost wholly that of twisting resistance. In the square plate supported on four sides the resistance to flexure is half bending and half twisting. A curved dam, because it is fixed at the base so that it cannot deflect down stream, tends to oppose water pressure predominantly by twisting, rather than by arch action. The applied external force consists of the normal hydraulic pressure that increases uniformly, downward from the top, along the vertical up-stream face.

The horizontal reaction between the dam and its base is represented by the sum of the horizontal down-stream components of the hydraulic pressures on a vertical up-stream face. The components of these pressures parallel to the chord of the arc of the dam furnish the external reactions to the internal ring compression in the arched masonry or concrete of the dam. The intensity of these ring stresses for an economic design are small relative to those developed by the twisting shears.

A curved dam may be considered analogous to a vertical curved plate rigidly restrained at the base and ends, and subject to the pressure of parallel forces. These tend to twist the plate along its length, causing a maximum rotation at the deepest part. As the action is a twisting one there must be both a positive and a negative twisting deformation. Were the plate free at the base, restrained at its end, and then twisted from the center, the points of equilibrium would be at the quarter-points and a vertical plane at a quarter-point would be the locus of equilibrium of the positive and negative

* Cons. Engr., Minneapolis, Minn.

twisting shears. However, because the arch is rigid both at its base and at its ends at the quarter-point of the free crest, the direction of the plane of equilibrium will rotate from the vertical to an angle of 45° with the horizontal projection of the crest of the dam.

In a plate deformed by twisting and bending, contours of curvature may be developed by graphic methods as applied to uniform elastic plates supported, restrained, and bent in any manner as previously outlined by the writer. To apply the method to the curved plate of the dam, treat the down-stream component of the pressures separately as these component pressures and the reactions thereto constitute the applied torsional forces.

The first step in this analysis is to fix the travel of the pressure toward its support. This travel of the load or pressure follows a straight line and in the case of plates which are twisted these lines intersect at some given point which may be termed a focus. The plane of equilibrium of the positive and negative twist would represent one of these planes of zero shear and the focus of intersection of the other planes will lie along this line at some point to be determined. Curves of greatest shear will be normal to those of zero shear and the co-ordinated intersections will determine one series of the twisting shear curves. The co-ordinated intersections of the planes of zero shear and of greatest twist will fix another or complement series of twisting shears in the opposite direction from the first set. Symmetrical intersections of the twisting shears will fix the contours of curvature which are principal stress lines at the mid-thickness of the plate.

Because when an element is twisted in one direction on one side of the plate and in the other direction on the other side, equilibrium will occur at mid-length, there are two independent series of shear curve intersections which locate the same principal stress line or contours of curvature.

In Fig. 18, a graphic analysis is offered of an opening between rock walls similar in form to the experimental dam at Stevenson Creek, in which the sides have a slope of 45 degrees. The first problem is to locate the foci of the planes of zero shear representing the transference of the down-stream hydraulic pressure to its reaction at the base. Because the crest of the dam is free to deform in an elastic manner, the length of the projected positive and negative twisting deformation will be equal and the deflection of the crest will pass through zero at the quarter-point of its down-stream projected length. The equilibrium of the positive and negative twisting, that occurs at the mid-thickness on a line at 45° to the crest, will represent one plane of zero shear and the focus of the series or pencil of planes of zero shear will lie somewhere along the length of this line.

The abscissa of the focus for each respective side of the dam about its center line will lie at the same distance from the center as the center of the line of equilibrium of the positive and negative twist, because twisting deformation accumulates along the length of the member twisted and this length fixes the horizontal position of the focus.

It is then necessary to co-ordinate the lines of greatest shear, greatest twist, and zero shear. For this purpose it is generally convenient to use four equal

divisions for the co-ordinates in the positive and negative areas, respectively, treating the twist about the vertical as productive of equal shifts. Equal pressures must be represented by the spacing of the horizontal planes of greatest twist; that is, take the water pressure increasing from zero at the crest to a maximum at the bottom, and the projected crest of the dam will be the first plane of greatest twist. The half depth will represent the second

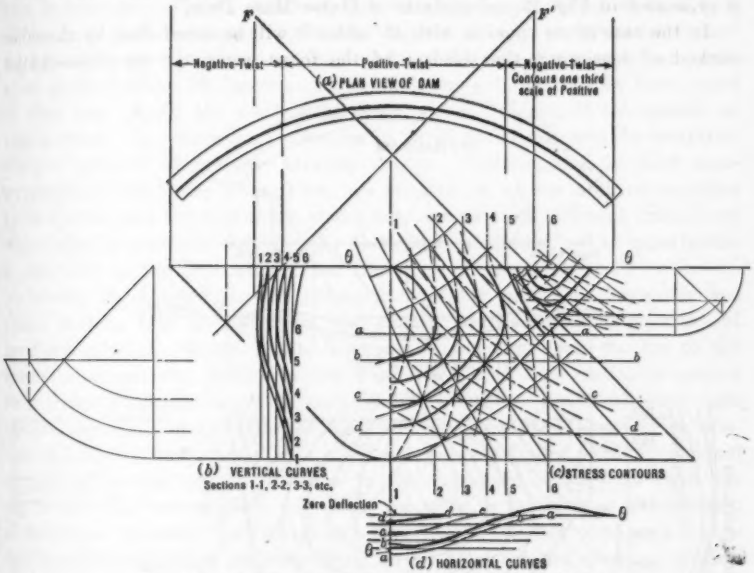

FIG. 18.—GRAPHIC ANALYSIS, STEVENSON CREEK DAM.

plane, and 0.7071 times the depth at the center will represent the third, etc. The vertical areas between the planes of greatest twist will represent equal areas of pressure. Having divided the vertical pressure (for the positive area twisted) into equal pressure areas or parts, it is necessary to co-ordinate the circular curves of greatest shear by dividing the vertical height (from the crest to the base) into four equal parts and drawing circles from the foci as a center to represent the curves of greatest shear. Then the twisting spirals are drawn as shown in Fig. 18 (*b*) and (*d*) and the contours of curvature, Fig. 18(*c*), are located therefrom. The area of negative twist is treated in like manner.

In treating the negative area of curvature from twist by proceeding along like lines the contours would represent a different magnitude of negative deflection. This difference would vary in proportion as the depth of the base of the negative area varies with the depth of the base from the water level in the positive area. On this scale, the deflection curves may be readily co-ordinated and contours interpreted. As applied to the Stevenson Creek Dam, the graphic method develops deflections in striking agreement with those measured.

As the method outlined is general rather than special it must also apply to a different form or shape of opening between rock walls. Its accuracy as a general solution is to be judged by the rationality of the result developed by wide variation in the areas of positive and negative twisting. A rectangular opening between rock walls, nearly as deep or deeper than the width, will give a satisfactory opportunity for the application of the method. This is presented in Fig. 19, an analysis of Horse Mesa Dam.

In the case of an opening with 45° sides it will be noted that, by the same method of reasoning, the abscissa of the focus occurs at the three-eighths

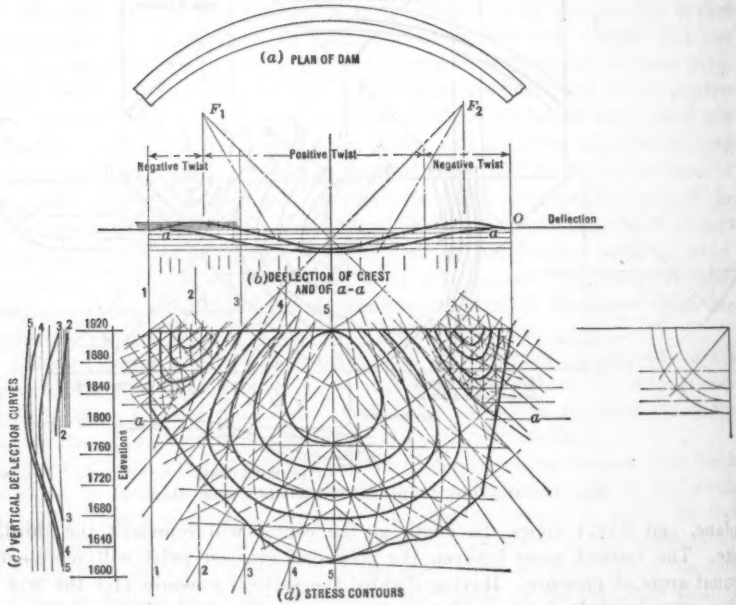

FIG. 19.—GRAPHIC ANALYSIS OF CURVED DAM, HORSE MESA DAM PROFILE.

point of the half chord of the arc. For the rectangular opening it occurs at the quarter-point measured, in each case, from the end of the arc. Thus, the focus shifts horizontally and vertically with the change in the configuration of the opening. In like manner the relative spacing of the planes of greatest twist change, in the positive and negative areas, with the change in configuration of the opening.

It is now possible to compare the contours determined by this method and the exact method of torsional analysis. The authors have assumed that all the load is carried by the horizontal and vertical elements instead of diagonally in the most direct line to the support. The contours in Fig. 9 form a cusp at the vertical center line of the dam. It is a fundamental property of internal elastic stress as stated by Eddy* that the stress on an

* "Graphical Statics," 1878.

ideal plane of division that traverses any given point of a body cannot change suddenly, either as to direction or magnitude, while that plane is turning in any way about the given point. A sudden change can only take place at a surface where there is change in the material.

Because a contour of curvature is identical with the principal stress line at the mid-thickness of the plate, the error embodied in the authors' assumption is apparent. The direction of the contour of zero deflection in Fig. 9 differs from the true contour by convex instead of concave curvature toward the negative area. In direction it differs from the true direction by an angle equal to from 45 to 80 degrees. Accordingly, as principal stress lines, some of them may occupy the position of shear curves. Hence, if interpreted as tensile stress, the strength of concrete in shear resistance may be mistaken for the weakness of concrete in pure tension. Furthermore, in their computations of the Horse Mesa Dam, no recognition of the area of negative twist appears and the formation of the contours is quite different from those which may be correctly developed by the graphical method or by experiment, as was done at the Stevenson Creek Dam.

It may be objected that in presenting graphic methods, the writer has failed to take into consideration the change in the torsional moment of inertia incident to change in the thickness of the dam from the top to the bottom and that any method which would disregard such variation cannot be considered approximate even to a moderate degree. Such criticism fails to take into consideration the fact that the graphic method determines relative not actual deflections; that a fairly wide variation in the torsional moment of inertia (due to increase in the thickness of the dam from the top toward the bottom) does not affect the relative position or the location of deflection contours. For that reason the graphic analysis presents a simple and expeditious manner of determining elastic behavior and a correct method of finding the distribution of the reaction along the length of the dam. With this distribution known it should not be difficult to compute the vertical couples which oppose overturning and the stresses resulting therefrom.

The trial-load method endeavors to treat a torsional phenomenon as if there were a flexural equivalent thereto, to wit, cantilever action and arch action. As the trial-load method depends on distribution of the applied pressure toward the support in vertical and horizontal directions, the resultant of these distributions at each unit of vertical height may readily be determined. It will then be found that the resultants do not follow a regular law of distribution and do not, in the most direct manner, convey the pressure to its support as required by the law of least work.

The twisting moments brought into action by the restraint of the dam at its base and ends takes effect by changing the direction of the pressure and altering the distribution of the reaction thereto along the base of the dam. The effect of any variation in thickness under such action differs wholly from the phenomenon of flexure and the graphic method permits an analytical investigation of the variation in contours of relative deflection to the extent that they are affected by the variation in form and thickness of the structure.

The curves of greatest shear are, of necessity, circles drawn from the foci as centers. The planes of greatest twist are fixed by the intensity of the applied hydraulic pressure such that their spacing, per unit, represents equal pressure areas. The only variation then, that may be effected by a change in the thickness of the dam, is the position of the focus and spacing of the radials of zero shear and the depth of the negative area. Provided the crest of the dam is made of a constant width, the point of inflection (where the positive twisting changes into negative) will remain substantially fixed and the spacing of the radials (because they depend on this locus) remain unchanged even though the lower portion of the dam is increased in thickness.

The deflection is reduced by thickening the dam at the base, but the locus of the contours of equal deflection remains substantially fixed because the co-ordinates that determine the twisting shears remain substantially fixed. An abrupt change in the thickness would affect the accuracy of this generalization. That the function of the curved dam is to oppose twisting moments rather than flexure substantiates the trend of practice toward a more uniform section along the length of the dam than has been practiced in many examples of older construction.

An acceptable elastic analysis must be verified by its elastic deportment. Unfortunately, the elastic behavior of curved dams has been investigated systematically only in the single example of the Stevenson Creek Dam.*

Deflection of the dam is shown graphically in diagonal projection in Fig. 20. A similar diagonal projection of the relative deflections, determined graphically from Fig. 18, may be compared therewith. It will be noted that the contours of negative twist fix a slightly different curvature from that shown in the report of Engineering Foundation, referred to, in that the restraint at the end of the dam manifests itself in an additional point of contraflexure neglected by the draftsman in drawing the curves through measured points on the experimental dam. This does not show a difference in relative deflections where measured, but rather tends to correct an error of interpretation of the measurements made. The curved contour of zero deflection, measured at Stevenson Creek, matches those determined by the graphic method.

Every elastic plate or curved dam, in which sudden jogs in the thickness of the material are avoided, will deflect in a smooth regular curve and contours, whether determined graphically or by computation, and, if rational, should determine smooth consistent flexure curves. The results, by graphic analysis, treating the arch resistance as torsion (Fig. 18), present such curves. The diagonal projection of Fig. 20 may be compared to the Progress Report No. 3, of Engineering Foundation, and the agreement between the relative theoretical and measured deflections is sufficiently close to carry conviction.

In the experiments on the Stevenson Creek Dam, a slight shrinkage crack on the surface was noted, which was observed to close up as the water pressure approached the crest of the dam. This results from the ring stresses by the component of the hydraulic pressure parallel to the chord of the arch.

* See Progress Rept. No. 3, Engineering Foundation, Fig. 2.

The graphic method of analysis permits the simple derivation of the curves of flexure of a plate bent in any manner and subjected to any kind of restraint, manner of support, or applied load. This solution is not always obvious but, when once worked out, the procedure is simple and the method gives the investigator an exact conception of the displacement curves and equi-potential curves, in addition to the curves of shear and principal stress. It permits the development of the contours of distortion which the plane normal section undergoes during the twisting action.

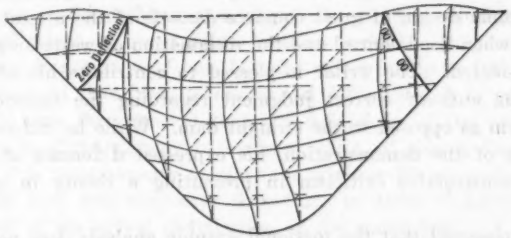

FIG. 20.—DIAGONAL PROJECTION OF CONTOURS OF DEFLECTION, GRAPHIC ANALYSIS, STEVENSON CREEK DAM.

For example, in a round shaft under torsion, half the end area is increased in length and half decreased. The entire area within a radius of $0.7071R$ is elongated by the radial compressions and circular tensions developed in the twisting process. If the cross-section is square, the rotational couples about consecutive radii are not equilibrated by uniform intensity of the shearing stress in the normal planes as is the case in the circular shaft. The result is a deformation consisting of alternate octantal bulge and depression which, in a particular octant, is dependent on the direction of the twisting force.

When the shape of the specimen is changed to rectangular, and the long side is one and one-half times the breadth, the alternate bulge and depression occur in alternate quadrants and in the case of a curved dam the area of depression would be the upper down-stream quadrant. The quadrants of bulging distortion would be the upper up-stream and the lower down-stream quadrants. This torsional distortion would manifest itself in a thrust at the base, although the elastic strain therefrom would be relatively slight as measured in the Stevenson Creek experiments.

Torsional analysis of the curved dam indicates that material has been used with lavish wastefulness in the deeper portion of the dam and, in general, it has been thinned down too rapidly toward the ends. A more uniform section is better adapted to resist the torsional stresses and would result in greater strength with less material.

The economic form of the arch in a V-opening is a third degree curve rather than a circular one. Such a structure, to be well proportioned, should cut the cost of the ordinary gravity dam in half allowing a greater degree of safety. This is particularly true when the concrete is properly reinforced,

thereby insuring toughness, dependability, and resistance to temperature stress.

In pure bending, the distance the load is shifted in its travel to the support, multiplied by the weight shifted, equals the applied moment. Therefore, in torsion, the distance the pressure is shifted by twist, times its weight, equals the portion of applied moment balanced thereby when the shift lies in the plane of action of the applied moment. In the straight dam this shift does not lie in the plane of the over-turning moment and therein the curved dam derives its great advantage over the straight dam.

Safe economic design of great concrete dams is of the utmost importance to the public when flood control and the reclamation of waste areas by irrigation are considered. The writer is pleased to contribute his effort in substantiating the authors' correct judgment regarding the superior merit of the curved dam as opposed to the straight dam. While he differs with them in the details of the demonstration, his expressed difference of opinion is intended as constructive criticism in presenting a theory in accord with experiment.

It will be observed that the torsional graphic analysis does not primarily take the curvature of the dam into consideration; that is, it is applicable alike to the straight and curved dam, but it deals only with the torsional effects in distributing the load along the base. Torsion shifts pressure or shear in its transfer to the support. In the curved dam there is a down-stream shift by virtue of curvature, accompanying the longitudinal shift.

In a V-opening the longitudinal shift distributes the reaction at a higher elevation and may thereby reduce the applied moment a substantial amount in either a straight or a curved dam. The shift of the reaction along the base when the dam is curved, has a down-stream component and this adds to the lever arm of the reaction in opposing over-turning moment. The sharper the curvature the greater the arm; also the greater the length of the dam. A balance between the disadvantage of increased cost of additional length and the advantage of greater lever arm and reduced thickness, constitutes the problem of economic design.

In an examination at a school of engineering, if the student should undertake to compute the strength of a shaft by a beam formula, he would be considered deficient in knowledge of the principles of elementary mechanics; and yet many post-graduate engineers, with years of experience, undertake to calculate the torsional problem of the curved dam by the ordinary old beam formula for a gravity type structure unadapted to the conditions of the problem.

In conclusion, the credit for this graphic solution is in a large measure due to the laborious and painstaking effort of Messrs. Howell and Jaquith in their endeavor to reduce curved dam analysis to a rational basis. Interest in their work and an attempt to analyze it led to the writer's first application of graphical principles to the problem under discussion. Ernest McCulloh, M. Am. Soc. C. E., assisted in the preparation of this discussion and furnished many helpful suggestions.

F. H. CONSTANT,* M. AM. SOC. C. E. (by letter).—The authors present four general conclusions to which the writer wishes to add comments, as follows:

1.—If the cantilever acts, the arch elements are not under uniform loading. With this conclusion the writer is in hearty accord. Any treatment of arches which considers only uniform loading is of little practical importance in the solution of arch dams.

2.—Computing proportionate loads and deflections in the two systems at one vertical section only, such as at the crown of the arches, is not sufficient for the solution of the problem as a whole. A complete solution should find coincident deflections at every point in every section. It is clear that the method of trial is not an easy one, but the writer has gone far enough with it to feel convinced that in spite of its real difficulties, it is practical. He found (as did also the authors) that the deflections of the cantilevers are very sensitive to slight changes of loading, while, of course, the stresses are not. Hence, it is not necessary to carry the trials so far as to secure absolute coincidence of arch and cantilever deflections in order to arrive at a close approximation of the actual distribution of the water load.

3.—Rational formulas, for a complete solution, must take account of the shape of the canyon. The trial method does this by using a great many vertical and horizontal sections. It is not possible to do it by direct mathematical means. The rational formulas that have been heretofore devised fit only special and very simple cases, and any attempt to adapt them to some other type of dam section makes them hopelessly complex.

4.—In place of the authors' fourth conclusion the writer presents somewhat simpler formulas for the special (and yet very common) case of the circular dam of constant thickness throughout any horizontal section and symmetrical relative to the vertical section at the crown. Unsymmetrical dams do occur, of course, but on the whole there is a general symmetry about most narrow profiles. The dams cited by the authors are quite symmetrical.

The writer also feels justified in treating the case of arches of constant thickness. The curve of pressure in an arch dam does not deviate from the axis of the arch nearly as much as in arch bridges, and there would not seem to be any necessity for varying the thickness, except possibly at the very end. In an approximate solution of the Stevenson Creek Dam, assuming a parabolic distribution of the water load, and neglecting temperature effects, the writer found that the curve of pressure remained practically within the middle third throughout, at least in the upper 40 ft. of the dam. It would be possible to change the shape of the arches slightly to conform more closely with the curve of pressure, and thus eliminate all but temperature moments. The error thus introduced in using the formulas for circular arches would be negligible.

The following formulas were derived from the principle of work by well-known methods and the derivations will not be given. They have been carefully checked by independent methods and are believed to be correct. For example, the deflections check by Maxwell's principle of reciprocal deflections.

* Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

The following notation (see Fig. 21), has been used. All angles refer to the half arch. They are in radians, when they occur alone; in degrees, when they occur in functions:

ϕ_1 = the central angle between the center and the end of arch;
ϕ = the central angle to the point at which the moment is required;
θ = the central angle to the point of application of the concentrated load, P;
θ_1 = the central angle to the point at which the deflection is required;
D = the radial deflection of the arch at θ_1 due to a pair of symmetrical radial loads, P;
R = the radius of the axis of the arch;
I = the moment of inertia of the arch, with a vertical width of 1 ft.;
t = the constant horizontal thickness of the arch;
M_0 = the bending moment at the crown, produced by a pair of symmetrical radial loads, P;
H_0 = the horizontal thrust at the crown, produced by a pair of symmetrical radial loads, P;
M = the bending moment at a section, under the same loading;
P = the applied radial force, taken as unity. There is a symmetrical force on the other half of the arch (not shown in Fig. 21);
p_1, p_2, etc. = intensities of water pressure on the arch at Points 1, 2, etc.;
E = the modulus of elasticity of concrete. If the same value of E is used for the cantilevers, it may be omitted from the equations in equalizing deflections. The deflections found, then, will be E times the actual deflection;
$A = t$ = area of cross-section of an arch element, in square feet; and,

$$C = \frac{\sin \phi_1}{\phi_1}.$$

$$M_0 = R\,\frac{1 - \cos(\phi_1 - \theta)}{\phi_1} - H_0\,R\left(1 - \frac{\sin \phi_1}{\phi_1}\right) \quad \ldots\ldots\ldots (58)$$

$$H_\theta = \frac{\frac{1}{2}\left[\sin(\phi_1 - \theta)\sin\phi_1 - (\phi_1 - \theta)\sin\theta\right] - C\left[1 - \cos(\phi_1 - \theta)\right]}{\frac{1}{4}\sin 2\phi_1 - 2\,C\sin\phi_1 + \phi_1\left(\frac{1}{2} + C^2\right) + \frac{I\,\phi_1}{A\,R^2}\left(= \frac{t^2\,\phi_1}{12\,R^2}\right)} \quad \ldots\ldots\ldots (59)$$

$$M = M_0 - R\sin(\phi - \theta) - H_0\,R(\cos\phi - C) \quad \ldots\ldots\ldots (60)$$

$$\frac{E\,I}{R^2}\,D = (M_0 + C\,R\,H_0)\left[1 - \cos(\phi_1 - \theta_1)\right] - \frac{R}{2}\left[\left(\phi_1 - \begin{matrix}\theta\\ \theta_1\end{matrix}\right)\cos(\theta - \theta_1)\right.$$
$$\left. - \sin\left(\phi_1 - \begin{matrix}\theta\\ \theta_1\end{matrix}\right)\cos\left(\phi_1 - \left(\begin{matrix}\theta_1\\ \theta\end{matrix}\right)\right)\right] - \frac{R\,H_0}{2}\left[\sin(\phi_1 - \theta_1)\sin\phi_1\right.$$
$$\left. - (\phi_1 - \theta_1)\sin\theta_1\right] \quad \ldots\ldots\ldots (61)$$

In the double value expressions, $\begin{matrix}\theta\\ \theta_1\end{matrix}$ and $\begin{matrix}\theta_1\\ \theta\end{matrix}$, use the upper values if $\theta > \theta_1$; the lower values if $\theta_1 > \theta$.

By varying the angles in Equations (58) to (61) influence values for the four quantities, in all the arches, can be found. The computations should be made in tabular form and they then become quite simple and mechanical. They should be made with a calculating machine, and all results set down to at least six decimal places.

Fig. 23 is a typical deflection influence line. It shows the change in deflection at the crown of the top arch as a pair of radial unit loads move from the crown symmetrically over the left and right halves of the arch, respectively.

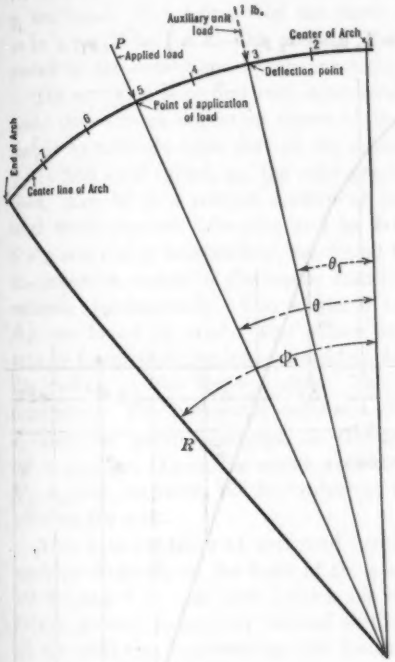

FIG. 21.

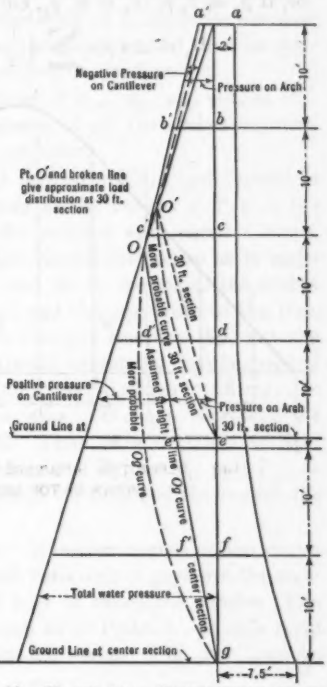

FIG. 22.—WATER LOAD DISTRIBUTION DIAGRAM.

An assumption is now made in regard to the variation in radial water pressure along any horizontal arch. If the intensity of the radial water pressure, p, is uniform along the arch, the deflection at any point would be the area of the corresponding influence line multiplied by p. If p is not uniform, but varies in some assumed manner, as shown in Fig. 23(*b*), the deflection of any arch at any point can be found as follows.

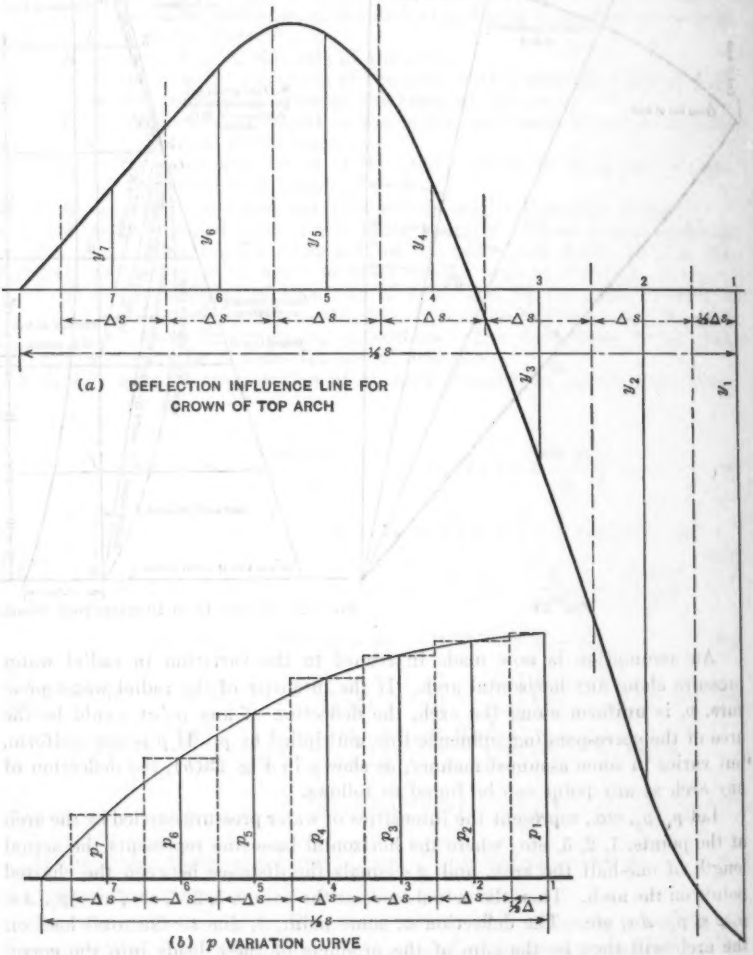
Let p_1, p_2, etc., represent the intensities of water pressure carried by the arch at the points, 1, 2, 3, etc., where the horizontal base line represents the actual length of one-half the arch, and Δs equals the distance between the charted points on the arch. Then the actual loads at the points, 1, 2, 3, etc., are $\frac{1}{2}p_1$, Δs, $p_2 \Delta s$, p_3 Δs, etc. The deflection at some point, 3, due to the total load on the arch will then be the sum of the products of these loads into the corresponding ordinates of the influence line for Point 3 of that particular arch. It is best to express p_2, p_3, etc., as some fraction of p_1. For example, to find

the deflection, D_3, at the point, 3, of an arch, let the ordinates in the influence line at 1, 2, 3, etc., be y_1, y_2, y_3, etc. Then,

$$D_3 = \Delta s \sum \left(\frac{1}{2} p_1 y_1 + p_2 y_2 + \cdots \right)$$

or, if $p_2 = k_2 p_1$, $p_3 = k_3 p_1$, etc.,

$$D_3 = \Delta s \, p_1 \sum \left(\frac{1}{2} y_1 + k_2 y_2 + k_3 y_3 + \cdots \right) = K_3 p_1$$



(a) DEFLECTION INFLUENCE LINE FOR CROWN OF TOP ARCH

(b) p VARIATION CURVE

FIG. 23.

For the assumed distribution and the given deflection influence lines, values of K can be obtained for each point of each arch, and the deflection

of that point will be known as soon as p_1 is found. It might be convenient to construct a complete table of the values of K to include all the charted points, using some notation such as K_{13}, K_{25}, etc., meaning thereby, Point 3 of Arch 1, Point 5 of Arch 2, etc. The values of K_{11}, K_{21}, etc., will give the crown deflections of the several arches as soon as the corresponding values of p_1 are found. For a first trial the curve of variation of p might be assumed to be a parabola, for all the arches. Further modification will then be suggested by the deflections which parabolic distribution produces.

The next step is to find such numerical values of p_{11}, p_{21}, p_{31}, etc., as will cause the vertical deflection curve of the crowns of all the arches approximately to coincide with that of the center cantilever.

To find such values, p_1, the semi-graphical method of Cain and Noetzli is used. Fig. 22 is a vertical section of the dam at the crown; $a\ g'\ g$ is the total water-pressure triangle; and by trial the positive and negative areas, $O\ g'\ g$ and $O\ a'\ a$, respectively, are found by the Noetzli method so as to make the deflection curves of the center cantilever and of the crowns of the arches coincide approximately. The points, O and a', and the curvature of the line, $O\ g$, are found by trial. The writer used a straight line for $O\ g$, but the authors found that $O\ g$ has a considerable outward curvature, thus increasing the loading on the lower arches. The writer's investigation confirms this conclusion. The horizontal ordinates of the area, $g\ O\ a'\ a\ g$, represent the p_1-values, or crown pressures, on the arches. Thus (Fig. 22), $aa' = p_{11}$; $bb' = p_{21}$; etc. Then, the crown arch deflections are, $D_{11} = K_{11}\ p_{11}$; $D_{21} = K_{21}\ p_{21}$; etc., in which, the first subscript indicates the arch and the second, the point on the arch.

After a coincidence of arch and cantilever deflection curves at the crown has been obtained, on the basis of the assumed variation of pressure throughout the length of each arch (which for short may be called the p-curve (Fig. 23(b)), proceed to another vertical section, such as at Point 3. At this point all the ordinates representing the loading on the arches (Fig. 22), namely, aa', bb', etc., must be reduced in the fixed ratio, $\frac{p_3}{p_1} = k_3$. The point, O, will accordingly lie nearer the top, and the lower part of the diagram is cut off to conform to the ground level. The dotted lines in Fig. 22 represent the approximate condition. The cantilever and arch deflection curves are constructed as at the crown in the usual manner. Thus, the deflection curve of the arches at Section 3 can be drawn from $D_{13} = K_{13}\ p_{11}$; $D_{23} = K_{23}\ p_{21}$; etc., in which, $p_{11} = aa'$; $p_{21} = bb'$, etc. (Fig. 22). If the p-curve has been correctly assumed these arch and cantilever deflection curves should be coincident at Section 3. If they are not, within reasonable limits, a new p-variation curve, or a different center section distribution (Fig. 22) will have to be assumed until a fair check is obtained. For accurate results several sections should be tested in this manner.

Instead of a parabolic variation of water pressure on a horizontal arch the authors have used Fig. 5(c), "Final Proportional Load," which shows a nearly uniform distribution over the middle two-thirds of the arch, decreasing

rapidly to zero near the ends. As the area enclosed is greater than that by a parabola having the same center height, the use of such a curve instead of the parabola would result in increased calculated compressive fiber stresses.

The writer is led to believe, as a result of his own investigations on a similar dam, that the proportionate load distribution found by the authors, and shown in their Figs. 5 and 7, must be nearly correct. It is obvious, as experience is acquired in the use of this method, closer first assumptions will be made and the goal reached much more quickly than at present.

The writer wishes to express his appreciation of the valuable assistance given by Joseph B. Reynolds, Professor of Mathematics, Lehigh University, and D. B. Sloan, Jun. Am. Soc. C. E. Professor Reynolds checked all the mathematical work and made valuable suggestions which led to the present compact form of the working equations.

F. W. HANNA,* M. AM. SOC. C. E. (by letter).—The trial and error method of analysis used by the authors conforms to the customary mathematical practice of solving involved equations by successive approximations. The method, therefore, will produce reliable results, if the fundamental equations are based on sound assumptions. However, in any mathematical problem, it is more satisfactory to proceed by direct methods if it is economical and feasible to do so.

The authors have given a comprehensive and clear development of stress and deflection formulas comprising the effects of bending moment and thrust, but have omitted the very important effects of shear which, in the lower arches of a high arch dam, are too great to be neglected. The writer has found, in dams of this type, that the effects of shear amount to as much as 12½%, or more, on computed compressive stresses, 146% on tensile stresses, and 3% on crown deflections.

Using the authors' nomenclature and Fig. 14, the movement of C about D due to shear distortion may readily be found and combined with the movements due to bending moment and thrust. Consider the voussoir, the center of which is D. Let Δr be the radial movement of its upper end relative to its lower end; V, the radial shear at D acting negatively inward; E', the modulus of elasticity of the masonry in shear; and V_L, the shear at D due to the water load between C and D. The following relations may now be written:

$$\Delta y = \sum_C^A \Delta r \cos \alpha \quad \ldots\ldots (62)$$

$$\Delta x = -\sum_C^A \Delta r \sin \alpha \quad \ldots\ldots (63)$$

$$\Delta r = \frac{n V s}{E' T} = \frac{3 V s}{E T} \quad \ldots\ldots (64)$$

$$V = H_C \sin \alpha + V_C \cos \alpha + V_L \quad \ldots\ldots (65)$$

* Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

$$\Delta y = 3 \sum_C^{A_0} \frac{\cos \alpha}{E\,T} (H_C \sin \alpha + V_C \cos \alpha + V_L) \ldots\ldots\ldots (66)$$

$$\Delta x = -3 \sum_C^{A_0} \frac{\sin \alpha}{E\,T} (H_C \sin \alpha + V_C \cos \alpha + V_L) \ldots\ldots\ldots (67)$$

The value of Δy and Δx given in Equations (66) and (67) may now be added to Equations (22) and (23), respectively. Proceeding in a manner similar to that followed by the authors in the development of Equations (28) and (29), and noting that Δx and V_C should have their signs changed for the right half of the arch, new general equations, Equations (68) and (69), have been derived that include the combined effects of bending moment, thrust, and shear. Since shear does not affect the value of $\Delta \phi$ in Equation (10), Equation (27) remains unchanged; but Equations (28) and (29) are changed as follows:

$$M_C \left(\sum_L \frac{x\,s}{I} - \sum_R \frac{x\,s}{I} \right) + H_C \left(\sum_L \frac{x\,y\,s}{I} - \sum_R \frac{x\,y\,s}{I} + 2 \sum_L \frac{s \sin \alpha \cos \alpha}{T} - 2 \sum_R \frac{s \sin \alpha \cos \alpha}{T} \right) + V_C \left(\sum_L \frac{x^2\,s}{I} + \sum_R \frac{x^2\,s}{I} + \sum_L \frac{s \sin^2 \alpha}{T} + \sum_R \frac{s \sin^2 \alpha}{T} + 3 \sum_L \frac{s \cos^2 \alpha}{T} + 3 \sum_R \frac{s \cos^2 \alpha}{T} \right) = \sum_L \frac{M_L\,x\,s}{I} - \sum_R \frac{M_R\,x\,s}{I} + \sum_L \frac{H_L\,s \sin \alpha}{I} - \sum_R \frac{H_R\,s \sin \alpha}{T} - 3 \sum_L \frac{V_L\,s \cos \alpha}{T} + 3 \sum_R \frac{V_R\,s \cos \alpha}{T} - c\,t\,E\,(h_L - h_R) \ldots\ldots\ldots\ldots\ldots\ldots (68)$$

$$M_C \left(\sum_L \frac{y\,s}{I} + \sum_R \frac{y\,s}{I} \right) + H_C \left(\sum_L \frac{y^2\,s}{I} + \sum_R \frac{y^2\,s}{I} + \sum_L \frac{s \cos^2 \alpha}{T} + \sum_R \frac{s \cos^2 \alpha}{T} + 3 \sum_L \frac{s \sin^2 \alpha}{T} + 3 \sum_R \frac{s \sin^2 \alpha}{T} \right) + V_C \left(\sum_L \frac{x\,y\,s}{I} - \sum_R \frac{x\,y\,s}{I} + 2 \sum_L \frac{s \sin \alpha \cos \alpha}{T} - 2 \sum_R \frac{s \sin \alpha \cos \alpha}{T} \right) = \sum_L \frac{M_L\,y\,s}{I} + \sum_R \frac{M_R\,y\,s}{I} - \sum_L \frac{H_L\,s \cos \alpha}{T} - \sum_R \frac{H_R\,s \cos \alpha}{T} - 3 \sum_L \frac{V_L \sin \alpha}{T} - 3 \sum_R \frac{V_R \sin \alpha}{T} + \frac{c\,t\,E}{s} (l_L + l_R) \ldots\ldots\ldots\ldots\ldots\ldots (69)$$

M_C, H_C, and V_C, having been computed by means of Equations (27), (68), and (69), the moments, thrusts, and shears may be computed by Equations (7), (18) and (65).

If the arch is assumed to be symmetrical, Equations (27), (68), and (69) may be greatly simplified; and inasmuch as generally in the design of an arch dam it is possible and desirable to make each arch symmetrical, it will be of interest and of value to impose the conditions of symmetry on these equations. In this procedure the $\sum_L$ and $\sum_R$ for like quantities are equal

and algebraically additive. Having due regard for signs, dividing by 2 in each case, and omitting the effects of temperature, Equations (27), (68) and (69) assume the following forms:

$$M_C \sum_L \frac{s}{I} + H_C \sum_L \frac{s\,y}{I} = \sum_L \frac{M_L\,s}{I} \quad \ldots\ldots\ldots\ldots (70)$$

$$V_C = 0 \quad \ldots\ldots\ldots\ldots (71)$$

$$M_C \sum_L \frac{y\,s}{I} + H_C \left(\sum_L \frac{y^2\,s}{I} + \sum_L \frac{s \cos^2 \alpha}{T} + 3 \sum_L \frac{s \sin^2 \alpha}{T} \right) = -\sum_L \frac{M_L\,y\,s}{I} - \sum_L \frac{H_L\,s \cos \alpha}{T} - 3 \sum_L \frac{V_L \sin \alpha}{T} \quad \ldots\ldots\ldots (72)$$

M_C, V_C, and H_C, for the left half of the arch, having been found from Equations (70), (71) and (72), the moments, thrusts, and shears for the left half of the arch may be found by use of Equations (7) and (18) and Equation (65), by noting that the V_C-terms become zero. The moments, thrusts, and shears will be the same, of course, for corresponding voussoirs for the right half of the arch.

The authors have extended the customary method of distributing the computed water load on an arch dam between the horizontal arches and the single vertical cantilever through the crowns on the basis of relative rigidity. In making this extension, the cantilevers are assumed to deflect in radial planes perpendicular to the extrados of the dam. There is considerable error involved in this assumption. The sections of the horizontal arches cannot deflect in a radial direction except at the crown, and the divergence from a radial direction increases from the crown of the arch toward the abutments. All the lateral cantilevers, therefore, will be affected by the torsional force of each intersecting arch that tends to twist them around into coincidence with the motion of the arch. This tendency will be different for the horizontal arches because of their variable lengths, thicknesses, and loads. Moreover, the components of the arch-deflecting forces perpendicular to the radial plane through the central axes of the cantilevers have different intensities in the various arches, and they will tend to distort the cantilever tangentially and warp it out of shape in this direction also. The lateral cantilevers are, therefore, not only called upon to carry their share of the water load in the assumed radial directions, but must resist torsional stresses and lateral distortion stresses of considerable amounts. In this they are not dependent on their resistance alone, but on the enormous torsional and tangential resistance of the dam itself.

In order to show the directions and amounts of the deflections for various points in any single arch element and in different arch elements of the same dam, the writer has had the deflections computed for two circular symmetrical arches each of 100 ft. mean radius and 120° central angle; one with a uniform thickness of 4 ft. and a normal load of 2 500 lb. per sq. ft.; the other with a uniform thickness of 20 ft. and a normal load of 12 500 lb. per sq. ft. The results are given in Table 10 and Figs. 24 and 25 show the deflection of the 20-ft. arch ring, as an example.

It will be noted that the points, A, B, C, and D, at 15° intervals on the center line of the arches, $L\,R$ (Fig. 24), are deflected to the points, A', B',

C', and D'. To measure the deflections divide the scale values by 1 000. Curve I is the locus of points bisecting the deflections $A\,A'$, $B\,B'$, etc. The deflection of D is coincident with the assumed radial deflection of the cantilever, but the deflections at C, B, and A diverge from radial deflections by 7° 27′, 16° 59′, and 31° 27′, respectively. This lack of direction coincidence will cause torsional stress in the cantilevers. $A''\,A'$, $B''\,B'$, and $C''\,C'$, perpendicular to the respective radii, may be taken to represent graphically the peripheral deflections necessary to make the movements of the cantilevers coincide

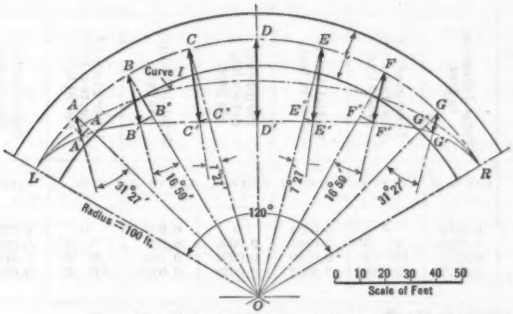


FIG. 24.—SECTION THROUGH ARCH RING.

with those of the arches. Since the points, A, B, C, and D, must deflect to the same respective points in the arches and cantilevers, the cantilevers must be distorted laterally by considerable amounts. In Fig. 25 four curves are plotted, that are of interest in connection with this subject, Curve A showing the total deflections, AA', etc.; Curve B, the radial deflections, AA'', etc.; Curve C, the peripheral deflections, $A''\,A'$, etc.; and Curve D, the divergence of the arch deflections from radial lines.

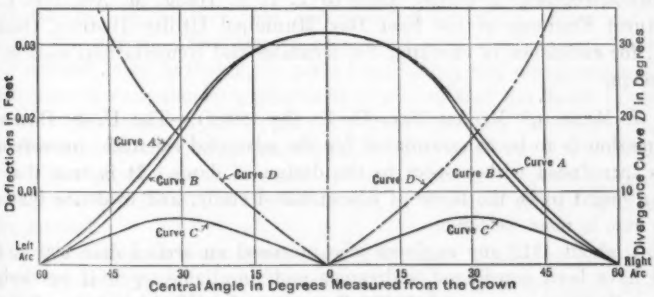

FIG. 25.—DEFLECTIONS OF ARCH RING.

In addition to the torsional and lateral distorsion forces already referred to as affecting the lateral radial cantilevers, these cantilevers are also affected by the moment, thrust, and shearing forces of the arches, gravity, and water pressure, all of which must be taken into consideration in determining their value

in the distribution of stresses in the dam. In view of these conditions, it appears that cantilevers other than the crown cantilever must be used with great care and keen judgment in order to appraise their true value in determining stress distribution in arch dams.

† $t = 4$ ft.; $w = 2\,500$ lb. per sq. ft.
‡ $t = 20$ ft.; $w = 12\,500$ lb. per sq. ft.

While the writer prefers to use the elastic center, rigid bracket, unit load method of developing arch deflection and stress formulas and a series of cantilevers of varying widths, each symmetrical with respect to a vertical section through the arch crowns of the dam, he feels that the authors have presented an excellent method of arch analysis and have rendered the Engineering Profession a distinct service for which they deserve its thanks.

Acknowledgment is hereby made to T. L. E. Haug, M. Am. Soc. C. E., Structural Engineer of the East Bay Municipal Utility District, Oakland, Calif., for assistance in checking the formulas and computations used in this discussion.

L. J. MENSCH,* M. AM. SOC. C. E. (by letter).—The U. S. Bureau of Reclamation is to be congratulated for the advanced scientific improvements it has introduced with respect to the design of dams. It is true that this Bureau ought to be the home of concentrated study, and evidence that such is the case is most welcome.

Until about 1912 any engineer who proposed an arched dam 300 ft. high would have been considered a dreamer and unreliable, even if he designed it for cylindrical stresses of 30 000 lb. per sq. ft. Nothing but a full-sized gravity dam, with an additional safeguard provided by making it an arched structure, was considered proper. Although quite a large number of successful arch dams—many of them considerably less than 100 ft. in height—had been built in the United States and foreign countries since 1870, con-

* Chicago, Ill.

servative engineers would not favor them because the distribution of stress in such structures appeared to them a mystery.

Since 1904, the Society has published quite a number of papers and discussions, in which many earnest workers have tried to clear up this subject. The general trend has been to solve the problem by assuming the arched structure to consist of two systems of members, namely, a horizontal system of arches fixed at the abutments and a vertical system of cantilevers fastened to the bed-rock.

The writer has shown, by the use of the elastic theory,* that the stresses in such horizontal arches of relatively considerable thickness are much greater than those given by the cylinder formula. He also showed that the assumed vertical cantilevers behave more like beams simply supported at the base of the dam rather than rigidly fixed at that point. Other efforts have been made to explain the arch action by the same two systems of members, giving simplified approximate formulas.† William Cain, M. Am. Soc. C. E., has treated‡ the thick cylindrical arch in a more general form.

These papers only showed that there are very much higher stresses than were formerly supposed in horizontal arches and cantilevers, but they did not explain the safety of many existing daring arched dam structures. It has been known for more than ten years that theoretical investigations along the old line were futile and the writer has previously pointed out§ that, in thick sections, secondary arches are formed which are stable and which prevent the failure of the main arch. He has also shown that arches of increased thickness at the abutments are much more economical than arches of uniform thickness.

The engineers of the Bureau of Reclamation, according to the authors, also have adopted the system of horizontal arches and vertical cantilevers, but have gone farther than the previous designers by investigating the influence of the cantilevers not only in the center of the dam, but also those nearer the abutments. In addition, they have assumed secondary arches and arches of increasing depth. They deserve great credit for this advance because it finally enabled them to design, in perfect confidence and along rational lines, arched dams of such slender proportions as no engineer has dared to consider since the construction of the Upper Otay Dam in 1900. The fact is that the dams discussed by the authors show stresses of from 80 000 to 100 000 lb. per sq. ft., if computed by the common cylinder formula (neglecting cantilever action), and from 120 000 to 190 000 lb. per sq. ft., if calculated by Professor Cain's method.

The paper shows the enormous amount of labor it takes to design such a dam by the trial method, and the slow steps by which the latest perfected design was reached. It is possible, however, to obtain results with a still

greater economy of material and labor by using more calculus and less arithmetic in the design.

Before showing this simpler method the writer wishes to restate the theory of arches under normal loads.

Let $A\,C\,B$ (Fig. 26) be the center line of a circular arch of a constant width of 1 ft. and a constant depth of t, subjected to water pressure of p lb. per sq. ft. If this arch were considered to be free at the abutments, and to act as a portion of a full circular cylinder subjected to uniform normal pressure, it would diminish in diameter and take a new position, A', C', B', concentric to its original position. The diminution of radius can be found by the following consideration: The shortening of the whole cylinder equals uniform stress per square foot, $\frac{(p\,r)}{t}$, times length of periphery of cylinder, $(2\,r\,\pi)$, divided by modulus of elasticity, (E).

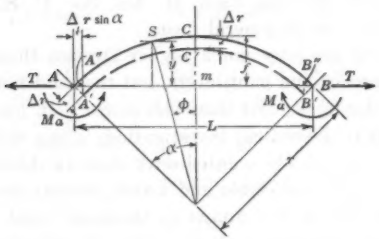

FIG. 26.

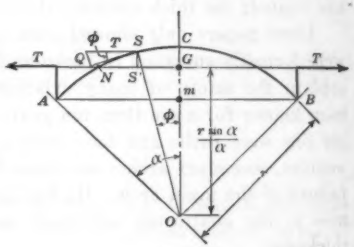

FIG. 27.

Dividing the shortening of the cylinder by $2\,\pi$ gives the shortening of the radius,

$$\Delta\,r = \frac{p\,r}{t} \times \frac{2\,r\,\pi}{E} \times \frac{1}{2\,\pi} = \frac{p\,r^2}{E\,t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (73)$$

From Fig. 26 it can be seen that the chord of the unrestrained arch, A', C', B', has been shortened in each half of the span an amount, $A\,A''$, equal to $\Delta\,r \sin \alpha$, or the shortening of one-half the arch span,

$$\Delta\,x = \Delta\,r \sin \alpha = \frac{p\,r^2}{E\,t} \sin \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots (74)$$

This value is also given by Equation (14),

$$\Delta\,x = \int_0^{\alpha} \Delta\,s \cos \phi = \int_0^{\alpha} \frac{p}{E\,t}\,r\,r\,d\phi \cos \phi = \frac{p\,r^2}{E\,t} \sin \alpha \ldots\ldots (75)$$

As the arch is fixed at A and B, there have to be applied horizontal forces, T, acting outward at the abutments to lengthen the chord of the arch, $A'B'$, to the original length, $A\,B$, and moments at the abutments, M_a, to keep the ends of the arch fixed in direction.

Then the moment due to the uniform shortening of the arch at any point, S, for example, is,

$$M = T\,y - M_a \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76)$$

Since the angles of the tangents at A and C cannot change, then according to Equation (1),

$$\Delta\theta = \int_0^a \frac{M\,d\,s}{E\,I} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

Substituting Equation (76) in Equation (77), and transposing:

$$M_a = \frac{\int_0^a y\,d\,s}{\int_0^a d\,s} \times T \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (78)$$

The term, $\dfrac{\int_0^a y\,d\,s}{\int_0^a d\,s}$, equals $G\,m$, the distance of the center of gravity of the line, $A\,C\,B$, from the chord, $A\ B$, when G is the center of gravity of the center line of the arch, as shown in Fig. 27. It is known that $G\ O = r\,\dfrac{\sin\alpha}{\alpha}$; hence,

$$G\,m = r\,\frac{\sin\alpha}{\alpha} - r\cos\alpha = r\left(\frac{\sin\alpha}{\alpha} - \cos\alpha\right)$$

and,

$$M_a = T\,r\left(\frac{\sin\alpha}{\alpha} - \cos\alpha\right)\ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

Hence, substituting Equation (79) in Equation (76),

$$M = T\,(r\cos\phi - r\cos\alpha) - T\,r\left(\frac{\sin\alpha}{\alpha} - \cos\alpha\right) = T\,r\left(\cos\phi - \frac{\sin\alpha}{\alpha}\right)$$
$$= T \times S\,S' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

This means that it is permissible to assume T acting on a line through the center of gravity, G, of the center line of the arch (see Fig. 27).

Hence, there is only one statically unknown quantity for the solution of the effect of the shortening of the arch, namely, T, which can be found by the well known principle of least work,

$$L = \int \frac{Q^2\,d\,s}{2\left(\frac{E}{3}\right)t} + \int \frac{N^2\,d\,s}{2\,E\,t} + \int \frac{M^2\,d\,s}{E\,I} \ldots\ldots\ldots\ldots\ldots (81)$$

in which, Q, N, and M are the shear, force normal to, and moment at any section, respectively, due to the action of T only. By differentiating according to T and integrating over one-half the span only, the horizontal movement, $A''\,A$ (Fig. 26), due to the unknown force, T, can be determined as follows:

$$\frac{\delta\,L}{\delta\,T} = A\,A'' = \frac{p\,r^2}{E\,t}\sin\alpha = 3\int_0^a \frac{Q}{E\,t}\,\frac{\delta\,Q}{\delta\,T}\,d\,s + \int_0^a \frac{N}{E\,t}\,\frac{\delta\,N}{\delta\,T}\,d\,s$$
$$+ \int_0^a \frac{M}{E\,I}\,\frac{\delta\,M}{\delta\,T}\,d\,s \ldots\ldots\ldots\ldots\ldots\ldots\ldots (82)$$

From Fig. 27,

$$Q = T \sin \phi; \frac{\delta Q}{\delta T} = \sin \phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (83)$$

$$N = T \cos \phi; \frac{\delta N}{\delta T} = \cos \phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (84)$$

$$d s = r \, d \phi$$

From Equation (80),

$$\frac{\delta M}{\delta T} = r \left(\cos \phi - \frac{\sin \alpha}{\alpha} \right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (85)$$

Substituting in Equation (82), the proper values from Equations (83), (84), and (85), and integrating:

$$\frac{p \, r^2}{E \, t} \sin \alpha = \frac{T \, r}{E \, t} \left\{ 2 \alpha - \frac{1}{2} \sin 2 \alpha \right\} + \frac{T \, r^3}{E \, I} \left\{ \frac{1}{4} \sin 2 \alpha + \frac{\alpha}{2} - \frac{\sin \alpha}{\alpha} \right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (86)^*$$

If the value, j, is substituted for $\left(2 \alpha - \frac{1}{2} \sin 2 \alpha \right)$ and the value, k, for $\left(\frac{1}{4} \sin 2 \alpha + \frac{\alpha}{2} - \frac{\sin \alpha}{\alpha} \right)$, Equation (86) becomes:

$$\frac{p \, r^2}{E \, t} \sin \alpha = \frac{T \, r}{E \, t} \left[j + \frac{12 \, r^2}{t^2} k \right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (87)$$

from which, T can be readily found.

If the uniform shortening is produced by a drop of temperature, t_0, or an equivalent shrinkage of concrete, the term, $\frac{p \, r^2}{E \, t}$ (which is $\Delta \, r$) must be replaced by $c \, t_0 \, r$. This value, substituted in Equation (87), gives:

$$c \, t_0 \, r \sin \alpha = \frac{T \, r}{E \, t} \left[j + \frac{12 \, r^2}{t^2} k \right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (88)$$

Equations (87) and (88) become more useful by introducing the rise of the arch, f (Fig. 26), instead of the radius:

$$f = r \, (1 - \cos \alpha)$$

For water pressure:

$$T = \frac{p \, r \sin \alpha}{j + \frac{12}{(1 - \cos \alpha)^2} \frac{f^2}{t^2} k} \quad \ldots\ldots\ldots\ldots\ldots\ldots (89)$$

For change of temperature:

$$T_0 = \frac{E \, c \, t_0 \, t \sin \alpha}{j + \frac{12}{(1 - \cos \alpha)^2} \frac{f^2}{t^2} k} \quad \ldots\ldots\ldots\ldots\ldots\ldots (90)$$

Equations (89) and (90) are more readily solved by the use of Table 11.

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 237, Equations (10) and (11); also, p. 249.

The equations of T in this form show the influence of the thickness of the arch very clearly. For example, assume the ratio of rise to thickness, $\frac{f}{t} = 3$, and assume $\alpha = \frac{\pi}{6}$. Then, from Table 11,

$$T = \frac{p\ r}{1.13 \times 9 + 1.228} = \frac{p\ r}{11.398} = 0.0878\ p\ r.$$

T acts at a point, below the crown, $r - r\ \frac{\sin\ \alpha}{\alpha} = r - 0.95494\ r = 0.0451\ r$. The rise of the arch, f, $= 0.133\ r$, and $t = \frac{f}{3} = 0.0444\ r$. Hence, the shortening of the arch in this case produces a moment at the crown equal to $p\ r \times 0.0878 \times 0.0451\ r = 0.00396\ p\ r^2$; a moment at the abutment of $0.0878\ p\ r\ (0.133\ r - 0.0451\ r) = 0.00775\ p\ r^2$; a normal force at the crown of $p\ r - 0.0878\ p\ r = 0.9122\ p\ r$; and a normal force at the abutment of $p\ r - 0.0878\ p\ r \cos 30 = 0.924\ p\ r$.

TABLE 11.—TABLE OF CONSTANTS FOR VARIOUS VALUES OF α.

α.	j.	k.	$\frac{\sin\ \alpha}{\alpha}$.	f.	T.	T_0.
$\frac{\pi}{6}$	0.642	0.00084	0.9549	$0.133\ r$	$\frac{p\ r}{1.13\ \frac{f^2}{t^2} + 1.228}$	$\frac{E\ c\ t_0\ t}{1.13\ \frac{f^2}{t^2} + 1.228}$
$\frac{\pi}{4}$	1.0708	0.00608	0.900	$0.293\ r$	$\frac{p\ r}{1.21\ \frac{f^2}{t^2} + 1.515}$	$\frac{E\ c\ t_0\ t}{1.21\ \frac{f^2}{t^2} + 1.515}$
$\frac{\pi}{3}$	1.6614	0.0239	0.8276	$0.50\ r$	$\frac{p\ r}{1.33\ \frac{f^2}{t^2} + 1.92}$	$\frac{E\ c\ t_0\ t}{1.33\ \frac{f^2}{t^2} + 1.92}$
$\frac{\pi}{2}$	3.1416	0.1488	0.6366	$1.00\ r$	$\frac{p\ r}{1.785\ \frac{f^2}{t^2} + 3.14}$	$\frac{E\ c\ t_0\ t}{1.785\ \frac{f^2}{t^2} + 3.14}$

The eccentricity of the normal force at the crown is,

$$\frac{0.00396\ p\ r^2}{0.9122\ p\ r} = 0.00435\ r = 0.098\ t$$

and that at the abutment is,

$$\frac{0.00775\ p\ r^2}{0.924\ p\ r} = 0.0084\ r = 0.189\ t$$

While the eccentricity at the crown is less than one-tenth the thickness of the arch, the point of application of the normal force at the abutment is outside the middle third. From the equations in Table 11, it is clear that tensile stresses are produced in all arches, whether flat or steep, whenever $\frac{f}{t}$ is less than 3.

The tensile stresses are, in fact, much larger than shown when a fall of temperature or shrinkage of concrete is taken into consideration, as the following calculations show.

Assume in the same arch, $p = 4\,000$ lb.; $r = 270$ ft.; $f = 270\ (1 - \cos 30) = 36$ ft.; $t = \frac{f}{3} = 12$ ft.; then,

$$E\ c\ t_0 = 288 \times 10^6 \times 0.0000055 \times 12 = 19\,000 \text{ lb.}$$

for the very low drop of only 12°, and from Table 11,

$$T_0 = \frac{E\ c\ t_0\ t}{1.13\ \frac{f^2}{t^2} + 1.228} = \frac{19\,000 \times 12}{11.398} = 20\,000 \text{ lb.}$$

The moment at the crown is,

$$20\,000 \times \left(r - r\,\frac{\sin\,\alpha}{\alpha}\right) = 20\,000 \times 0.0451\ r = 243\,000 \text{ ft-lb.}$$

and the moment at the abutment is,

$$20\,000 \times (f - 0.0451\ r) = 20\,000 \times 0.0882\ r = 478\,000 \text{ ft-lb.}$$

The normal force at the crown is,

$$0.9122\ p\ r - 20\,000 = 965\,000 \text{ lb.}$$

and the normal force at the abutment is,

$$0.924\ p\ r - 20\,000 \cos 30 = 979\,000 \text{ lb.}$$

The eccentricity at the crown due to temperature only is,

$$\frac{243\,000}{965\,000} = 0.252 \text{ ft.} = 0.021\ t$$

and the eccentricity at the abutment due to temperature only is,

$$\frac{478\,000}{979\,000} = 0.489 \text{ ft.} = 0.0407\ t$$

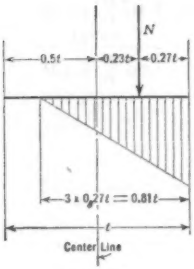

FIG. 28.

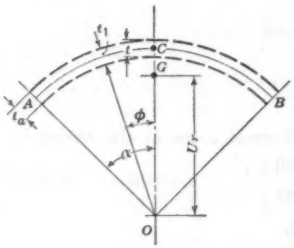

FIG. 29.

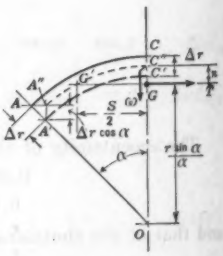

FIG. 30.

Hence, the total eccentricity from shortening of the arch and drop of temperature at the crown $= 0.098\ t + 0.021\ t = 0.119\ t$, and at the abutment $= 0.189\ t + 0.0407\ t = 0.230\ t$.

The maximum stress (see Fig. 28) $= \frac{N}{0.81\ t} \times 2 = 2.48\ \frac{N}{t}$, or nearly $2\frac{1}{2}$ times the stress from the cylinder theory.

Therefore, where $\frac{f}{t}$ is less than 3, secondary arches are forming and economical design requires that the arch should not be of constant thickness throughout but should have its section enlarged where tensile stresses occur.

If the influence of shear is omitted from consideration,*

$$T = \frac{p\,r}{1.130\,\frac{f^2}{t^2} + 0.9568} = 0.0899\,p\,r$$

instead of $0.0878\,p\,r$; or T is 2% larger than when shear is considered.

Where (as in the Gibson Dam) $\frac{f}{t} = 1$, it is easily found that T, without consideration of shear, becomes 7% larger; but where (as in the lower part of the Bear Valley Dam), $\frac{f}{t} = 0.22$, Table 11 shows that,

$$T = \frac{p\,r}{1.13 \times 0.22^2 + 1.228} = 0.778\,p\,r$$

and from Professor Cain's formula,

$$T = \frac{p\,r}{1.13\,\frac{f^2}{t^2} + 0.9568} = 0.989\,p\,r$$

This is a great difference and it shows that the dam could not exist without secondary arch action.

None of these formulas applies to non-reinforced arches in which tensile stresses occur, and such stresses do occur in nearly all arches (plain and reinforced), in which $\frac{f}{t}$ is less than 3. Secondary arches are then acting within such arches, having a larger rise, a smaller radius, a smaller thickness, and also a different pressure than the original arch. The water pressure will be different because the water will intrude in the cracks at the extrados near the abutments.

It is known that the eccentricity of the normal force at the abutments is about twice as large as that at the crown, and it is a mystery to the writer why arched dams are not designed in the first place in the shape of the future secondary arches, with enlargements at the dangerous sections.

Possibly one reason is that the summation method of designing arches of various depths is too laborious for most engineers. Secondary arches, such as have been used by the Bureau of Reclamation, can be much more simply designed by the following method.

Let $A\,C\,B$ (Fig. 29) be the center line of a circular arch having a thickness of t at the crown and t_a at the abutment. Assume that the thickness varies as:

$$\frac{1}{t_1} = \frac{1}{t}\left(1 - K\,\frac{\sin\phi}{\sin\alpha}\right) \qquad (91)$$

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 233.

in which, K is a constant; I = the moment of inertia at the crown; I_a = the moment of inertia at the abutment; and I_1 = the moment of inertia at any point.

For all practical purposes:

$$\frac{1}{I_1} = \frac{1}{I}\left(1 - L\frac{\sin\phi}{\sin\alpha}\right) \quad \ldots\ldots (92)$$

in which, L is another constant. When the thickness of the abutment is $1\frac{1}{2}$ times the thickness at the crown, K may be assumed as $\frac{1}{3}$ and the corresponding L as $\frac{3}{4}$. When the thickness at the abutment is 2, assume that $K = \frac{1}{2}$ and the corresponding $L = \frac{9}{10}$. The writer has checked this assumption in numerous cases with the summation method and found only very slight variation in results.

In order to solve the arch (Fig. 29) by the same method as for an arch of constant depth, it is necessary to know the new value, $A\,A'' = \Delta\,x$ (see Fig. 30) and the new line in which T is acting, which does not now go through the center of gravity of the arch but through the center of gravity of the so-called elastic weight, $\frac{d\,s}{I_1}$. By the use of Equation (75) modified by Equation (91),

$$\Delta\,x = \int_0^a \Delta\,s\cos\phi = \int_0^a \frac{p\,r}{E\,t}\left(1 - K\frac{\sin\phi}{\sin\alpha}\right) r\,d\,\phi\cos\phi$$

$$= \frac{p\,r^2}{E\,t}\sin\alpha\left(1 - \frac{K}{2}\right) \quad \ldots\ldots (93)$$

The new distance, $G\,O$ (Fig. 30), is,

$$\frac{\int_0^a \frac{y\,d\,s}{I_1}}{\int_0^a \frac{d\,s}{I_1}} = \frac{\frac{r^2}{I}\sin\alpha\left(1 - \frac{L}{2}\right)}{\frac{r}{I}\left[\alpha - L\frac{(1-\cos\alpha)}{\sin\alpha}\right]} = \frac{\left(1 - \frac{L}{2}\right) r\sin}{\alpha - L\frac{(1-\cos\alpha)}{\sin\alpha}} = U\,r. \quad (94)$$

Assigning actual values to α, the corresponding values of U (See Equation (94)) for values of $t_a = 1\frac{1}{2}\,t$, and $2\,t$, respectively, are as given in Table 12.

The moment at any point, due to the shortening of the arch, is:

$$M = T\,(r\cos\phi - U\,r) \quad \ldots\ldots (95)$$

In the least work equation,

$$L = \int \frac{Q^2\,d\,s}{2\left(\frac{E}{3}\right)t_1} + \int \frac{N^2\,d\,s}{2\,E\,t_1} + \int \frac{M^2\,d\,s}{E\,I_1} \quad \ldots\ldots (96)$$

Let,

$$Q = T\sin\phi\,;\ \frac{\delta\,Q}{\delta\,T} = \sin\phi \quad \ldots\ldots (97)$$

$$N = T\cos\phi\,;\ \frac{\delta\,N}{\delta\,T} = \cos\phi \quad \ldots\ldots (98)$$

$$M = T\,r\,(\cos\phi - U);\quad \frac{\delta M}{\delta T} = r\,(\cos\phi - U)\ldots\ldots\ldots\ldots(99)$$

$$\frac{d\,s}{t_1} = \frac{r\,d\,\phi}{t}\left(1 - K\frac{\sin\phi}{\sin\alpha}\right);\ \text{and}\ \frac{d\,s}{I_1} = \frac{r\,d\,\phi}{I}\,1 - L\frac{\sin\phi}{\sin\alpha}\ldots\ldots(100)$$

TABLE 12.—Tables of Constants for Corresponding Values of α.

α.	$t_a = 1\frac{1}{2}\,t$.				$t_a = 2\,t$.			
	U.	j.	k.	T.	U.	j.	k.	T.
$\frac{\pi}{6}$	0.968	0.5020	0.00038	$\frac{pr}{0.64\,\frac{f^2}{t^2} + 1.20}$	0.970	0.4459	0.000268	$\frac{pr}{0.48\,\frac{f^2}{t^2} + 1.19}$
$\frac{\pi}{4}$	0.931	0.8619	0.002733	$\frac{pr}{0.65\,\frac{f^2}{t^2} + 1.46}$	0.943	0.7542	0.00186	$\frac{pr}{0.491\,\frac{f^2}{t^2} + 1.40}$
$\frac{\pi}{3}$	0.880	1.3086	0.010611	$\frac{pr}{0.707\,\frac{f^2}{t^2} + 1.81}$	0.903	1.1322	0.006968	$\frac{pr}{0.515\,\frac{f^2}{t^2} + 1.74}$
$\frac{\pi}{2}$	0.762	.....	.....	.....	0.819	.....	.....	.....

Substituting Equation (93) in Equation (96) and differentiating according to T, $\frac{\delta L}{\delta T} = \Delta x$, is the movement of one abutment. Then,

$$\Delta x = \frac{p\,r^2}{E\,t}\sin\alpha\left(1 - \frac{K}{2}\right) = \frac{3\,T\,r}{E\,t}\int_0^\alpha \sin^2\phi\left(1 - K\frac{\sin\phi}{\sin\alpha}\right)d\,\phi$$
$$+ \frac{T\,r}{E\,t}\int_0^\alpha \cos^2\phi\left(1 - K\frac{\sin\phi}{\sin\alpha}\right)d\,\phi + \frac{T\,r^3}{E\,I}\int_0^\alpha (\cos\phi - U)^2$$
$$\left(1 - L\frac{\sin\phi}{\sin\alpha}\right)d\,\phi\ldots\ldots\ldots\ldots\ldots\ldots\ldots(101)$$

This reduces again to the form:

$$\frac{p\,r^2}{E\,t}\sin\alpha\left(1 - \frac{K}{2}\right) = \frac{T\,r}{E\,t}\left\{j + \frac{12\,r^2}{t^2}k\right\}\ldots\ldots\ldots(102)$$

The values of j, k, and T for various values of α, are as given in Table 12. The change of temperature, T_0, is obtained by substituting the expression, $\Delta x = c\,t_0\,r\sin\alpha$, in Equation (96). Then, for values of $\alpha = \frac{\pi}{6}$ and $t_a = 1\frac{1}{2}\,t$,

$$T_0 = \frac{E\,c\,t_0\,t}{\left(1 - \frac{K}{2}\right)0.64\,\frac{f^2}{t^2} + 1.20}\ldots\ldots\ldots\ldots(103)$$

A study of Table 12 shows that the expression for T will hardly change for values of α smaller than $\frac{\pi}{6}$, and it will be quite as permissible to use the

same formula for smaller values of α as for $\frac{\pi}{6}$. The authors advise using Fig. 4 for estimating the change of length, due to a drop of temperature. Presumably this includes the influence of shrinkage also. The Bureau of Reclamation has probably the most complete information on this subject, and a statement issuing from its office, containing observations on which this diagram is based, would be highly welcome. What influence has the gradual widening of the arch to $1\frac{1}{2}\ t$, near the abutment, on the stresses of an arch as discussed on pages 1255 and 1256?

From Table 12:

$$T = \frac{p\ r}{0.64 \times 3^2 + 1.20} = 0.144\ p\ r$$

From Equation (103),

$$T_0 = \frac{19\,000 \times 12}{\left\{\left(1 - \frac{1}{6}\right) 0.64 \times 3^2\right\} + 1.20} = 39\,400 \text{ lb.}$$

N at the crown equals,

$$p\ r - 0.144\ p\ r - 39\,400 = 0.856\ p\ r - 39\,400 \text{ lb.} = 885\,000 \text{ lb.}$$

N at the abutment equals,

$$p\ r - (0.144\ p\ r + 39\,400) \cos 30 = 0.8772\ p\ r - 34\,000 \text{ lb.} = 913\,000 \text{ lb.}$$

M at the crown equals,

$$(T + T_0)\ (1 - U)\ r = 195\,000 \times 0.032\ r = 1\,670\,000 \text{ ft-lb.}$$

M at the abutment equals,

$$(T + T_0)\ (U\ r - r \cos 30) = 195\,000 \times 0.101\ r = 5\,350\,000 \text{ ft-lb.}$$

Eccentricity at the crown equals,

$$\frac{1\ 670\ 000}{885\ 000} = 1.89 \text{ ft.} = 0.1575\ t$$

Eccentricity at the abutment equals,

$$\frac{5\ 350\ 000}{913\ 000} = 5.86 \text{ ft.} = 0.325\ t_a$$

The maximum stress at the abutment (see Fig. 28) is,

$$S = \frac{N}{3\left(\frac{1}{2}\ t_a - 0.325\ t_a\right)} \times 2 = 3.82\ \frac{N}{t_a} \quad \ldots\ldots\ldots\ldots (104)$$

or, notwithstanding the enlargement of the arch, the stresses, due to the shortening of the arch and a drop of temperature, become larger than before, which shows that the selection of a shape of the arch, according to Fig. 29, is not always a fortunate one.

In the authors' method of designing it is very important to find the deflection of the arches at several points. This can be done simply by the following consideration: In Fig. 30, assume $A\ C$ to be the center line of the arch and, after uniform compression, the arch moved upward into the position, $A''\ C''$. Then apply a force, T, in order to bring A'' back to A.

In this position the crown of the arch, C'', is already lowered a distance,

$$\Delta r - \Delta r \cos \alpha = \frac{p r^2}{E t}(1 - \cos \alpha) \ldots\ldots\ldots\ldots\ldots (105)$$

The deflection can be found* by assuming the left half of the arch to be fixed at A'', and the force, T, acting at G and a fictive force, w, acting at the crown, then by differentiating Equation (81) according to w, making $w = 0$ afterward:

$$Q = T \sin \phi + w \cos \phi; \frac{\delta Q}{\delta w} = \cos \phi \ldots\ldots\ldots\ldots\ldots (106)$$

$$N = - T \cos \phi + w \sin \phi; \frac{\delta N}{\delta w} = \sin \phi \ldots\ldots\ldots\ldots\ldots (107)$$

$$M = - T r \left(\cos \phi - \frac{\sin \alpha}{\alpha}\right) + w r \sin \phi; \frac{\delta M}{\delta w} = r \sin \phi \ldots\ldots (108)$$

The vertical movement of the crown of the arch in position, $A'' C'' B''$ (Fig. 30) is:

$$\frac{\delta L}{\delta w} = 3 \int_0^\alpha \frac{T r}{E t} \sin \phi \cos \phi \, d \phi - \int_0^\alpha \frac{T r}{E t} \sin \phi \cos \phi \, d \phi$$

$$- \int_0^\alpha \frac{T r^3}{E I}\left(\cos \phi - \frac{\sin \alpha}{\alpha}\right) \sin \phi \, d \phi \ldots\ldots\ldots\ldots\ldots (109)$$

Integrating and adding $\Delta r (1 - \cos \alpha)$, the total deflection of the crown is,

$$\Delta f = \frac{p r^2}{E t}(1 - \cos \alpha)$$

$$+ \frac{T r}{E t}\left\{ \sin^2 \alpha + \frac{12 r^2}{t^2}\left[\frac{\sin \alpha}{\alpha}(1 - \cos \alpha) - \frac{\sin^2 \alpha}{2}\right]\right\} \ldots\ldots (110)$$

The vertical displacement of an arch with a depth increasing from the crown to the abutment is found, similarly, by using Equations (91) and (92) in Equation (81).

The vertical displacement of the point, G', in relation to C'' is easily found from the well known equation,

$$\Delta y = \int \frac{M x \, d s}{E I} \ldots\ldots\ldots\ldots\ldots\ldots (111)$$

Consider $G' C''$ as y in the well known equation,

$$y = \frac{4 n}{S^2}(S x - x^2) \ldots\ldots\ldots\ldots\ldots\ldots (112)$$

with the origin at G': $M = T y$ for this section, and, with normal force and shear neglected,

$$\Delta y = \int_0^{\frac{s}{2}} - \frac{T y x \, d s}{E I} = \frac{4 n}{S^2} \frac{1}{E I} \int_0^{\frac{s}{2}} (S x^2 - x^3) \, d x = \frac{5}{48} \frac{T s n}{E I} \ldots\ldots (112)$$

This point and the tangents at the crown and abutment being known, it should not be much trouble to draw the deflection for the whole arch.

The writer has not mentioned Poisson's ratio because most engineers find it safer to forget it. Positive proof of its beneficial influence is still sadly lacking. The so-called curved beam action has been ignored, because theory

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 236.

and tests show that, for the extraordinary case where $\frac{r}{t} = 1$, the stresses are influenced 25%; for the very rare case of $\frac{r}{t} = 4$, they are influenced 9%, and for $\frac{r}{t} = 10$ (still a very thick arch), they are influenced to the amount of 4 per cent.

The stresses in the lower arches of a dam are very high, due to the shortening of the arch and a drop of temperature and shrinkage. Very daring dams are standing, however, and an explanation is urgently needed.

In seeking help from the cantilevers near the crown of the arch, it is found that the cantilevers themselves, according to theory, are stressed to the limit in nearly all cases.

The authors sought help from the cantilevers near the abutments. They assumed that the cantilevers at the crown take a very much smaller load than was formerly ascribed to them by most engineers and, in fact, they considered the horizontal arches to have a horizontal and vertical abutment at the end. This amounts, in effect, to the assumption of a horizontal arch of a smaller span.

In large arch dams as a rule, it is uneconomical to assume the arch rings to be affected only by water pressure. If the weight of the arch ring is also considered, it will be found that the most economical design is obtained by inclined arches, the inclination being given by the water pressure per square foot to the weight of the inclined ring per linear foot.* The importance of this statement will be seen in the following demonstration.

Fig. 31 shows a section through the crown of the Dam No. II, mentioned by the authors. At Elevation 5 280, the water pressure is 10 400 lb. per sq. ft., the weight of the arch ring is 5 200 lb. per lin. ft., and the ratio of water pressure and weight of ring is exactly 2 to 1.

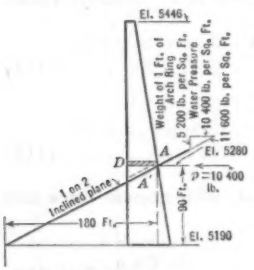

FIG. 31.

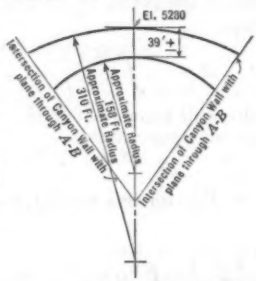

FIG. 32.

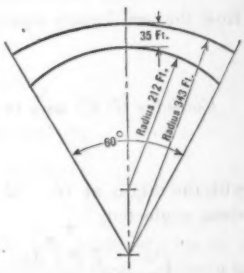

FIG. 33.

Draw Line $A\,A'$ with an inclination of 1 on 2, and lay, through Line $A\,A'$, a plane perpendicular to the plane of the paper. This plane will intersect the dam as shown in Fig. 32, while the horizontal section $A\,D$, is shown in Fig. 33. It is apparent that the radius of the inclined arch is very much shorter than the horizontal arch and will, by the principle of least work, support a much

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 253.

greater part of the water pressure than the horizontal arch. Of course, the inclined arch has to carry a larger load, the resultant of both vertical and horizontal load, namely, 11 600 lb. per lin. ft. Its thickness is also about 10% less than that of the horizontal arch, but it is 10% deeper and the transmission of the water pressure to the assumed arch will be different from that shown in Fig. 31. The water pressure will center around A' and will be transmitted by shear and friction. The assertion that $A\,A'$ ought to be inclined in exactly this ratio should be modified to admit that there might be cases, depending on the configuration of the canyon, where another inclination will be of greater advantage.

The writer still maintains that it would be of much greater satisfaction to most engineers if cantilever action were entirely ignored with respect to the assistance cantilevers would give to horizontal or inclined arches, and he recommends starting the design of an arched dam by properly designing the inclined arches, and assuming them to carry their own weight and water pressure, these inclined arches to be affected by a shortening of the arch and a drop of temperature.

The writer is quite convinced that the arches are, in fact, very much stronger than given by the standard design for the following reasons.

It is well known that a concrete beam, when tested to destruction, is much stronger than given by the formula,

$$M = S\,\frac{b\,d^2}{6} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (114)$$

In fact, S, computed from bending tests, is generally twice as high as the estimated tensile strength of the concrete. The reason is that the stresses do not follow Hooke's law; and instead of a straight line distribution of stresses, there is, especially near the ultimate load, a parabolic distribution of some power greater than 2.

Tests on eccentrically loaded columns also show a much greater strength, than the old straight line formula indicates.*

Assuming a distribution of stress based on a cubic parabola (see Fig. 34), tensile stresses are found to act in a rectangular section, when the eccentricity of loading is larger than $\frac{1}{10}\,t$ $\left(\text{not } \frac{1}{6}\,t \text{ as according to the old theory}\right)$; but the maximum stresses are then only $1.33\,\frac{N}{t}$.

Considère† compared a 16-in. column, loaded with an eccentricity of 4 in., with an identical column axially loaded. The latter failed at 3 600 lb. per sq. in., while the former failed (according to the old theory) at 4 950 lb. per sq. in. As the concrete strength was only 3 600 lb. per sq. in., the column actually carried $\frac{4\,950}{3\,600} = 1.37$ times the load the old theory would lead one to expect, and this result agrees, within 1%, with the cubic parabola stress dis-

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 1671.

† Rept., Commission du Beton Armé, 1907.

tribution. Careful comparisons with many other tests* also check the writer's theory.

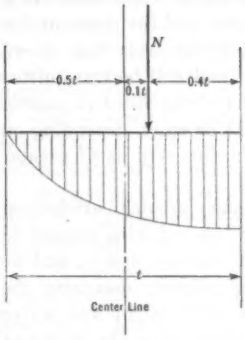

FIG. 34.

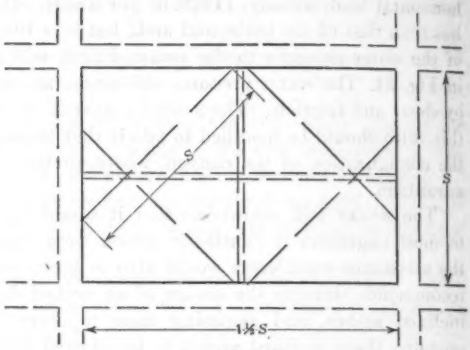

FIG. 35.

Table 13 lists the maximum stresses for various concrete sections having no tensile strength (on account of joints), e being the eccentricity and t, the depth of a rectangular section, 1 ft. wide.

TABLE 13.—MAXIMUM STRESSES IN COLUMNS FOR VARIOUS VALUES OF e.

0.017	1.06	1.104
0.080	1.10	1.18
0.051	1.17	1.306
0.084	1.28	1.504
0.100	1.33	1.60
0.120	1.41	1.72
0.140	1.48	1.84
0.160	1.57	1.96
0.180	1.67	2.08
0.200	1.78	2.22
0.260	2.22	2.78
0.340	3.33	4.16
0.420	6.67	8.35
0.480	20.00	33.33

Table 13 shows that the stresses are in most cases 20% smaller than was formerly believed. The arches are, besides, much stronger than the common elastic theory indicates for the reason that the modulus of elasticity does not remain constant. At the abutments, the stresses first reach high values, and the modulus of elasticity becomes rapidly smaller. This means that the deformation of the arch near the abutments is relatively larger than the theory assumes. It has the effect of lowering the point of application of T, so that the greatest moment (which occurs always at the abutments), is decreased and the moment at the crown is increased. A similar effect is found in contin-

* *Beton und Eisen*, 1916, p. 56; and, also, *Forschungsarbeiten*, Verein Deutscher Ingenieure, Heft 166–169, 1914.

uous beams, and this induced the Joint Committee on Specifications for Concrete and Reinforced Concrete to recommend that continuous beams be fully loaded and fully fixed at the support in order to be designed for a moment of $\frac{p\,l^2}{16}$ $\left(\text{instead of } \frac{p\,l^2}{12} \text{ at the support, and } \frac{p\,l^2}{24} \text{ in the center}\right)$.

It is very probable that for this reason alone the arches are 33% stronger than the elastic theory teaches. It is high time that the colleges discard the archaic hypotheses, on which they build their theories. Tests ought to be made with the proper spirit of finding the true laws of the strength of materials, regardless of tradition, and tests to destruction on small model dams would soon demonstrate to the most conservative engineers the enormous strength of arched dams.

The problem of the arched dam has a corollary in the slab, supported on four beams used in building construction. In Fig. 35 such a slab is shown with a center strip in two directions. In all building ordinances in Germany, it is required that the division of the load for each system of strips throughout the center slab shall be assumed in the inverse ratio of the fourth power of their respective spans, for the only reason that the center strips have the same deflection at the center of the slab, when uniformly loaded in that ratio. Even in the United States building ordinances require a division according to the third power of the ratio of the spans. In France, however, it was found by tests, nearly thirty years ago, that the division of the loads ought to be according to the second power of the ratio of the spans. The explanation was not forthcoming for a long time, until an Italian engineer (Danusso) demonstrated that diagonal strips, near the corners, as shown in Fig. 34, greatly reduce the span in the long direction. The authors have demonstrated a very similar fact for the arched dam.

William Cain,* M. Am. Soc. C. E. (by letter).—The writer agrees with the authors that, for the complete solution of the arch dam, the whole dam must be considered, which thus involves the shape of the canyon. Friction between the horizontal arches and between the vertical cantilevers is ignored and a series of proportional loads on these two elements are, in turn, assumed until one series is found to give the same radial deflections at the same points for both elements. Of course, for an exact solution, the friction referred to should be considered as it plays a very important rôle in transferring stress toward the abutments, particularly across cracks (either vertical or horizontal) and it doubtless increases in going from the crown to the abutments where the deflection is zero. This friction or shear is not of much importance in a dam, without cracks, that is fixed (encastrée) at the base; but for the usual arch dam, that is not fixed at the base, and, with cracks, it adds materially to the strength and stability of the structure. Necessarily, by the authors' tentative method of solution it has to be ignored.

With regard to the division of the normal water pressure between a horizontal arch and the vertical cantilevers crossing it at the depth considered, some general conclusions can be given. To avoid going over old ground, the

* Prof. Emeritus, Univ. of North Carolina, Chapel Hill, N. C.

writer would refer to his discussion of the paper by Fred A. Noetzli, M. Am. Soc. C. E., entitled, "Gravity and Arch Action in Curved Dams",* especially to Fig. 15 in connection with the analysis for the Wooling Dam. The diagram refers to a cantilever at the crown, but it equally applies to one anywhere if subjected to its proper proportional water load, the arch deflection being computed for the point considered. On any cantilever, there is one point, K, where all the water pressure is carried by the arch and none by the cantilever. Under its proportional water load, the cantilever would bend so as to be concave down stream; but above K, it is found that, under this load, it tends to deflect more than the arch. This excess deflection is resisted by the arch, which exerts a horizontal pull on it acting up stream with a consequent equal reaction from the cantilever. The part of the cantilever above K thus bends so as to become concave up stream. The smaller the down-stream deflection of the arch, the greater its pull on the cantilever; so that for points above K, if the deflection of the arch decreases in going from the crown, C, to the abutment, A, the up-stream pulls on the cantilever should increase from C to A, provided all the cantilevers are of the same stiffness, as for a level dam site with cantilevers of the same size and height, that are not cracked or that have similar cracks.

The same conclusions hold when the dam site is a canyon, since then the stiffness of the cantilevers increases in going from C to A. If the deflection of the arch decreases irregularly in going from C to A, or if the cracks in the cantilever are not similar, then the variation in the load on the cantilever will likewise be irregular.

Next, consider points below K on any cantilever on which the total horizontal water pressure is p lb. per sq. ft.

Let p' = the unit normal pressure carried by the arch; and,
p'' = the unit normal pressure carried by the cantilever; so that
$p' + p'' = p$, a constant.

First, assume that, for a level dam site, the radial deflections of the arch diminish from the crown, C, to the abutment, A, where the deflection is zero. Then, since the deflections of the arch and any cantilever, at the same point, must be equal, it follows that the deflections of the cantilevers must decrease from a maximum at the crown to zero at the abutment. Further, suppose the cantilevers to be alike and without cracks or with exactly similar cracks similarly placed, so that each one will deflect the same amount for the same load; then, in order that the deflection shall decrease from some value at C, to zero at A, the unit normal pressure p'', acting on a cantilever must decrease in going from C to A. Consequently, since $p' + p'' = p$ (a constant), then p', the unit normal pressure on the arch, must increase in going from C to A.

If, however, it is assumed that the more central cantilevers are the only ones weakened by cracks, then p'' can be much less than before at C, and it may actually increase from C to a point near the abutment. The fixing of the cantilever by the side walls at the abutment will prevent any deflection, no matter what the value of p'', and this influence will extend some distance out,

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), pp. 73–79.

so that it is possible for p'' (and therefore, p') to remain constant from C to A, or for p'' to increase, in which case, p' decreases in going from C to A.

In the case of the canyon, Fig. 1 (c), the cantilevers becoming shorter in going from C to A, increase in stiffness and their deflections decrease for the same load, so that it is possible for p'' to remain constant throughout (considering the fixation caused by the side walls). In that case, p' is constant, or p'' can actually increase and p' can decrease in going from C to A, particularly if cracks occur in some of the cantilevers in the middle portion. In no case is it necessary that p' should be zero at A, as seems to be assumed by the authors.

All the deflections were assumed to be down stream and to decrease in going from C to A. In the arches at the crest, near the crown of the Stevenson Creek Experimental Dam, the deflection was down stream at the crown, but up stream nearer the abutment, the neutral line forming a reversed curve. Evidently, the loading on the arch was such as to produce this curve and thus to prove an exception to what would naturally be expected. From all that precedes, it is seen that the proportionate loads sustained by arch and cantilever cannot be predicted. Such loads may increase or decrease in going from crown to abutment, or they may be nearly uniform, depending on the shape of the canyon and the cracks, or portions subjected to tension, particularly in the cantilevers.

In Fig. 5, referring to Dam No. I, the load over most of the horizontal arch was uniform. In this dam, tension was supposed to be provided for; but in the other dams, where the material everywhere was supposed to be incapable of taking tension, the proportional loadings were very variable. Most arch dams are not fixed (encastrée) at the base in that no provision is made for the inevitable tension at that point for dams supposed to be fixed at the base. The authors have properly excluded the parts of the sections where tension is found, which occurs when the resultant on the section falls outside its middle third, so that only the part of a section in compression is considered in the computation.

The cantilever loads must include the weight of the concrete above the section and that of the water vertically over the up-stream face, the negative load due to the arches near the top, and the assumed proportional part of the water load on the part of the cantilever above the section considered. When the resultant of such loads cuts the section outside its middle third, say, at a distance, c, from the nearest edge, then only a length, $3c$, of the section, measured from the edge, will be supposed to be in compression; also, the neutral axis will be taken at the center of this compressed portion, and the moments and moment of inertia must be taken about this center. For sections where the resultant falls within the middle third, the moments are taken, as usual, about the center of the section.

After these moments at the various sections have been computed, the deflections of the cantilever at various points are ascertained. This can be effected by calculation, but the writer prefers a neat graphical construction,* since the deflections can be read off to 0.001 in. with practical accuracy.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 74.

The authors do not make the usual erroneous assumption that the cantilever is fixed at the base. It is simply supposed to be supported at the base and to have there a vertical tangent to the neutral line. It can only be supposed to be fixed at the base when sufficient tension can be exerted, and this is ignored in the computation.

For very thick dams, the deflection due to shear should be added to that corresponding to moments. This is easily computed from the well-known formula for the deflection in feet, h ft., above the lower section, Fig. 36,

$$\Delta = \frac{1.2}{144\ G} \int_0^h \frac{S}{a}\, d\,x$$

corresponding to a parabolic distribution of shear on a cross-section of area, a. In this formula,

S = total horizontal shear due to loads acting on the cantilever, x ft. above the lower section;

a = area of horizontal section, the shear of which is S;

G = modulus of rigidity, in pounds per square inch.*

The integral gives the value of the shaded area, so that the deflection, in inches, is, for a trapezoidal section,

$$\Delta = \frac{0.1}{G} \frac{1}{2} \left(\frac{S_1}{a_1} + \frac{S_2}{a_2} \right) h$$

If preferred, the shaded area can be written, $\frac{S_0}{a_0} h$, in which, S_0 and a_0 represent the shear and area, respectively, of the section of the cantilever at the distance, $\frac{h}{2}$, above the lower section. The cantilever having been divided into a number of parts, each of approximate trapezoidal section, the deflection of the top of each part with respect to its base can be computed from this formula and the sum taken for the total deflection at a given height.

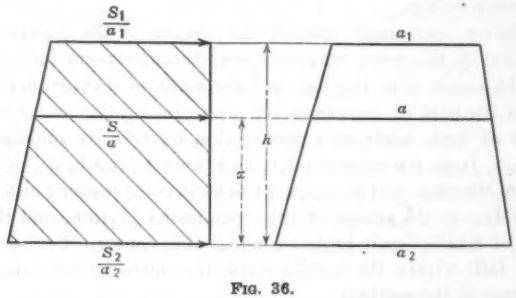

FIG. 36.

It will be seen from this discussion that the authors' method, of counting as effective only the parts of the sections of cantilevers in compression in computing moments, must necessarily lead to different results from those found

* In *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 100, B. F. Jakobsen, M. Am. Soc. C. E., gives reasons for taking $G = \frac{E}{2.4}$

on the assumption that the cantilever can resist the tension. As a matter of fact, American dams are not usually reinforced (the Wooling Dam is the only reinforced dam as far as the writer knows) and cracks are to be expected. Where they occur, it is manifestly absurd to count on tension being exerted across the cracks, or that the dam remains intact, and yet this assumption is the basis of the usual analysis. This basis, not agreeing with the facts, should be rejected for other than reinforced dams. The authors deserve thanks for fearlessly working from the facts and dealing with the actual dam with supposed openings (or cracks) where tension would occur and not with an ideal dam without cracks.

In the usual analysis, the dam is supposed to remain intact. Then, the solution is effected for the dam without weight and omitting the weight of water vertically over it. The latter forces are to be included later. By the authors, they are included from the start, so that it is possible to find the points where tension would be exerted and the sections under compression which alone are to be regarded as effective in computing deflections and stresses.

Similar computations are to be made for cantilevers at other points than the crown and for arches at various elevations. The labor of so many hundreds of trial computations is enormous and looks prohibitive except with a large office force; so that any hints that may reduce this labor may prove welcome.

By shifting the origin to the "elastic center", the number of terms in Equations (24) to (29) is greatly reduced and the solution more easily effected. Otherwise, in place of normal loads, equivalent vertical and horizontal loads can be taken. The solution, where such loads are taken as unit loads for symmetrical arches, has been given by Charles S. Whitney, M. Am. Soc. C. E.* Very simple formulas are derived for finding the reactions when bending only is considered, the effects of direct thrust being treated separately. The writer† derived very simple formulas for the reactions for both vertical and horizontal loads (including symmetrical horizontal loads) where the chances for mistake seem to be reduced to a minimum. However, the graphical method given by Mr. Whitney‡ for finding reactions and deflections at any point will especially appeal to the computer as giving quickly the quantities sought.

If a uniform thickness of a symmetrical arch is assumed, it is possible to derive formulas for moments, thrusts, and crown deflections for two symmetrically placed single loads, acting normally to the extrados, and then, for any assumed continuous loading, to sum the results for the whole load. This is probably the quickest method of effecting a solution for an arch nowhere subjected to appreciable tension; but it fails otherwise. When the thickness of the arch varies, the arch will have to be divided into a number of parts and a method of summation will have to be used.§ For the unsymmetrical arch, Melan's method may suffice.

FRED A. NOETZLI,* M. AM. SOC. C. E. (by letter).—Much effort has been spent during recent years to evolve an analysis of arch dams which should accord, as nearly as practicable, with the theoretical principles used in the design of other types of concrete structures.

The authors base their method on the generally accepted assumption that an arch dam is composed of a system of horizontal arches and vertical cantilevers. The partial loads carried by the individual elements are then determined by successive trials until the deflections of the two systems are equal. The principal advance represented by this paper is in the number of vertical sections considered, and the development of practical methods for the required computations.

The fact that this method of analysis originated in the offices of the U. S. Bureau of Reclamation and has been used in the design of several large arch dams, notably the Horse Mesa, Gibson, and Owyhee Dams, should give it much weight.

In certain respects, the same principles were used in the design of the La Jogne Arch Dam,† in Switzerland, although the required load distribution was determined by a different method. For that dam there were investigated nine vertical cantilevers and four horizontal arch elements. The partial loads carried by each element were evaluated by a mathematical process so that the deflections of the arch and cantilever elements were identical at corresponding points of intersection of the two systems. The tension stresses in the La Jogne Dam were limited to 52 lb. per sq. in. (4 kg. per sq. cm.), however, and secondary arches were not considered.

In detailed application the authors' method utilizes assumptions which mark a radical departure from the principles ordinarily used in the design of concrete structures in general, and dams in particular. For instance, the authors frankly assume that high tension stresses and numerous cracks are likely to occur in arch dams under load. By their method of analysis the parts of the arch and cantilever sections presumably cracked or in tension are neglected, and the final analysis of stresses is made by considering the reduced sections, that is, those in compression, only.

When, in 1920,‡ the writer suggested that arch dams designed according to the cylinder formula were likely to develop cracks in both horizontal and vertical planes, criticism arose. It is a source of satisfaction to the writer that his conclusions, as then stated, have since been substantially vindicated by tests.

There is some uncertainty regarding the depth of the open cracks assumed by the authors and the corresponding forces acting in the cracks due to the hydrostatic pressure of the water in the reservoir. Evidently, the cracks on the air side of the dam are not subject to such pressure.

After a crack has developed in the concrete, the adjacent parts, formerly stressed in tension, will immediately be relieved of stress by the formation

‡ "Gravity and Arch Action in Curved Dams," *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

of the crack. There is no reason for additional cracks forming in the immediate vicinity of the first one, and the thickness, area, and moment of inertia of the primary and secondary arches are substantially the same, except, of course, in the immediate vicinity of the cracks.

Thus, in an arch dam subjected to load there may be excessive tension stresses at both abutments at the extrados, and at the crown of the intrados, producing cracks at all three points. In the immediate vicinity of the cracks, areas that were plane before bending evidently are no longer plane after bending of the arch. In other words, deformations equivalent to a slight rotation are taking place near the cracks. This has an effect similar to that of "restrained" hinges, and the "hingeless" primary arch with cracks at both abutments and at the crown, therefore, will be converted into a structural element resembling a three-hinged arch.

Secondary arching may occur in structures before cracks have occurred, in accordance with Castigliano's law of "least work". This is observed frequently in tunnel excavations. In some such cases, material has been removed to the surface of the theoretical secondary arch without impairing the strength of the structure.

It has been thoroughly demonstrated that the older and simpler methods of designing thick arch dams were at best only roughly approximate and frequently erroneous. The need of refinements in design was evident, and has led to many studies and much progress in the art. The advances in theory, however, have also served to emphasize the inherent uncertainties involved in the assumptions on which the theory must be applied. In other words, the more designers are able to visualize the mechanics of the thick arch dam, the more they appreciate its complexity and the practical limitations of its accurate stress analysis. In view of these multiplying difficulties, to say nothing of other aspects of the matter, it is perhaps indicated that future efforts should be directed toward alterations in the type of structure, such as would eliminate, in part at least, if possible, some of the uncertainties which are inherent in, and somewhat peculiar to, the thick arch dam. In other words, a too great complexity of structural action may reasonably suggest the desirability of a change in the design in the direction of simplicity.

An effort in this direction, with gratifying success, was made by the writer in the design of the Railroad Canyon Arch Dam, in California, built in 1927-28. The dam is approximately 100 ft. high. It is of the variable radius arch type and has an up-stream slope at the arch crown of 10 on 4. Instead of designing the dam on the ordinary arch principle, then assuming cracks in the concrete, and neglecting the concrete cracked or in tension, as in the authors' method, the writer shaped the arches, as constructed, directly along the outline of the "secondary" arches, thereby eliminating tension, at least in any appreciable amount, together with the numerous attendant uncertainties. Incidentally, this design saved the concrete which, under the assumption of either "reduced" or "secondary" arches as portions of thick arches, would have been placed in the structure without any considerable increase in its strength.

FREDRIK VOGT,* ASSOC. M. AM. SOC. C. E. (by letter).—The authors deserve credit for having brought this method of calculation to discussion, since it may lead to improvements in the design of dams. Their main discussion is confined to the calculation of stresses under certain conditions, and the assumptions made are only partly dealt with. It seems to the writer that a discussion of the assumptions is the more important phase. A rough approximation based on correct assumptions with regard to shrinkage, temperature changes, yielding of foundation, etc., is more valuable than a highly refined computation based on incorrect assumptions. However, it is easily understood that the authors wished to limit the problem.

Ignoring all parts of the structure in which tensile stresses occur in order to calculate the greatest compression stresses seems at first glance to be on the side of safety. However, if at first a single crack is opened, due to high tension, the tensile stresses at the neighboring sections are at once reduced to such small magnitudes, that the occurrence of more cracks is not probable. A cantilever with only one horizontal crack at the foundation joint is less flexible than a cantilever without any tensile strength.† In order to obtain the necessary deflection of the arch rings, the eccentricity of the load on the cantilevers and the compression stresses at the toe must be greater if only a single crack is formed than if all the tensile strength can be neglected.

When a large part of the arch section is either affected by tensile stresses, or is cracked, the material is only partly utilized. However, when the dam is constructed in the usual manner, it is impossible to avoid this waste of material. The writer has worked on the problem of how to make the cylinder formula valid for arch dams, thus adding to the ability of the arches to take loads without increasing the stresses in order to improve the safety factor or to cut down the dimensions of the structure. He thinks that this result can be obtained by using a multiple-pressure grouting system, dividing a number of the contraction joints into closed compartments by vertical and horizontal water-stops, so that each of the compartments can be grouted under separate pressure. By such a system it is possible to apply initial stresses in the dam, distributed in such a way that the resulting stresses due to load, shrinkage, cooling, and grouting are approximately equalized over the section. Not only will the arch effect be improved by making the cylinder formula valid in this way, but by pressing grout into closed compartments an actual pressure grouting also can be obtained in order to reduce the stresses in the cantilevers and at least to some extent convert the tensile stresses into compression. The writer agrees with the authors that dams constructed as at present, without any actual pressure grouting, should be designed with constant radius where the canyon is wide as compared with the height of the dam. However, by applying a multiple-pressure grouting, the use of the constant-angle arch principle can also be made suitable for dams in wide canyons, since the cantilever load can be checked. Furthermore, the use of partly open joints of, say, ½-in. to 1-in. opening, makes it possible to cool the dam by circulating water in order

* Cons. Engr., U. S. Bureau of Reclamation, Denver, Colo.

† Some experiments on this subject have been made by E. Aarskog, Civ. Engr., Dept. of Public Roads, Oslo, Norway.

to get rid of the chemical heat before grouting and to apply the grouting without waiting for a natural opening of the joints due to shrinkage and cooling.

The method of calculation in itself does not seem quite adequate until three factors affecting the load distribution are taken into account: First, the bending of the cantilevers due to the lateral expansion which is caused by arch stresses and *vice versa;* second, the effect of stiffness against torsion; and, third, the effect of stiffness against tangential displacements in the structure.

At the crown, the water-load produces high compression stresses at the up-stream face and low compression on tensile stresses at the down-stream face. The lateral expansion due to these stresses tends to bend the cantilever down stream, thus reducing the bending stresses in the cantilevers. After the arch stresses are computed, this bending can easily be calculated for all cantilevers. The influence of lateral expansion—due to stresses in the cantilevers from water-load only—on the arch deflection will usually be negligible.

In two cases the writer has found that the stiffness against torsion of cantilevers and arch rings reduces the stresses slightly, but, since this effect is of little importance, at least for the examples dealt with, and as they are difficult to compute, he agrees that it is best to neglect it. Perhaps, the torsion may be of importance for very thick arch dams.

FIG. 37.

The stiffness against tangential displacements, on the other hand, may be of material importance in some cases, and when taken into account may cause a considerable redistribution of the stresses. The story of two dam failures described in the technical press* gives a convincing illustration of the importance of this stiffness. In one case the rock abutment of the arch was washed out; in the other case a gravity abutment turned over, so that both arches were without support for more than one-half their height. However, the arch itself did not fail in either case. If the dams were considered as consisting of arch rings and cantilevers, as discussed by the authors, and the arch rings were without support and were unable to take any load in the upper half of the height, then the cantilevers would be certain to fail since the sections were very slender. In the second case, the dam would have to stand the total water pressure without support from the abutment for some time before the water was lowered. Moreover, it would have to stand the shaking due to the failure of the abutment. Only factors other than those dealt with in the paper could save the arches, and among these the stiffness against the tangential displacements may be the most important. It also can be stated that the

* *Engineering News-Record*, Vol. 2, 1926, p. 616.

arch pressure in this case has been directed down to the remaining foundation, as indicated in Fig. 37.

In order to check the importance of this stiffness, in the case of dams with abutments which have not failed, the writer made tests on a small rubber model in Trondjhem, Norway. (See Figs. 38 and 39.) The model itself and the foundation were both of soft rubber mounted in a wooden frame and loaded with water. Radial and tangential displacements were measured for seven vertical and six horizontal sections (see Fig. 40). The diagrams show at once that there is a twisting at the foundation due to a bending moment which verifies the calculations made by the writer* for the yielding of elastic foundations. Furthermore, tangential displacements are found to have about the expected magnitude, and they cannot occur except in connection with tangential shear forces, which tend to increase the stiffness of the arch rings against deflection. All the different kinds of rubber considered showed a high "time effect" and did not give an entirely straight stress-strain diagram. Furthermore, Poisson's ratio was about 1:2.2 for the rubber chosen for the experiment, instead of 1:6 or 1:8 for concrete, and this makes some difference in the coefficients for the shear deformation.

Due to the time effect, it was difficult to get accurate measurements, and these may be taken mainly as qualitative and not quantitative. The radial deflection was measured directly by means of micrometer screws with electric contacts. The tangential displacements were converted into radial displacements by means of a lever system, and were measured by means of the same screws. These screws were mounted on a turnable post, one screw at each elevation for which the displacements were to be measured. The observations were read to the nearest 0.0002 in. and the maximum deflection was about 0.06 in. The stiffness against tangential displacements is of importance mainly at dams with a great ratio between span and height, that is, for all the dams referred to in the paper.

In a circular arch ring of constant thickness with a uniform distribution of the load, the computation of tangential displacements is relatively simple, and this case will be described in order to give an idea of its importance. To simplify the problem the foundation is assumed to be unyielding. By means of a trial load method the tangential displacements can be taken into account more accurately whether or not the foundation is assumed to be firm or yielding.† The matter of making the computations is mainly a question of patience and time.

The method of computing the radial deflection in arches is well known and the same method can also be applied to the calculation of the tangential displacements. Therefore, the writer gives the final formulas without derivations.

E., Vol. 90 (1927), p. 475, and the Report on the Stevenson Creek Test Dam, *Proceedings*, Pt. 3, Am. Soc. C. E., May, 1928, p. 129, where it is stated that the writer's formulas for the foundation yielding are checked by the experiments. These formulas are also included in the trial load method as used at present by the U. S. Bureau of Reclamation, see the discussion by J. L. Savage and Ivan E. Houk, Members, Am. Soc. C. E., p. 1289.

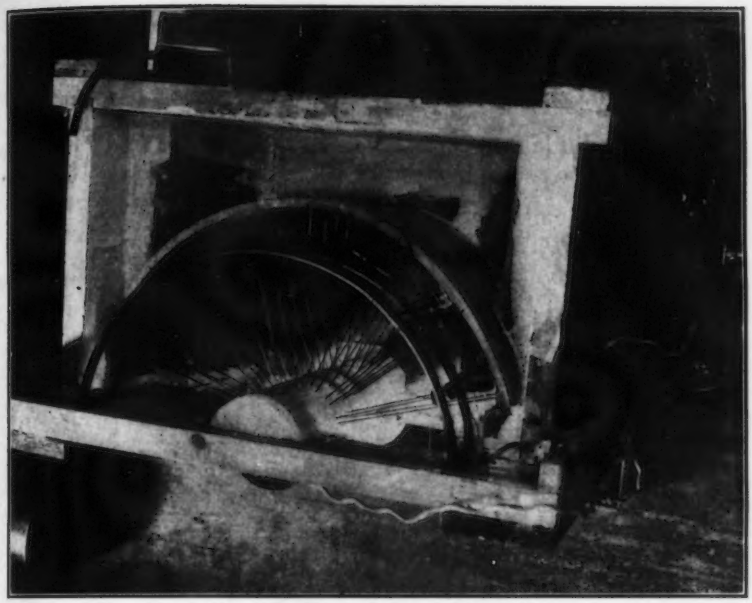

FIG. 38.—TOP VIEW OF RUBBER MODEL DAM.

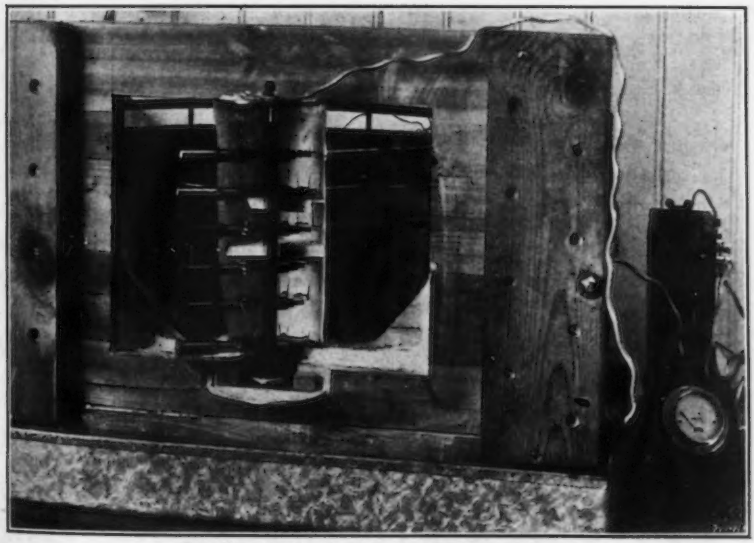

FIG. 39.—FRONT VIEW OF RUBBER MODEL DAM.

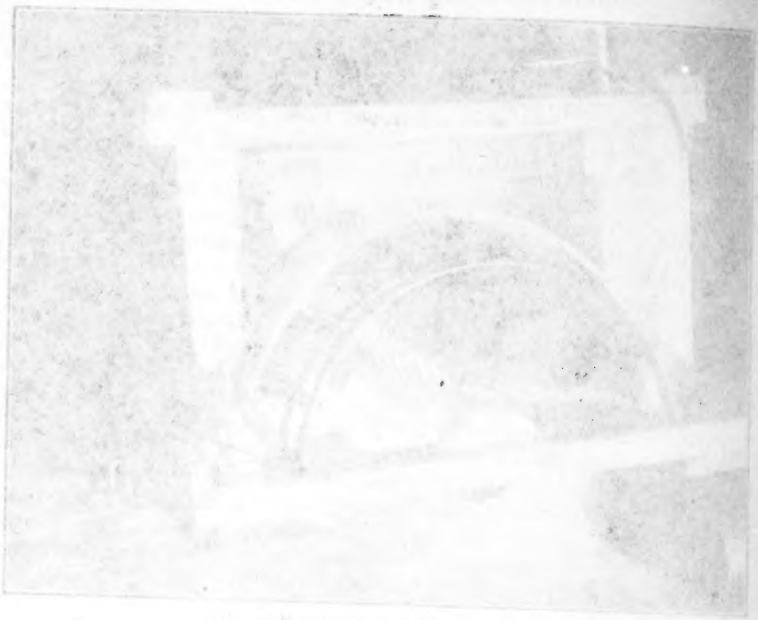

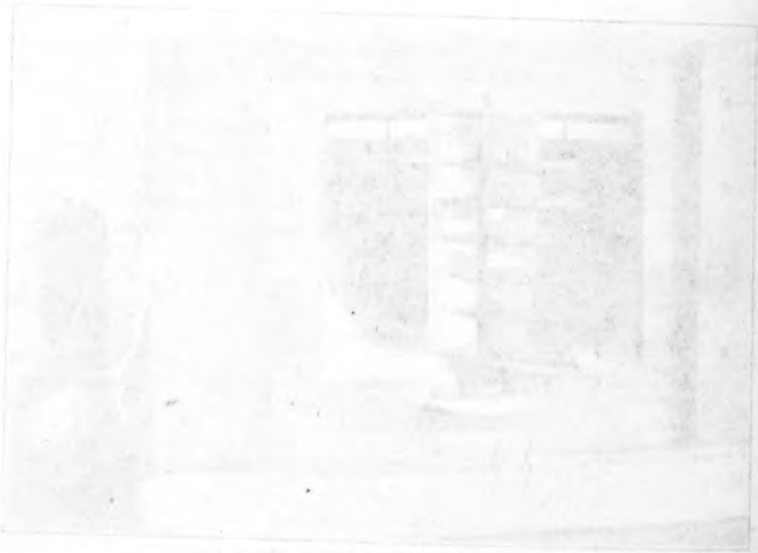

The radial deflection at the crown of the arch due to a uniform load, p_0 (Fig. 41), is:

$$\Delta r_0 = \lambda_0 \rho \frac{p_0 r_n r_e}{E t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (115)$$

in which, λ_0 and ρ are two coefficients;* r_n = the radius to the neutral axis; r_e = the radius to the up-stream face; t = the thickness of the arch; and E = the modulus of elasticity.

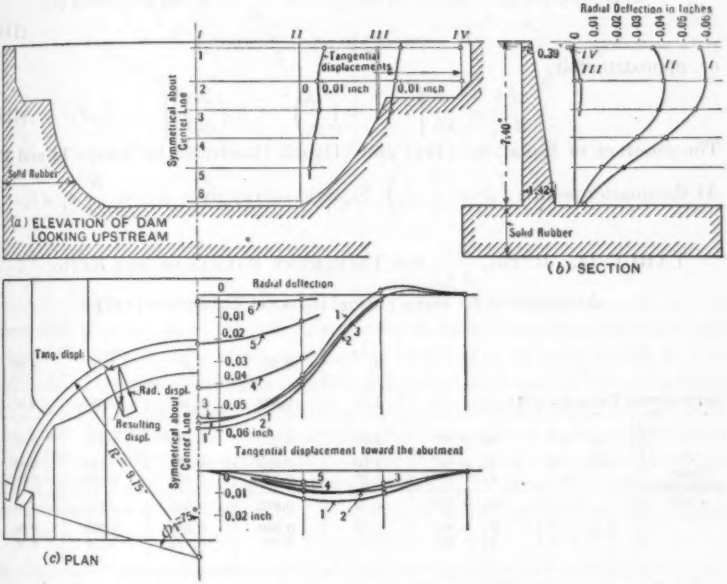

FIG. 40.—MODEL DAM MADE OF SOFT RUBBER. DEFLECTION DUE TO WATER-LOAD.

The radial deflection, Δr, at any point of the arch compared with the deflection at the crown is given by Equation (116):

$$\frac{\Delta r}{\Delta r_0} = \frac{a[\phi_1 (1 - \cos\phi_1 \cos\phi) - \phi \sin\phi \sin\phi_1] - b[\cos\phi - \cos\phi_1]\sin\phi_1}{(1 - \cos\phi_1)(a\,\phi_1 - b \sin\phi_1)} \quad (116)$$

in which,

$$a = 1 + \frac{1}{3}\left(\frac{\kappa E}{G} + 1\right)\left(\frac{t}{2 r_n}\right)^2$$

and,

$$b = 1 - \frac{1}{3}\left(\frac{\kappa E}{G} - 1\right)\left(\frac{t}{2 r_n}\right)^2$$

* See the writer's discussion on the paper by B. F. Jakobsen, M. Am. Soc. C. E., entitled "Stresses in Thick Arches of Dams," *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 544, Equations (120), p. 558, and (125), p. 564, and Fig. 46, p. 565.

Equation (116) equals approximately:

$$\frac{\Delta r}{\Delta r_0} = \left[1 - \left(\frac{\phi}{\phi_1}\right)^2\right]^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (117)$$

in which, ϕ_1 is one-half the central angle, and ϕ, the angular distance from the crown to the point in question, both in radians.

Furthermore, at any point except the crown and the abutments a tangential displacement, Δb, directed toward the abutments takes place, as follows:

$$\frac{\Delta b}{\Delta r_0} = \frac{a\,[\phi \cos \phi \sin \phi_1 - \phi_1 \cos \phi_1 \sin \phi] - 2\,\frac{\sin \phi_1}{\phi_1}\,[\phi_1 \sin \phi - \phi \sin \phi_1]}{(1 - \cos \phi_1)\,(a\,\phi_1 - b \sin \phi_1)} \quad \ldots\ldots (118)$$

or, approximately,

$$\frac{\Delta b}{\Delta r_0} = \frac{\phi}{15}\left[7 - 10\left(\frac{\phi}{\phi_1}\right)^2 + 3\left(\frac{\phi}{\phi_1}\right)^4\right] \quad \ldots\ldots\ldots\ldots\ldots (119)$$

The accuracy of Equations (117) and (119) is illustrated by Tables 14 and 15.

At the quarter-points, $\left(\phi = \frac{1}{2}\,\phi_1\right)$, Equation (119) gives $\Delta b = \frac{5}{32}\,\phi_1\,\Delta r_0$.

For instance, if one-half the central angle, ϕ_1, is equal to 1.0472 radians (60°), the tangential displacement midway between the crown and the abutment is found to be about one-sixth the radial deflection at the center.

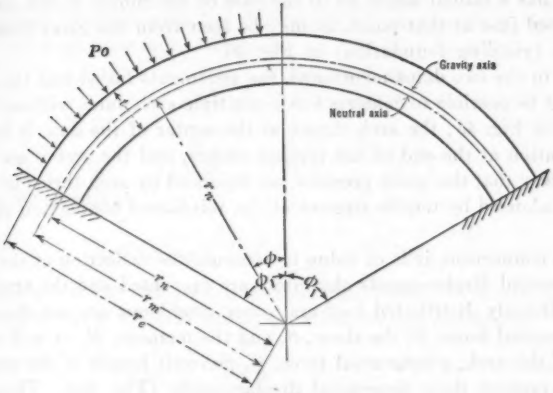

FIG. 41.

If the dam were divided by contraction joints very closely spaced, and if there were no friction in the joints, there would be no resistance against such tangential displacements, since each section would then be very flexible in this direction. However, the space between the contraction joints for most dams (very large dams excepted) is usually greater than the thickness of the dam, and hence the stiffness against tangential displacements of each section taken separately is greater than against radial deflections. Then, too, there is always a large amount of friction (due to the arch thrust) to resist the sliding of the two sections relative to each other. Especially if the joints are grouted, it must

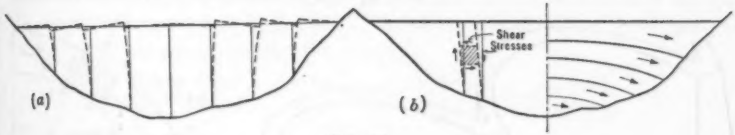

FIG. 42.

be assumed that this friction is great enough to make the dam act as a monolithic structure. If the sections can slide relative to each other, a tangential displacement can be produced by the bending of the sections, as shown in Fig. 42(*a*); but if the sections cannot slide relatively, the tangential displacement can be produced only as a shear deformation, each square being limited by vertical radial planes and horizontal planes must be deformed as shown in Fig. 42(*b*). This diagram also shows the shear stresses producing the deformation. If the bending deformation is taken away, and only the shear deformation remains, a relatively large force is needed to produce a certain displacement. In other words, such a condition makes a dam very resistant to tangential displacements.

If this shear is combined with the arch thrust, the direction of the principal stresses may be about as shown on the right side of Fig. 42(*b*); the arch thrust is bent downward in an inclined direction at the abutments. If the abutment has a salient angle, as in the case of the rubber model, the thrust is concentrated just at that point, as may be seen from the great tangential displacement (yielding foundation) in Fig. 40.

Since, in the two dams mentioned, the abutments failed and the arches did not, it may be possible to construct safe multiple-arch dams without buttresses, as shown in Fig. 43; the arch thrust at the center of the dam is led down to the foundation at the end of the vertical arches, and the arches are connected in such a way that the water pressure not balanced by arch thrust or cantilever action is balanced by tensile stresses at the reinforced connection between the arches.

In this connection, it is of value to compute the deflection of the arch ring if all tangential displacements absolutely are prevented and the arch is loaded with a uniformly distributed load and other conditions are not changed. Besides the normal force, N, the shear, S, and the moment, M, at both ends of an element of the arch, a tangential force, Q, per unit length of the arch axis, is needed to prevent these tangential displacements (Fig. 44). This force, Q, is the resultant of the tangential shear at the upper and lower boundary of the arch ring. The thickness measured square on the plane of Fig. 44 is assumed to be equal to the unit. Three conditions are necessary in order that the hatched element in Fig. 44 shall be in equilibrium:

$$d\,N + Q\,r_n\,d\,\phi = 0 \quad \ldots\ldots (120)$$

$$N\,d\,\phi + d\,S - p_1\,r_e\,d\,\phi = 0 \quad \ldots\ldots (121)$$

$$S\,r_n\,d\,\phi - d\,M = 0 \quad \ldots\ldots (122)$$

The total radial deflection, y, can be considered as consisting of the deflection, y_1, due to the moment, M, and y_2 due to the shear, S:

$$y = y_1 + y_2 \quad \ldots\ldots (123)$$

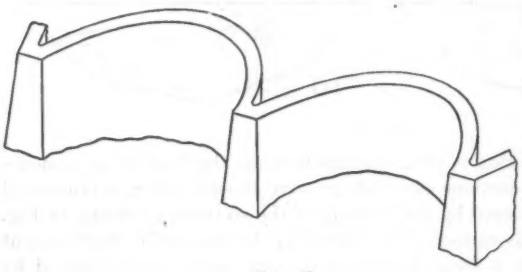

FIG. 43.

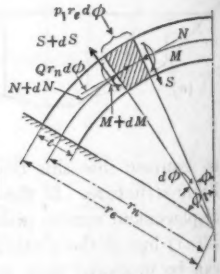

FIG. 44.

The unit axial compression, u, of the arch is determined directly by the radial deflection, y, since all tangential displacements are assumed to be prevented and only radial deflections are allowed:

$$u = \frac{y}{r_n} \quad \ldots\ldots (124)$$

Furthermore, the axial compression can be expressed by the normal force:

$$N = u\,E\,\frac{t}{\rho} = y\,E\,\frac{t}{\rho\,r_n} \quad \ldots\ldots (125)^*$$

The usual formulas give the derivatives of the terms, y_1 and y_2, which together constitute the total deflection:

$$\frac{d^2\,y_1}{r_n{}^2\,d\,\phi^2} = \frac{M}{E\,I} = \frac{12\,M}{E\,t^3} \quad \ldots\ldots (126)\dagger$$

$$\frac{d\,y_2}{r_n\,d\,\phi} = -\frac{\kappa\,S}{G\,F} = -\frac{\kappa\,S}{G\,t} \quad \ldots\ldots (127)$$

By using the notations,

$$y_1 = \rho\,\frac{p_1\,r_e\,r_n}{E\,t};\ a^4 = \frac{3\,r_n{}^2}{\rho\,t^2};\ b^2 = \frac{1}{4\,\rho}\,\frac{\kappa\,E}{G} \quad \ldots\ldots (128)$$

an elimination of the different unknown magnitudes by means of Equations (120) to (128) gives the differential equation for the deflection,

$$\frac{d^4\,y}{d\,\phi^4} - 4\,b^2\,\frac{d^2\,y}{d\,\phi^2} + 4\,a^4\,y = 4\,a^4\,y_1 \quad \ldots\ldots (129)$$

The moment and shear can be expressed by the deflection:

$$M = \frac{E\,t}{4\,a^4\,\rho}\left[\frac{d^2\,y}{d\,\phi^2} - 4\,b^2\,(y - y_1)\right] \quad \ldots\ldots (130)$$

$$S = \frac{E\,t}{4\,r_n\,a^4\,\rho}\left[\frac{d^3\,y}{d\,\phi^3} - 4\,b^2\,\frac{d\,y}{d\,\phi}\right] \quad \ldots\ldots (131)$$

From the symmetry of the arch it follows that at the crown ($\phi = 0$):

$$\frac{d\,y}{d\,\phi} = \frac{d^3\,y}{d\,\phi^3} = 0 \quad \ldots\ldots (132)$$

At the abutments ($\phi = \phi_1$), $y = 0$. Furthermore, the moment in itself produces no change in direction for the arch axis at the abutment if the dam is assumed to be fixed at both ends. The change in direction there can only be caused by the shear, so that for $\phi = \phi_1$:

$$\frac{d\,y}{d\,\phi} = \frac{d\,y_2}{d\,\phi} = -\frac{\kappa\,r_n}{G\,t}\,S = -\frac{b^2}{a^4}\left[\frac{d^3\,y}{d\,\phi^3} - 4\,b^2\,\frac{d\,y}{d\,\phi}\right] \quad \ldots\ldots (133)$$

or,

$$b^2\,\frac{d^3\,y}{d\,\phi^3} + (a^4 - 4\,b^4)\,\frac{d\,y}{d\,\phi} = 0 \quad \ldots\ldots (134)$$

The general differential equation is satisfied by the expression:

$$y = y_1 + C_1\,e^{\alpha\phi}\sin\beta\,\phi + C_2\,e^{\alpha\phi}\cos\beta\,\phi + C_3\,e^{-\alpha\phi}\sin\beta\,\phi + C_4\,e^{-\alpha\phi}\cos\beta\,\phi \quad \ldots\ldots (135)$$

in which,

$$\alpha = \sqrt{a^2 + b^2} \text{ and } \beta = \sqrt{a^2 - b^2} \quad \ldots\ldots (136)$$

---

* ρ is equal to unity for "thin" arches.

† For thick arches the moment of inertia, $I = \frac{t^3}{12}$, used as in Equation (126) does not give absolutely exact values for the bending, but the difference is without any importance, as shown by B. F. Jakobsen, M. Am. Soc. C. E., in his paper, "Stresses in Thick Arches of Dams," *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 475.

and C_1 to C_4 are four integration constants. These constants must be determined by the conditions at $\phi = 0$, and $\phi = \phi_1$, previously discussed. The single solution which agrees with these conditions is:

$$y = y_1 [1 - A \sinh \alpha \phi \sin \beta \phi - B \cosh \alpha \phi \cos \beta \phi] \ldots\ldots (137)$$

in which,

$$A = \frac{\alpha (3 \beta^2 - \alpha^2) \sinh \alpha \phi_1 \cos \beta \phi_1 - \beta (3 \alpha^2 - \beta^2) \cosh \alpha \phi_1 \sin \beta \phi_1}{\beta (3 \alpha^2 - \beta^2) \sinh \alpha \phi_1 \cosh \alpha \phi_1 + 2 (3 \beta^2 - \alpha^2) \sin \beta \phi_1 \cos \beta \phi_1} \ldots (138)$$

and,

$$B = \frac{\beta (3 \alpha^2 - \beta^2) \sinh \alpha \phi_1 \cos \beta \phi_1 + \alpha (3 \beta^2 - \alpha^2) \cosh \alpha \phi_1 \sin \beta \phi_1}{\beta (3 \alpha^2 - \beta^2) \sinh \alpha \phi_1 \cosh \alpha \phi_1 + \alpha (3 \beta^2 - \alpha^2) \sin \beta \phi_1 \cos \beta \phi_1} \ldots (139)$$

At the crest of the arch, $\phi = 0$, the deflection is found from Equation (137):

$$\Delta r_1 = y_1 [1 - B] = \lambda_1 \rho \frac{p_1 r_n r_e}{E t} \ldots\ldots (140)$$

in which,

$$\lambda_1 = 1 - B \ldots\ldots (141)$$

and y_1 is the deflection according to the cylinder formula.

As may be seen from this development, the final formula (Equation (140)) for the deflection at the crown of the arch is the same whether or not the arch ring is prevented from tangential displacements, except that the coefficient, λ_0, in Equation (115) must be replaced by λ_1, if these displacements are prevented. By calculating the coefficients, λ_0 and λ_1, the influence of the stiffness against tangential displacements on the stiffness against radial displacements can be judged. For instance, for an arch with a thickness, t, equal to one-twentieth the radius, r_n, of the neutral axis, Equation (115) shows that if $\frac{\kappa E}{G} = 2.8$, $\lambda_1 = 1.075$ if $\phi_1 = 30°$ and $\lambda_1 = 0.997$ if $\phi_1 = 60$ degrees.

The corresponding values for the coefficient, λ_0, are 1.67 and 1.87.* This means that if the dam is absolutely rigid against tangential displacements, the stiffness of the arch rings will be increased in a ratio of 1.075 to 1.67, or 55% for the first case and, correspondingly, 88% for the second case. Of course, the dam is not absolutely rigid against such displacements; it is only very rigid if the ratio between its span and height is relatively great. On the whole, the shear deformation in the arch does not influence the value of the coefficient, λ_1, very much. To neglect the shear deformation in the development given previously is the same as putting $\frac{\kappa E}{G}$ equal to zero, and then the coefficient, λ_1, is simplified as follows:

$$\lambda_1 = 1 - B = \frac{(\sinh w - \sinh w)(\cosh w - \cosh w)}{\sinh w \cosh w + \sin w \cos w}$$

$$= \frac{w^4}{6} \left[1 - \frac{163}{1\,260} w^4 + \ldots\right] \ldots\ldots (142)$$

in which,

$$w = a \phi_1 = \phi_1 \sqrt[4]{\frac{3 r_n^2}{\rho t^2}} \ldots\ldots (143)$$

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 565, Fig. 46.

This formula for the coefficient, λ_1, as a function of w is demonstrated graphically in Fig. 45. If the arch is prevented from tangential displacements by means of tangential reactions (shear forces), the arch thrust at any point is proportional to the deflection as given by Equation (125). Therefore, at the abutments the thrust in such an arch is equal to zero; or, in other words, all the thrust is taken up by the tangential shear forces between the crown and the abutment.

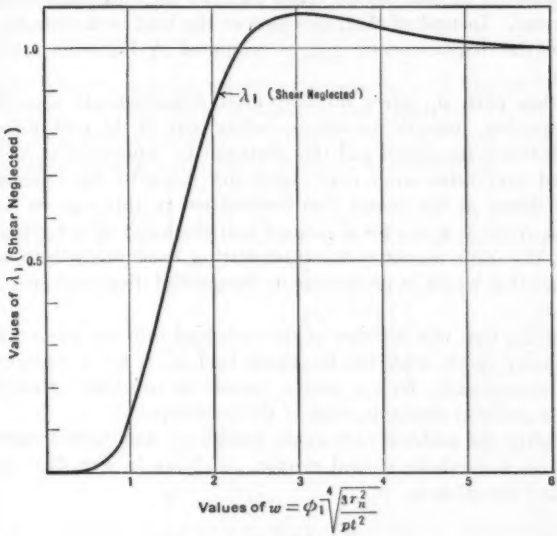

FIG. 45.

In an actual dam this should mean that the thrust in the upper arch rings is transferred to the lower arch rings by the shear forces between the different rings. Since the structure may allow some tangential displacements, not all the arch thrust is transmitted in this way, but only a part of it. How great this is depends mainly on the ratio between span and height and the other dimensions of the dam. Imagine, for instance, that the load, p_a, taken by arch action is divided into two parts, one part, p_0, being carried by the horizontal arch thrust over to the abutments, and another part, p_1, being transferred by tangential shear over to the other arch rings. Together these parts of the load give the total arch load:

$$p_a = p_0 + p_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (144)$$

The first part of the load contributes to the deflection at the crown,

$$\Delta r_0 = \lambda_0 \rho \frac{p_0 r_e r_n}{E t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (145)$$

and the second part contributes,

$$\Delta r_1 = \lambda_1 \rho \frac{p_1 r_e r_n}{E t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (146)$$

or, together,

$$\Delta r = \Delta r_0 + \Delta r_1 = \lambda \rho \frac{p_a r_e r_n}{E t} \quad \ldots\ldots (147)$$

in which,

$$\lambda = \frac{\lambda_0 p_0 + \lambda_1 p_1}{p_a} \quad \ldots\ldots (148)$$

The first part of the load, p_0, gives an arch thrust carried horizontally over to the abutments as mentioned, which signifies no tangential forces between the arch rings. Instead of that, this part of the load is inseparably connected with tangential displacements, Δb, as computed by Equation (118) or Equation (119).

The other part, p_1, gives no tangential displacements according to the assumptions; but, instead, the corresponding part of the arch thrust must be taken up between the crown and the abutment by tangential shear forces, and transmitted over other arch rings vertically down to the foundation. The total arch thrust at the center line transmitted in this way on each half of the arch is, $N = \lambda_1 p_1 r_e$, for a ring of unit thickness in a vertical direction. Of course, the shear necessary for transmitting these forces between the arch rings is just that which is producing the tangential displacements, Δb, in the cantilevers.

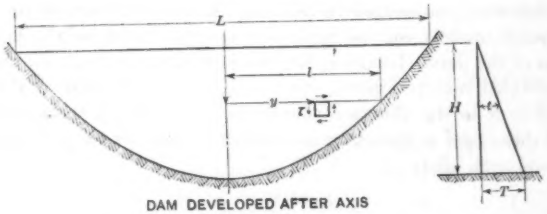
It is certain that this division of the arch load into two parts can only give an approximate result, since the total arch load, p_a, is not a constant along the arch and, consequently, both p_0 and p_1 cannot be constant. However, it may be useful in order to obtain an idea of the conditions.

To simplify the problem still more, consider a dam with triangular cross-section across a parabolic shaped canyon, as shown in Fig. 46. One-half the length at any elevation is,

$$l = \frac{L}{2} \sqrt{1 - \frac{x}{H}} = \phi_1 r_n \quad \ldots\ldots (149)$$

and the thickness is,

$$t = \frac{T}{H} x \quad \ldots\ldots (150)$$



DAM DEVELOPED AFTER AXIS

FIG. 46.

Introducing at any point the horizontal distance, y, from the center line, $y = \phi r_n$, the tangential displacement against the abutment (see Equation (119)) may be expressed as:

$$\Delta b = \lambda_0 \rho \frac{p_0 r_e r_n}{E t} \frac{y}{15 r_n} \left[7 - 10 \left(\frac{y}{l} \right)^2 + 3 \left(\frac{y}{l} \right)^4 \right] \quad \ldots\ldots (151)$$

The shear stresses, horizontal and vertical, in the plan of the dam are $\tau = -G\frac{\delta \Delta b}{\delta x}$, in which, G is the shearing modulus. When the thickness of the dam is t, the difference in shearing force per unit length of the axis between the lower and upper limit of an arch ring is $\frac{\delta (\tau t)}{\delta x}$, and the total difference in this shearing force from crown to abutment must be equal to the thrust from the load, p_1:

$$\lambda_1 p_1 r_e = \int_0^l \frac{\delta (\tau t)}{\delta x} d y \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (152)$$

For the integration assume that the product, $\lambda_0 \rho$, is approximately constant; the variation is negligible, at least for the upper part of the arch. By substituting the different expressions given for l, t, Δb, and τ, in Equation (152), the ratio between p_1 and p_0 will be found to be equal to:

$$\frac{p_1}{p_0} = \frac{\lambda_0 \rho}{120 \lambda_1} \frac{G}{E} \frac{L^2}{H^2} \left[\frac{1 + 3\frac{H}{x}}{1 - \frac{x}{H}} - \frac{3 H^2}{p_0} \left[\left(1 - 3\frac{x}{H}\right) \frac{\delta \left(\frac{\rho_0}{x}\right)}{\delta x} + x \left(1 - \frac{x}{H}\right) \frac{\delta^2 \left(\frac{\rho_0}{x}\right)}{\delta x^2} \right] \right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (153)$$

If Poisson's ratio, $\frac{1}{m}$, is $\frac{1}{6}$, then,

$$\frac{G}{E} = \frac{m}{2 (m + 1)} = \frac{3}{7}$$

and $\frac{\lambda_0 \rho}{\lambda_1}$ may be taken equal to 1.8, an average for the whole upper part of the arch.

A dam with zero thickness at the crest takes zero arch load at the crest, and both p_0 and p_1 must be zero at $x = 0$. This boundary condition is fulfilled if it is assumed that p_0 is proportional to $x\, e^{\frac{x}{H}}$, at least for small values of x. Then the ratio is,

$$\frac{p_1}{p_0} = \frac{\lambda_0 \rho}{120 \lambda_1} \frac{G}{E} \frac{L^2}{H^2} \frac{10 - 3\frac{x}{H} - 3\left(\frac{x}{H}\right)^2}{1 - \frac{x}{H}}$$

or, for $x = 0$,

$$\frac{p_1}{p_0} = \frac{\lambda_0 \rho}{12 \lambda_1} \frac{G}{E} \frac{L^2}{H^2} = 0.0643 \frac{L^2}{H^2} \quad \ldots\ldots\ldots\ldots (154)$$

This function for p_0 cannot be considered valid over its entire height because that would only lead to absurd conditions. At the base all the arch load must be taken by shear since the lowest arch is directly connected with the foundation along the entire length; that is, $p_0 = 0$ and $\frac{p_1}{p_0}$ is infinitely

great. The total arch load is always greater than zero at the bottom if the length profile of the dam is curved. These conditions are fulfilled, for instance, if p_0 is proportional to $x\left(1-\frac{x}{H}\right)$, except for small values of x. It does not matter very much if p_0 is determined by a more complicated function fulfilling the conditions at the limits. Nor does it matter how the transfer between the exponential function at the top and the parabola at some section below is assumed. The main thing is only that p_0 must increase at a rate nearly proportional with x at the top and then must follow any smooth curve down to zero at $x = H$. If p_0 is found by the parabola formula, the ratio is,

$$\frac{p_1}{p_0} = \frac{\lambda_0\,\rho}{60\,\lambda_1}\,\frac{G}{E}\,\frac{L^2}{H^2}\,\frac{3\,\frac{H}{x}-1}{1-\frac{x}{H}} \qquad \text{.....(155)}$$

Table 16 gives a comparison of values obtained for the ratio, $\frac{p_1}{p_0}$ by Equations (154) and (155), respectively.

TABLE 16.—Comparative Values of $\frac{p_1}{p_0}$.

As will be seen, the ratio is not a constant value, but in the central part of the dam the variation is not great. The same result will be found if other reasonable assumptions for p_0 are made. The value depends mainly on the ratio between the length, L, and the height, H.

A similar analysis can be easily made for other cross-sections and canyon profiles. Some difficulties may result if the arches near the crest are designed too strong, because this may sometimes lead to a negative value for the part, p_1, of the load. However, the fact remains that a certain fraction of the arch

load, the fraction depending mainly on the ratio, $\frac{L^2}{H}$, must be transmitted vertically down to the foundation by tangential shear between the arch rings. This fraction is found to be smaller than in the case of a triangular section if the thickness of the dam is the same for different elevations, as in the Stevenson Creek Dam. Since practical dams always have a more or less triangular-shaped cross-section, the writer has used the following formula in the computation of stresses in some dams:

$$R = \frac{p_1}{p_0} = \frac{1}{10}\left(\frac{L}{H}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (156)$$

It is possible that,

$$R = \frac{p_1}{p_0} = \frac{1}{8}\left(\frac{L}{H}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (157)$$

would give a better average.

The stiffness against tangential shear deformation is taken into account in this way, at least approximately, and without any noticeable increase in the numerical calculation. Equation (148) is then found to be:

$$\lambda = \frac{\lambda_0 + R\,\lambda_1}{1 + R} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (158)$$

Both λ_0 and λ_1 can be taken directly from the diagrams, and R is the ratio given by Equation (156) or Equation (157).

For instance, for the Gibson Dam, the length is about 4.5 times the height, the ratio between the coefficients, λ_0 and λ_1, is about 1.8 for the greatest part of the dam, and the stiffness of the arch rings against deflection in this way is found to be increased by about 40 to 45%; that is, with the same deflection, the arch load is increased by 40 to 45% due to this tangential stiffness. That, of course, will also change the load distribution between the arches and the cantilevers. However, the change in load will be less than 40% since the deflection also will be changed.

For arch dams in narrow canyons, the influence will be much less. The tangential stiffness is only of importance at wide dam sites, in which case it is a factor that cannot be neglected in any calculation of stresses. The next question is how to take it into account (at least, approximately) in a way that will not cause too much additional work.

Where only the deflection of one cantilever at the center is compared with the deflection of the arch rings, and the load on each arch ring is assumed to be uniformly distributed, the use of the coefficient, λ_1 (Equation (158)), instead of λ_0, at once gives the solution. As far as actual arch dams with approximately triangular cross-section and large central angles constructed in U-shaped canyons are concerned, the writer has found that these very simplified assumptions give the bending stresses in the highest cantilevers within a few per cent., and even give the arch stresses without very great errors. The distribution of load for that case may be found in one to two days instead of one to two months by the complete trial load method.

Where it is found necessary to take the deflection of more than the central cantilever into account in the computations, it may be convenient to use the following procedure: First, compute the approximate division of load by tak-

ing only the central cantilever into account as before, and by the arch-load diagram and the approximate division of the arch load in the two components, p_0 and p_1, calculate the approximate values of the horizontal arch thrust and the tangential shear force for a number of points at different vertical planes of the dam. By these values for arch thrust and shear the direction of the true thrust can be found in the same way as the principal stresses in an infinitely small cube. The slope of this direction may be ψ. Then,

$$\tan 2\psi = 2 \frac{\text{shear per unit length of arch}}{\text{thrust per unit height — vertical force per unit length of arch}}$$

After the declination of the thrust due to water pressure is found, at least approximately, the trajectories of thrust are plotted and the dam is divided into a number of arch rings limited by these trajectories as shown in Fig. 47. Between these arch rings no shear of any importance can occur, and they may be used for analysis instead of the horizontal arch rings used by the authors. The vertical component of the inclined arch thrust transfers part of the weight of the cantilevers at the center to the abutments of the different arch rings. These vertical forces can be computed directly from the horizontal forces, since the resultant at any point must follow the trajectories. The complication in the numerical computations then is mainly reduced to the use of arch rings of variable thickness, both vertically and horizontally, instead of rings with only the horizontal thickness being variable. The yielding of the foundation may be taken into account in the same manner as for the other arch rings.*

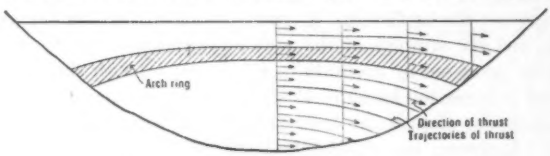

FIG. 47.

The results of the analysis will be changed as follows:

1.—The load taken by the arches is increased and the load taken by the cantilevers reduced, which reduces the bending stresses in the cantilevers.
2.—Part of the weight of the dam at the center will be carried by the vertical components of the arch thrust, and transmitted to either side of the dam. This reduces the compression stresses and increases possible tensile stresses at the central cantilevers and *vice versa* at the cantilevers near the abutments.
3.—The actual arch rings are much stiffer at the abutments than the horizontal arch rings, since the thickness there is increased both vertically and horizontally from the thickness at the crown, which may give quite a different distribution of the arch stresses.

Some of the dams referred to in the paper are made considerably thicker at the springing line than at the crown. It seems doubtful whether an extended analysis of these problems would justify this detail since the difference already is obtained with constant thickness in horizontal planes by using the true inclined arch rings.

* See discussion by Messrs. Savage and Houk, p. 1289.

J. L. SAVAGE* and IVAN E. HOUK,† MEMBERS, AM. SOC. C. E. (by letter).—Several important changes and improvements have been made by the U. S. Bureau of Reclamation in its methods of analyzing arch dams since this paper was prepared. These modifications are too elaborate to be adequately explained in a brief discussion. However, it seems advisable at this time to state briefly the nature of the changes that have been made and to discuss their effect on the analysis of the Gibson Dam now being built on the Sun River Project of Montana, this being one of the dams mentioned by the authors.

In the original analysis of the Gibson Dam the sides of the cantilevers were assumed to be parallel; the temperature curve shown in Fig. 4, which was established on an incomplete study of limited experimental data, was used as a basis for calculating temperature stresses in the arches; the effect of shear in the arches was neglected; the foundation and abutment rock was considered to be rigid; and no arch action was assumed to take place until the increasing water load had reduced the up-stream deflections of the cantilevers to zero. In the revised calculations, the sides of the cantilevers were taken as radial; a new temperature curve, founded on a careful study of many actual measurements of concrete temperature variations, was used as a basis for calculating temperature stresses in the arches; the effect of shear in the arches was considered; the foundation and abutment deformations were taken into account in both cantilever and arch elements; and transmission of load to the abutments by arch action was assumed to begin as soon as the reservoir begins to fill.

Thus far, the writers have not taken into account the saturation of concrete near the up-stream face of the dam, flow of concrete, effect of Poisson's ratio, transmission of load by tangential shear between arches, effect of vertical shear between cantilevers, effect of variations in the modulus of elasticity, the distribution of stress due to twisting of the horizontal and vertical elements, some of the effects introduced through foundation and abutment deformations, or the errors introduced through the assumption of a linear stress distribution. However, all these conditions are being investigated, and the writers hope, eventually, to be able to estimate the magnitude of some of their effects as regards the stresses within the structure and its safety against failure through any cause.

The fact that the sides of the cantilever should be taken as radial vertical planes instead of parallel vertical planes was recognized at the time the original analysis of the Gibson Dam was made. While it was realized that proper allowance for this condition would tend to increase the bending of the cantilevers under given loads, thus tending to increase the stresses at the down-stream face of the dam, it was not believed that the effect of the correction would be as important as it was later found to be, especially as regards bending where the cantilevers are already cracked. Of course, the increased bending and accompanying increased stress under a given load is not the final effect on the analysis of the structure. The arches must bend over to meet the

* Designing Engr., Denver Office, U. S. Reclamation Service, Denver, Colo.
† Research Engr., U. S. Bureau of Reclamation, Denver, Colo.

increased deflections of the cantilevers, and in order to do so they will carry some of the load formerly allotted to the cantilevers. Consequently, the net result of considering the cantilever sides as radial instead of parallel is a new load distribution with slightly increased deflections and stresses.

Fig. 48 shows the increase in down-stream deflection of the crown cantilever at the Gibson Dam, also the increase in tension area, caused by considering the sides of the cantilever as radial instead of parallel, the load being the same in each calculation. It will be noticed that, while the proportionate increase in total tension area is not as great as might be expected, the decrease in width of uncracked base and the increase in down-stream deflection of the cantilever, resulting from the corrected method of calculation, are both important. The latter is seen to be practically double the original deflection at all elevations.

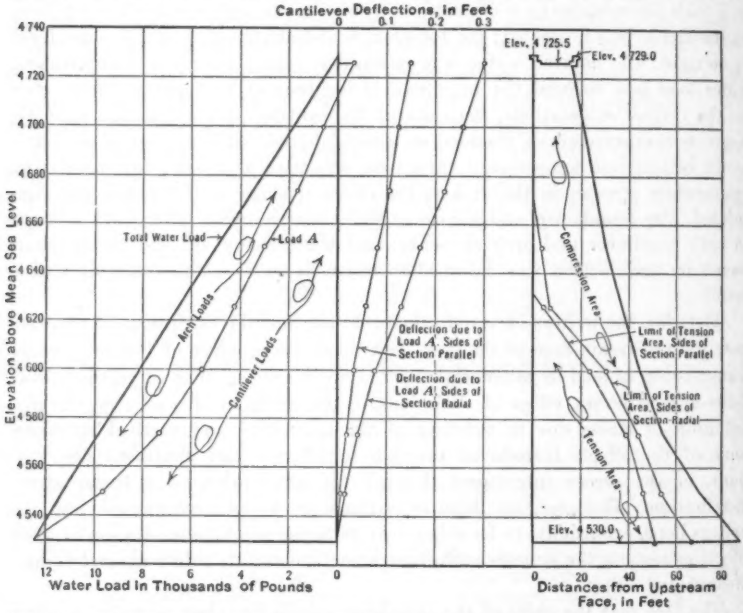

FIG. 48.—CHANGES IN TENSION AREA AND DEFLECTION OF CROWN CANTILEVER AT GIBSON DAM CAUSED BY CONSIDERING RADIAL SIDES OF CANTILEVER.

Fig. 49 compares the original temperature curve of Fig. 4 with the revised curve used in the latest analysis of the Gibson Dam. In determining the revised curve the variations in water temperature at different depths in the reservoir were taken into account, as well as the maximum and minimum air temperatures at the down-stream face of the dam. It will be noticed that the new curve is higher than the old one at all points. Consequently, its use tends to give higher temperature stresses. Since the curve gives the total annual range in concrete temperatures, only one-half the values shown need be used in calculating arch stresses, it being assumed that the contraction joints will be grouted, or closing plugs poured, when the concrete temperatures are equal

to, or less than, the mean annual temperature of the dam. Since the expansion accompanying a rise in temperature works against the water load, only the contraction accompanying the decrease in temperature need be considered. The new curve was not extended farther at the left of the diagram since 15 ft. is the minimum thickness of the Gibson Dam.

The effect of considering shear in the arch calculations was found to be practically negligible in the case of long thin arches, but to increase as the ratio of $\frac{l}{r}$ increased, becoming very important in the case of comparatively short, thick arches. For some of the thick arches analyzed, the deflections

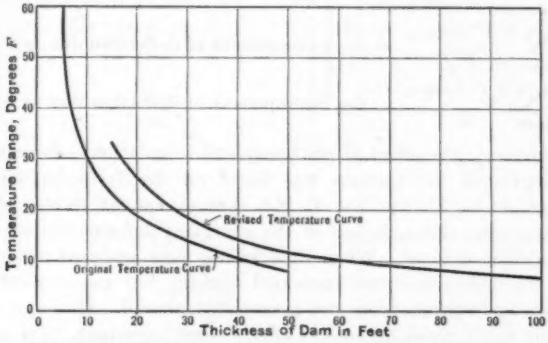

FIG. 49.—COMPARISON OF ORIGINAL AND REVISED TEMPERATURE CURVES USED IN DESIGN OF GIBSON DAM.

caused by shear were found to equal or exceed those produced by thrust and moment. Both positive and negative moments were found to be decreased numerically at all points; the thrust was increased materially at all points; the line of thrust was found to follow more closely the center line of the arch, reducing the eccentricity greatly at both crown and haunch; and the resultant compressive stresses were not changed greatly while the tensile stresses were decreased appreciably. Fig. 50 illustrates these effects as calculated for a comparatively short, thick, symmetrical arch, under a uniform load, investigated in connection with the design of another dam.

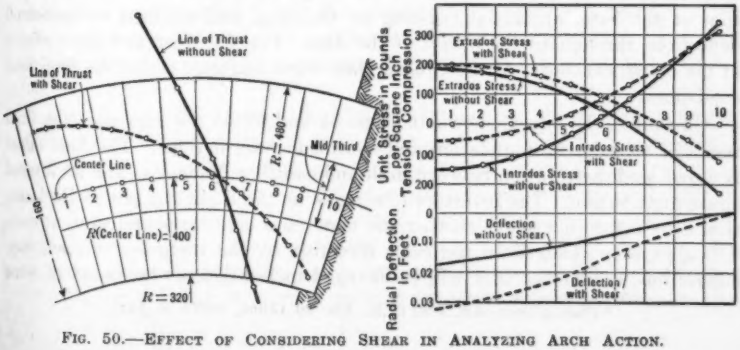

FIG. 50.—EFFECT OF CONSIDERING SHEAR IN ANALYZING ARCH ACTION.

Consideration of the shear effect in analyzing a symmetrical arch by the methods outlined in Table 5, requires the inclusion of columns for the following quantities, the notation being the same as that in Table 5:

$$V_L = \text{the shear due to external loads.}$$

$$\frac{3}{E}\sum\frac{S\,V_L\sin\alpha}{T} = \text{the } x\text{-component of deflection due to } V_L.$$

$$H_c\sin\alpha = \text{the shear component of the crown thrust.}$$

$$H_c\sin\alpha - V_L = \text{the net shear, } V.$$

$$3\,\frac{V\,s}{E\,T} = \text{the shear deformation.}$$

$$\sum\frac{3\,V\,s\cos\alpha}{E\,T} = \text{the } y\text{-component of deflection due to } V.$$

$$-\sum\frac{3\,V\,s\sin\alpha}{E\,T} = \text{the } x\text{-component of deflection due to } V.$$

The inclusion of the effect of abutment and foundation deformation in the cantilever and arch calculations was based on the formulas developed by Fredrik Vogt, Assoc. M. Am. Soc. C. E.* For the longer, thinner arches near the top of the dam, the inclusion of the abutment deformation effect did not result in material changes. When such arches were analyzed under the same water load the deflections were increased slightly, but the moments, thrusts, eccentricities, and stresses were not appreciably altered. However, as regards comparatively short, thick arches the effects were important. For such arches the inclusion of the abutment deformation effect increased the positive moments, decreased the negative moments, decreased the thrust, increased both compressive and tensile stresses at the crown, decreased both compressive and tensile stresses at the abutment, increased the eccentricity of the line of thrust, and practically doubled the deflections. Fig. 51 shows the results of an analysis of one of the heavier arches of the 405-ft. Owyhee Dam now being built on the Owyhee Irrigation Project of Eastern Oregon, no direct comparisons being available for the arches of the Gibson Dam.

In the analysis of cantilevers under the same loads consideration of foundation deformations resulted in increased bending, but did not alter the stresses. Consideration of foundation movements introduced an initial shear deflection at the base, an initial twisting at the base, and resulted in increased deflections throughout the height of the dam. Fig. 52 illustrates these effects at the crown cantilever of the Gibson Dam when analyzed under the final load conditions.

Of course, the effects shown in Figs. 51 and 52 do not represent the final result of considering foundation and abutment deformations. The final effect is a new load distribution between arch and cantilever elements and an altered stress distribution. The investigations made by the U. S. Bureau of Reclamation thus far do not show whether the maximum cantilever and arch stresses will always be changed in the same direction by the inclusion of such considerations, or whether they will be changed in location, or increased in some

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 554.

places and decreased in others. A great many uncertainties are involved in the consideration of foundation and abutment movements, such as the value of the modulus of elasticity for the rock formations. In the case of the Gibson Dam the modulus of elasticity for the limestone foundation and abutments was assumed to be the same as for the concrete which, on the basis of laboratory tests, was taken as 2 000 000 lb. per sq. in. As Dr. Vogt stated in the previously mentioned discussion, "no calculation of this kind may claim to be more than a rough approximation."

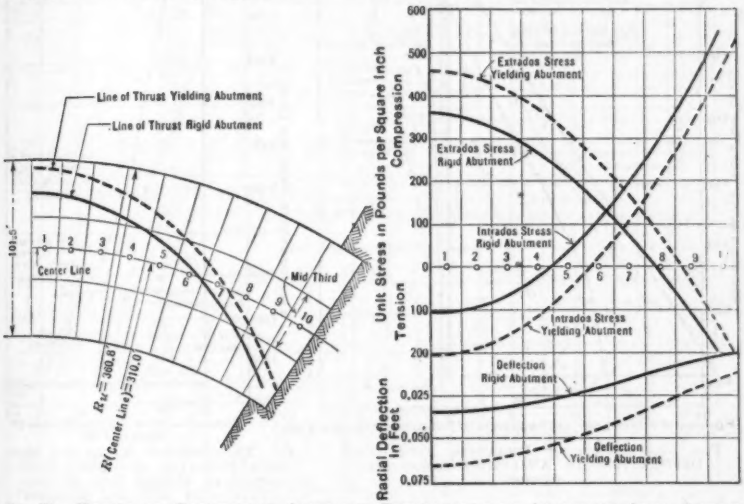

FIG. 51.—EFFECT OF CONSIDERING ABUTMENT DEFORMATION IN ANALYZING ARCH ACTION, OWYHEE DAM.

Assuming arch action to begin as soon as the reservoir begins to fill simply means that the arch deflections are to be measured from the up-stream cantilever deflections which occur when the reservoir is empty, instead of from a vertical axis as was done in the original calculations. Since the contraction joints are to be thoroughly grouted during the late winter, after the setting heat has been dissipated, the assumption made in the final analysis is believed to be more nearly correct than the one originally made. A number of electrical resistance thermometers are being installed in the Gibson Dam so that definite knowledge of internal temperatures will be available at the time the joints are grouted.

Figs. 53 and 54 compare the results obtained by the revised methods of analysis with those obtained by the original methods. Fig. 53 shows the differences in tension areas and maximum cantilever stresses at the crown cantilever, while Fig. 54 shows the difference in load distribution and deflections at the cantilevers, *A*, *C*, *F*, *G*, *H*, and *I*. By referring to Fig. 53 it will be noticed that for the crown cantilever the final result of all the revisions in methods was a slight reduction in tension area and maximum stresses, the latter being reduced to stresses parallel to the down-stream face by Cain's

theory in both cases. Reference to Fig. 54 shows that the deflection and load distribution curves were not altered appreciably, except in the case of the latter, at the lower elevations of the more central cantilevers where appreciable loads were transferred from the cantilever elements to the arch elements.

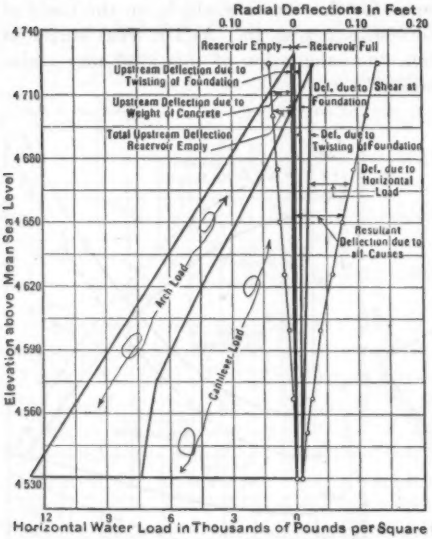

FIG. 52.—EFFECT OF INCLUDING FOUNDATION DEFORMATION IN ANALYZING CANTILEVER ACTION.

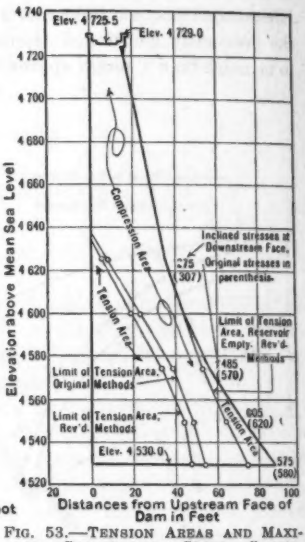

FIG. 53.—TENSION AREAS AND MAXIMUM STRESSES IN CROWN CANTILEVER OF GIBSON DAM BY ORIGINAL AND REVISED METHODS OF CALCULATION.

Fig. 55 shows the maximum cantilever and arch stresses in the Gibson Dam as calculated by the revised methods of analysis. Similar data are available for the original investigations, but the stresses are in no cases greatly different from the final results. The several revisions introduced since the first analysis was made, decreased the maximum cantilever stress from 620 to 605 lb. per sq. in., but did not change its original location which had been found to be at Elevation 4 560 on the down-stream face of the dam, as shown in Fig. 53. They increased the maximum arch stress from 309 to 364 lb. per sq. in. and changed its location from the extrados at Elevation 4 675 at the crown to the extrados at Elevation 4 650 at the crown. Maximum arch stresses at the lower elevations were increased by greater proportional amounts, due to the change in load distribution, but the final stresses were lower than at Elevation 4 650, as shown in Fig. 55.

The results of the revised analysis of the Gibson Dam were very gratifying. They showed that the section as originally designed is satisfactory and that the maximum stresses to be expected will be well within the limits of safety. The fact that the revised analysis did not show results greatly different from the original analysis does not mean that the modifications were not worth while. It simply means that, in the case of the Gibson Dam, the effects

of the various changes tended to compensate, so that the resultant effect was not of serious magnitude. For dams of different cross-section, in canyons of different shape, the final result of such changes might not be so satisfactory.

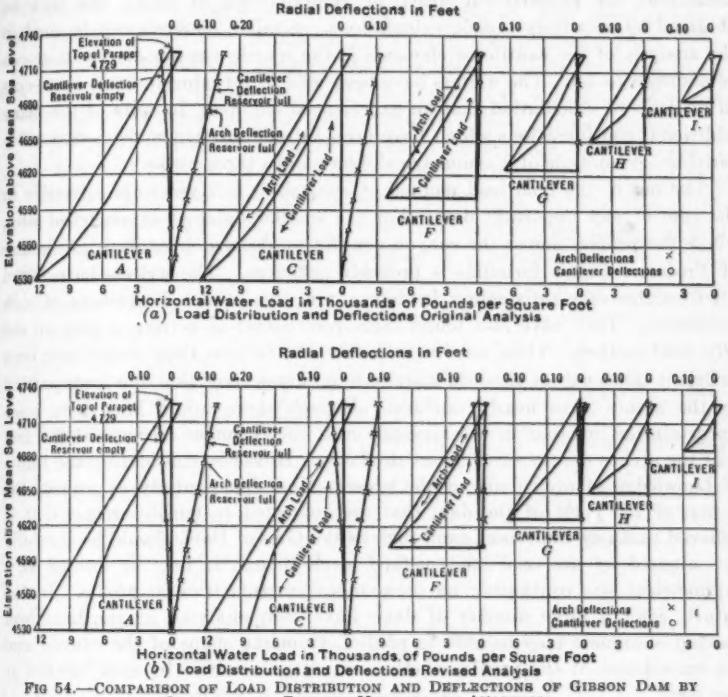

FIG 54.—COMPARISON OF LOAD DISTRIBUTION AND DEFLECTIONS OF GIBSON DAM BY ORIGINAL AND REVISED METHODS OF ANALYSIS.

The use of the trial load method of analysis is not so laborious as might first be supposed, especially after one becomes familiar with the action of arch dams and the changes in arch and cantilever deflections to be expected from

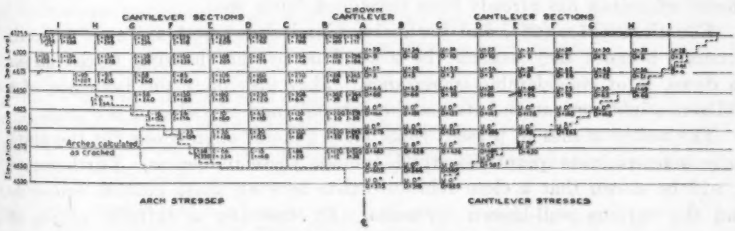

FIG. 55.—MAXIMUM CANTILEVER AND ARCH STRESSES IN THE GIBSON DAM CALCULATED BY REVISED METHODS OF ANALYSIS.

certain changes in load application. Of course, the use of a calculating machine is indispensable in such an investigation. The computation of unit load deflections for the arches results in a considerable saving of time since the deflections for proportional loads, or combinations of loads, can then be obtained by relatively simple calculations. Similar methods can be used in the analysis of the cantilever elements if the tensile stresses are small or can be assumed to act. The writers have been able to introduce enough short-cuts in methods of calculation that an experienced engineer, in spite of the many additional considerations which have been introduced, can make a reasonably satisfactory analysis of a symmetrical dam within three weeks.

The use of the trial load method of analysis is believed to be advisable in the case of any important dam. For the smaller dams at symmetrical sites, where the profiles across the canyon contain no decided irregularities, the use of Professor Cain's formulas is probably sufficient. The writers have found his formulas very satisfactory in determining the proper dimensions of such structures. They have also found them very useful in getting a start on the trial load method. Their use in the case of the Gibson Dam might have been sufficient inasmuch as the load distribution curves show that the loads carried by the arches were nearly uniform, although there would have been some uncertainties involved in the application of the formulas because of the fact that the arches are not of constant thickness. However, considering the limits of knowledge of arch dams at the present time (particularly as regards the action of the parts of the dam that are subjected to tensile stresses), it is believed that any important dam, such as the Gibson Dam, should be carefully investigated by the trial load method, even though it may be located at a symmetrical site containing no pronounced irregularities in profile. In the future, after a large number of dams have been analyzed by the trial load method, designers may be able to predict, from the shape of the canyon and the smoothness of the profile, whether or not an analysis by such method is necessary.

A. Floris,* Esq. (by letter).—The analysis of arches and particularly of arch dams has been treated repeatedly in recent years. Various writers have proposed formulas for the purpose of improving those in current use. This paper is another attempt in this direction in spite of the fact that the theory of arches has already been developed fairly well.

Equations (27), (28), and (29), also found elsewhere,† are not "perfectly general" because they neglect the work done by the shearing forces which, in dams, is of considerable importance. They also omit the influence of a difference in temperature between the extrados and intrados of the arch.

The writer wishes to present some more general expressions for the statically indeterminate quantities which include these influences. Furthermore, it will be shown that a close relation exists between these general equations and the various well-known formulas. By choosing a suitable origin of

* Los Angeles, Calif.

† "Plain and Reinforced Concrete Arches," by J. Melan; translated by D. B. Steinman, M. Am. Soc. C. E., N. Y., 1915, p. 30.

co-ordinates to which the fundamental equations are referred and by successive simplifications, these special formulas can be easily derived.

It is well known that a curved prismatic bar restrained at its supports is a statically indeterminate system in the third degree. For these unknown quantities, therefore, three equations of deformation are necessary. There are a number of methods of analysis available which provide these equations. The theorem of the derivatives of the internal work will be used herein because it leads to the solution of the problem in a most simple manner.

Generally, the theory of structures is based on assumptions* in order to make a practical treatment of the subject possible. With this object in view the writer has made the usual assumptions that Hooke's law and Bernoulli's hypothesis that plane sections remain plane after bending, are valid and that the shearing stresses are distributed according to a parabolic law.

If the radius of curvature of a curved bar is not less than about five times its thickness† the general equation of the internal work with all possible effects included is:‡

$$u = \int \frac{M^2\, d\,s}{2\,E\,I} + \int \frac{N^2\, d\,s}{2\,E\,A} + \kappa \int \frac{Q^2\, d\,s}{2\,G\,A} + \int \varepsilon \frac{\Delta\, t}{h}\, M\, d\,s + \int \varepsilon\, t\, N\, d\,s \ldots (159)$$

Differentiating Equation (159) with respect to X, Castigliano's theorem of partial derivatives is obtained:

$$L = \frac{\delta\, u}{\delta\, X} = \int \frac{M}{E\,I} \frac{\delta\, M}{\delta\, X} d\,s + \int \frac{N}{E\,A} \frac{\delta\, N}{\delta\, X} d\,s + \kappa \int \frac{Q}{G\,A} \frac{\delta\, Q}{\delta\, X} d\,s + \int \varepsilon \frac{\Delta\, t}{h} \frac{\delta\, M}{\delta\, X} d\,s + \int \varepsilon\, t \frac{\delta\, N}{\delta\, X} d\,s \ldots\ldots\ldots\ldots\ldots (160)$$

If the supports are rigid, this expression will be:

$$\int \frac{M}{E\,I} \frac{\delta\, M}{\delta\, X} d\,s + \int \frac{N}{E\,A} \frac{\delta\, N}{\delta\, X} d\,s + \kappa \int \frac{Q}{G\,A} \frac{\delta\, Q}{\delta\, X} d\,s + \int \varepsilon \frac{\Delta\, t}{h} \frac{\delta\, M}{\delta\, X} d\,s + \int \varepsilon\, t \frac{\delta\, N}{\delta\, X} d\,s = 0 \ldots\ldots\ldots\ldots\ldots\ldots (161)$$

which is the theorem of least work.

By using these equations, any prismatic bar can be analyzed in the shortest and most elegant manner. On this fact is based the superiority of the theorem of internal work as compared with the cumbersome and lengthy method preferred by the authors.

The integrals in Equations (159), (160), and (161) are those due to bending moments, normal forces, shearing forces, unequal temperature variation within the section of the bar, and uniform temperature change throughout the section, respectively.

* "Calcul des arcs élastiques," par S. Timoshenko, Paris, 1922, pp. 4–6.

† "Applied Elasticity," by S. Timoshenko and J. M. Lessels, East Pittsburgh, 1925, p. 221; or "Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen," von H. Müller-Breslau, Berlin, 1924, p. 242.

‡ "Kinetic Theory of Engineering Structures," by D. A. Molitor, M. Am. Soc. C. E., N. Y., 1911, p. 42.

In these equations, $G = E \frac{m}{2(m+1)}$*, $\nu = 2\kappa \frac{m+1}{m}$, and for rectangular sections, $\kappa = \frac{6}{5}$†.

Substituting these values, the integral of the shearing forces in Equations (159), (160), and (161) becomes,

$$\nu \int \frac{Q}{E A} \frac{\delta Q}{\delta x} d s$$

Concrete tests show‡ that m varies between 6.5 and 8.0. Taking an average value of 7.25, then $\nu = 2.74$ and not 3.0 or 2.88 as is assumed by various writers.

A restrained arch which is either unsymmetrically formed or unsymmetrically loaded is statically indeterminate in the third degree. Taking any point as the origin of the co-ordinates and introducing X, Y, and μ as the statically indeterminate quantities, the bending moment, normal force, and shearing force for any point on the arch axis will be (see Fig. 56):

$$M = M_0 + X y + Y x + \mu \ldots\ldots\ldots\ldots\ldots\ldots (162)$$

$$N = N_0 + X \cos \phi + Y \sin \phi \ldots\ldots\ldots\ldots\ldots\ldots (163)$$

$$Q = Q_0 - X \sin \phi + Y \cos \phi \ldots\ldots\ldots\ldots\ldots\ldots (164)$$

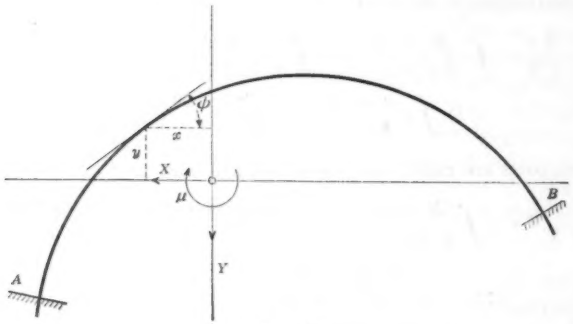

FIG. 56.

The corresponding derivatives will be:

$$\frac{\delta M}{\delta X} = y; \quad \frac{\delta M}{\delta Y} = x; \quad \frac{\delta M}{\delta \mu} = 1 \ldots\ldots\ldots (165)$$

$$\frac{\delta N}{\delta X} = \cos \phi; \quad \frac{\delta N}{\delta Y} = \sin \phi; \quad \frac{\delta N}{\delta \mu} = 0 \ldots\ldots\ldots (166)$$

$$\frac{\delta Q}{\delta X} = -\sin \phi; \quad \frac{\delta Q}{\delta Y} = \cos \phi; \quad \frac{\delta Q}{\delta \mu} = 0 \ldots\ldots\ldots (167)$$

‡ "Researches in Concrete," by W. K. Hatt, M. Am. Soc. C. E., *Bulletin No. 24*, Eng. Experiment Station, Purdue Univ., p. 38.

M_0, N_0, and Q_0, in Equations (162) to (164) are the bending moment, normal force, and shearing force, respectively, of the statically determinate system which is sometimes called the principal or base system.

Because there are three unknowns, X, Y, and μ, Equation (161) must be written out three times as follows:

$$\int_A^B \frac{M}{EI}\frac{\delta M}{\delta X}ds + \int_A^B \frac{N}{EA}\frac{\delta N}{\delta X}ds + \nu\int_A^B \frac{Q}{EA}\frac{\delta Q}{\delta X}ds + \int_A^B \varepsilon\frac{\Delta t}{h}\frac{\delta M}{\delta X}ds + \int_A^B \varepsilon t\frac{\delta N}{\delta X}ds = 0. \quad (168)$$

$$\int_A^B \frac{M}{EI}\frac{\delta M}{\delta Y}ds + \int_A^B \frac{N}{EA}\frac{\delta N}{\delta Y}ds + \nu\int_A^B \frac{Q}{EA}\frac{\delta Q}{\delta Y}ds + \int_A^B \varepsilon\frac{\Delta t}{h}\frac{\delta M}{\delta Y}ds + \int_A^B \varepsilon t\frac{\delta N}{\delta Y}ds = 0 \quad (169)$$

$$\int_A^B \frac{M}{EI}\frac{\delta M}{\delta \mu}ds + \int_A^B \frac{N}{EA}\frac{\delta N}{\delta \mu}ds + \nu\int_A^B \frac{Q}{EA}\frac{\delta Q}{\delta \mu}ds + \int_A^B \varepsilon\frac{\Delta t}{h}\frac{\delta N}{\delta \mu}ds + \int_A^B \varepsilon t\frac{\delta N}{\delta \mu}ds = 0 \quad (170)$$

In Equations (168), (169), and (170), it is assumed that the uniform temperature variation in the arch is acting in the same direction with the outer forces. This is the case when a drop in temperature takes place in the arch. For a rise in temperature the sign before the integral, expressing this uniform change, must be reversed. Introducing the values given by Equations (162) to (167) in the proper place in Equations (168), (169), and (170), the following expressions are derived:

$$X\left[\int_A^B \frac{y^2}{I}ds + \int_A^B \frac{\cos^2\phi}{I}ds + \nu\int_A^B \frac{\sin^2\phi}{I}ds\right] + Y\left[\int_A^B \frac{xy}{I}ds + (1-\nu)\int_A^B \frac{\sin\phi\cos\phi}{I}ds\right] + \mu\int_A^B \frac{y}{I}ds + \int_A^B \frac{M_0}{I}y\,ds + \int_A^B \frac{N_0}{A}\cos\phi\,ds - \nu\int_A^B \frac{Q_0}{A}\sin\phi\,ds + E\varepsilon\int_A^B \frac{\Delta t}{h}y\,ds + E\varepsilon t\int_A^B \cos\phi\,ds = 0 \quad (171)$$

$$X\left[\int_A^B \frac{yx}{I}ds + (1-\nu)\int_A^B \frac{\sin\phi\cos\phi}{A}ds\right] + Y\left[\int_A^B \frac{x^2}{I}ds + \int_A^B \frac{\sin^2\phi}{A}ds + \nu\int_A^B \frac{\cos^2\phi}{A}ds\right] + \mu\int_A^B \frac{x}{I}ds + \int_A^B \frac{M_0}{I}x\,ds + \int_A^B \frac{N_0}{A}\sin\phi\,ds + \nu\int_A^B \frac{Q_0}{A}\cos\phi\,ds + E\varepsilon\int_A^B \frac{\Delta t}{h}x\,ds + E\varepsilon t\int_A^B \sin\phi\,ds = 0 \quad (172)$$

$$X\int_A^B \frac{y}{I}ds + Y\int_A^B \frac{x}{I}ds + \mu\int_A^B \frac{ds}{I} + \int_A^B \frac{M_0}{I}ds + E\varepsilon\int_A^B \frac{\Delta t}{h}ds = 0 \quad (173)$$

Equations (171), (172), and (173) are the most general expressions for the statically indeterminate quantities of an unsymmetrically formed and un-

symmetrically loaded arch with complete restraint at its abutments. However, if the abutments are not perfectly rigid then, instead of being equal to zero, Equations (168), (169), and (170) must be made equal to these elastic movements; or, what is the same thing, Equation (160) must be used. Obviously, the expressions for these movements would appear in Equations (171), (172), and (173), which can be solved only if the magnitudes of the displacements or the rotations are measured or are known in advance in some way. For this reason these formulas are omitted because, in practice, the abutments of arch dams are generally assumed to be perfectly rigid.

In order to integrate Equations (171), (172), and (173), the axis of the arch must be shaped according to a mathematical curve and the thickness of the arch must vary according to some known law. Otherwise, the desired result must be obtained by summation as is done by the authors.

Neglecting the influence of the shearing forces and of the unequal temperature variation on the arch and also referring the system to the origin of the co-ordinates at the crown where the arch is assumed to be cut in two, Equations (171), (172), and (173) immediately become:

$$X\left[\int_A^B \frac{y^2}{I}\,ds+\int_A^B \frac{\cos^2\phi}{A}\,ds\right]+Y\left[\int_A^B \frac{x\,y}{I}\,ds+\int_A^B \frac{\sin\phi\cos\phi}{A}\,ds\right]$$
$$+\mu\int_A^B \frac{y}{I}\,ds+\int_A^B \frac{M_0}{I}y\,ds+\int_A^B \frac{N_0}{A}\cos\phi\,ds+E\varepsilon t\int_A^B \cos\phi\,ds=0\ldots(174)$$

$$X\left[\int_A^B \frac{y\,x}{I}\,ds+\int_A^B \frac{\cos\phi\sin\phi}{A}\,ds\right]+Y\left[\int_A^B \frac{x^2}{I}\,ds+\int_A^B \frac{\sin^2\phi}{A}\,ds\right]$$
$$+\mu\int_A^B \frac{x}{I}\,ds+\int_A^B \frac{M_0}{I}x\,ds+\int_A^B \frac{N_0}{A}\sin\phi\,ds+E\varepsilon t\int_A^B \sin\phi\,ds=0\ldots(175)$$

$$X\int_A^B \frac{y}{I}\,ds+Y\int_A^B \frac{y}{I}\,ds+\mu\int_A^B \frac{ds}{I}+\int_A^B \frac{M_0}{I}\,ds=0\ldots(176)$$

which are the authors' Equations (29), (28), and (27), in a somewhat different form.

In these expressions the integration must be extended over the entire arch. However, bearing in mind that in Equations (162) and (163) the terms containing Y must be negative for the right half of the arch, the integrals in Equation (175) are obtained by subtracting the integrals of the right half from those of the left half. On the other hand, x^2 and $\sin^2\phi$ being positive, the corresponding integrals must be added and not subtracted. In the same way the integrals of Y in Equations (174) and (176) must be also subtracted. The remaining integrals are the sums of the left and right-hand parts of the arch.

Considering, furthermore, that the integrals, $\int_A^B \cos\phi\,ds$ and $\int_A^B \sin\phi\,ds$, are the projections of the arch upon the x and y-axes, respectively, it follows therefrom that they define the distances between the projections on the x and y-axes of the points, A and B, of the arch at its abutments, respectively. With this fact in view the term denoting the influence of the uniform temperature variation in the authors' Equation (29) seems to be incorrect.

In a symmetrical arch, but with an unsymmetrical loading, the integrals corresponding to the left and right-hand parts of the arch are equal, so that their difference will be zero.

In this case, therefore, the effect will be to make the integrals of Y in Equations (174) and (176) and the integrals of X and μ in Equation (175) equal to zero. At the same time the last integral in Equation (175) vanishes also for the reason that the deformation of the arch due to a uniform temperature variation being symmetrical no Y-force can be produced. This result is based on the supposition that the arch is cut in two at the crown.

This choice of the principal system facilitates the computations appreciably because, by taking the origin of the co-ordinates at the left abutment, for instance, and cutting the arch at this point, Equations (174), (175), and (176) must be used even in a symmetrical arch under unsymmetrical loading. It is needless to say that in this case the integrals in these equations are the sums and not the differences of the two halves of the arch.

In bridges the thickness of the arch is small as compared with the radius and, consequently, the work done by the shearing forces is always neglected. The deformation due to the normal forces is also neglected if the arch is not too flat. In Equations (168), (169), and (170), therefore, the integrals due to the bending moments alone are taken into consideration and the general Equations (171), (172), and (173), neglecting the influence of temperature, are simplified as follows: In Equation (171), the second, third, fifth, eighth, ninth, tenth, and eleventh integrals vanish; in Equation (172), the second, fourth, fifth, eighth, ninth, tenth, and eleventh integrals are equal to zero; and in Equation (173), the last integral disappears.

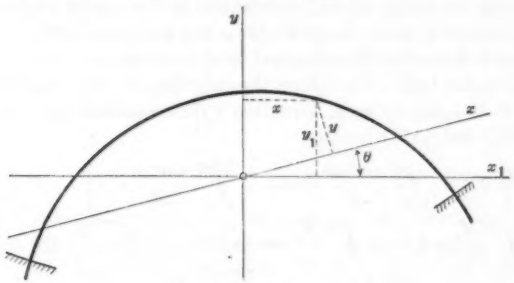

FIG. 57.

Müller-Breslau was the first to show* that the integrals, $\int_A^B \frac{y}{I}\,ds$ and $\int_A^B \frac{x}{I}\,ds$, representing the static moments, and $\int_A^B \frac{x\,y}{I}\,ds$, the centrifugal moment of the symmetrical arch ring, vanish if they are referred to the elastic center of gravity of the ring. The elastic center, on the other hand, is determined by considering $\frac{ds}{I}$ as forces acting in two directions. In the case of a symmetrical arch the y-axis

* "Vereinfachung der Theorie der statisch unbestimmten Bogentraeger," H. von Müller-Breslau, *Zeitschrift* des Architekten und Ingenieur-Vereins zu Hannover, 1884, p. 575.

being an axis of symmetry the condition, $\int_A^B \frac{x}{I}\, d\,s = 0$, is satisfied without further proof. However, if the arch is unsymmetrical, the centrifugal moment, $\int_A^B \frac{x\,y}{I}\, d\,s$, vanishes only in the case when it is referred to an inclined axis, the slope of which is given by* (see Fig. 57):

$$tg\,\theta = \frac{\int_A^B \frac{x\,y_1}{I}\, d\,s}{\int_A^B \frac{x^2}{I}\, d\,s}$$

The great advantage of this arrangement is that all the more complicated formulas are reduced to three single equations with one unknown each. They are obtained as follows: In Equation (171) all integrals except the first and seventh are equal to zero; in Equation (172) all integrals vanish with the exception of the third and seventh; and, lastly, in Equation (173) all integrals, except the third and fourth, are equal to zero.

In arch dams, in which the work done by the normal forces usually predominates, there are no methods available to reduce Equations (171), (172), and (173) to three equations with one unknown each. It is true that in bridges with a comparatively small rise it can be assumed approximately in Equation (163) that $X \cos \phi = X$ and $Y \sin \phi = 0$, if a special analysis is made for the dead load of the arch.† With the aid of these assumptions it is possible to reduce Equations (171), (172), and (173), to three equations with one unknown each by referring the origin of the co-ordinates to the elastic center of the arch. In arch dams, however, these simplifications are not permissible.

Usually, arch dams are symmetrical and, as such, are always stressed by a symmetrical water load. Therefore, the calculations are simplified considerably. Since Y is equal to zero, Equation (172) vanishes and the remaining Equations (171) and (173) become:

$$X\left[\int_A^B \frac{y^2}{I}\, d\,s + \int_A^B \frac{\cos^2 \phi}{A}\, d\,s + \nu \int_A^B \frac{\sin^2 \phi}{A}\, d\,s\right] + \mu \int_A^B \frac{y}{I}\, d\,s + \int_A^B \frac{M_0}{I}\, y\, d\,s + \int_A^B \frac{N_0}{A} \cos \phi\, d\,s - \nu \int_A^B \frac{Q_0}{A} \sin \phi\, d\,s + E\,\varepsilon \int_A^B \frac{\Delta\, t}{h}\, y\, d\,s + E\,\varepsilon\, t \int_A^B \cos \phi\, d\,s = 0 \quad \ldots\ldots\ldots (177)$$

$$X \int_A^B \frac{y}{I}\, d\,s + \mu \int_A^B \frac{d\,s}{I} + \int_A^B \frac{M_0}{I}\, d\,s + E\,\varepsilon \int_A^B \frac{\Delta\, t}{h}\, d\,s = 0 \quad \ldots\ldots (178)$$

These are the fundamental equations derived by Professor Cain arranged in a more general form.‡ They are referred to the origin of the co-ordinates at the crown.

* "Gewölbte Brücken," von E. Mörsch, *Beton-Kalender*, Berlin, 1915, p. 303.

† *Loc. cit.*, pp. 295 and 302.

‡ "The Circular Arch Under Normal Loads," by William Cain, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), Equations (7) and (9), p. 237.

Assuming the elastic center of the arch as the origin of the co-ordinates, then, $\int_A^B \frac{y}{I}\, d\,s = 0$, as stated previously, and Equations (177) and (178) become:

$$X\left[\int_A^B \frac{y^2}{I}\, d\,s + \int_A^B \frac{\cos^2\phi}{A}\, d\,s + \nu \int_A^B \frac{\sin^2\phi}{A}\, d\,s\right] + \int_A^B \frac{M_0}{I}\, y\, d\,s + \int_A^S \frac{N_0}{A}\cos\phi\, d\,s - \nu \int_A^B \frac{Q_0}{A}\sin\phi\, d\,s + E\,\varepsilon \int_A^B \frac{\Delta\, t}{h}\, y\, d\,s + E\,\varepsilon\, t \int_A^B \cos\phi\, d\,s = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (179)$$

$$\mu \int_A^B \frac{d\,s}{I} + \int_A^B \frac{M_0}{I}\, d\,s + E\,\varepsilon \int_A^B \frac{\Delta\, t}{h}\, d\,s = 0 \quad \ldots\ldots\ldots (180)$$

in which the unknowns, X and μ, are separated. Similar expressions, in a less complete form, were developed by Dr. N. Kelen for arches of constant thickness.*

When it is required to determine the influence of an unequal temperature variation on an arch of constant thickness, h, Equation (179) vanishes entirely because,

$$E\,\varepsilon\, \frac{\Delta\, t}{h} \int_A^B y\, d\,s = 0$$

in which,

$$\int_A^B \frac{y}{I}\, d\,s = \int_A^B y\, d\,s = 0$$

since it is referred to the elastic center of the arch. The remaining Equation (180), therefore, will be,

$$\mu \int_A^B \frac{d\,s}{I} + E\,\varepsilon\, \frac{\Delta\, t}{h} \int_A^B d\,s = 0 \quad \ldots\ldots\ldots\ldots\ldots (181)$$

Substituting for I its equivalent, $\frac{h^3}{12}$:

$$\mu = E\,\varepsilon\, \frac{h^2}{12}\, \Delta\, t\dagger \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (182)$$

in which, $\Delta\, t$ is the difference, $t_1 - t_2$, between the up-stream and down-stream temperatures. This difference determines the sign of μ since compression is developed in the warmer side of the arch.

One can introduce a further simplification by designing the arch so that the line of resistance in the principal system coincides exactly with the arch axis. In this case $\int_A^B \frac{M_0}{I}\, y\, d\,s$ and $\int_A^B \frac{M_0}{I}\, d\,s$ in Equations (179) and (180) vanish; consequently, $\int_A^B \frac{Q_0}{I} \sin\phi\, d\,s$ is equal to zero, since the shearing forces are produced by the difference of the moments in two adjacent sections of the arch which presumably are equal to zero. Equations (179) and (180), therefore, take the extremely simple form:

* "Die Staumauern," von N. Kelen, Berlin, 1926, p. 17.

† "Statica delle dighe per laghi artificiali," C. Guidi, Turin, 1921, p. 49.

$$X\left[\int_A^B \frac{y^2}{I}\,ds + \int_A^B \frac{\cos^2\phi}{A}\,ds + \nu\int_A^B \frac{\sin^2\phi}{A}\,ds\right] + \int_A^B \frac{N_0}{A}\cos\phi\,ds + E\,\varepsilon\int_A^B \frac{\Delta t}{h}\,y\,ds + E\,\varepsilon\,t\int_A^B \cos\phi\,ds = 0 \quad \ldots(183)$$

which is Professor E. Moersch's generalized equation.*

It is unfortunate that this elegant and simple method of analysis (Equation (183)) has found little favor among American designers although it was made known several years ago.†

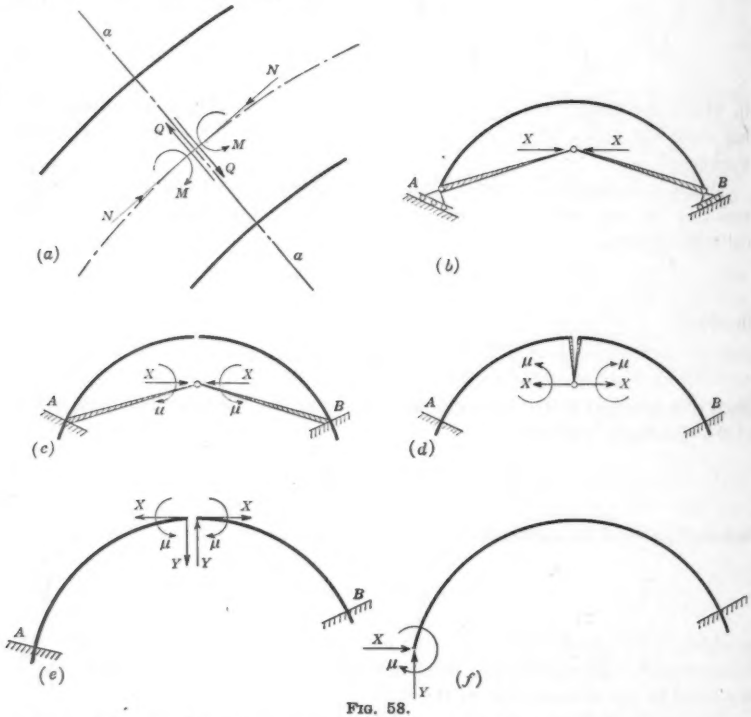

FIG. 58.

Since Equations (177) to (181), inclusive, and Equation (183) are applied to symmetrically formed and symmetrically loaded arches, it follows that their integration can be referred to one-half of the arch only.

In order to apply correctly the equations already derived to the various principal systems it must be remembered that the positive directions of N, Q, and M to the left and to the right of a given section, a-a, are as shown in Fig. 58(a). It is also assumed that a positive bending moment, M, produces compression in the extrados of the arch.

* "Berechnung kreisförmiger Gewölbe gegen Wasserdruck," von E. Mörsch, *Schweizerische Bauzeitung*, 1908, p. 233.

† "The Relation Between Deflections and Stresses in Arch Dams," by F. A. Noetzli, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 302.

With these definitions in mind the statically indeterminate quantities, X, Y, and μ, in Fig. 58(b), 58(c), and 58(f), being reactions, are acting to the left of a given section, a-a. On the other hand, the same quantities in Fig. 58(d) and 58(e) belong to the arch itself and, consequently, they must act to the left side of this section.

In both cases, Fig. 58(c) and 58(d), the moment due to X is, for sections below the x-axis, positive, and, for sections above this axis, negative.

The bending moment, M_0, of the curved cantilever, Fig. 58(c), 58(d), 58(e), and 58(f), is negative because it produces tension in the extrados of the arch. On the other hand, the principal system, Fig. 58(b), is free of bending moments, M_0.

The force, X, acting in the elastic center of the arch is sometimes called a pool,* which is misleading from the point of view of precise thinking. This force is a compression, except in the case of a rise in temperature in the arch, and its relative direction depends only on the choice of the principal system.

As regards the most suitable principal system for a given case the following may be of interest.

There are many methods of obtaining this principal system, depending entirely on the ease of making the computations. In a symmetrical arch, the principal system represented in Fig. 58(b) is convenient for uniformly distributed water load and also uniform change of temperature or shrinkage, while either of the principal systems Fig. 58(c) and 58(d) are preferable for the dead load of the arch or for a variable water pressure.† In other words, the first case is applicable to arch dams while the second case is to be used in multiple-arch dams. The unequal temperature variation between the extrados and intrados of the arch belongs to either of the cases shown in Fig. 58(b), 58(c), or 58(d).

If the arch is circular and of constant thickness and the water pressure is uniform, the line of resistance in the principal system coincides with its geometrical axis. In this case Equation (183) is strictly correct. For a variable water pressure and for the dead load of an arbitrarily formed arch, the line of resistance does not coincide with its axis and, consequently, Equations (179) and (180) must be used. However, Equation (183) can be applied also with a sufficient degree of accuracy if the condition that $M_0 = 0$ is not strictly satisfied.‡

In an unsymmetrical arch under water pressure there are no advantages in choosing the elastic center of the arch as the origin of the co-ordinates. For this reason it can be assumed that this origin is either at the crown or at the left abutment. In the first case the principal system consists of two cantilevers, Fig. 58(e), while in the second case one cantilever stretches over the entire span of the arch, Fig. 58(f). To both cases Equations (174), (175), and (176) must be applied.

‡ "Improved Type of Multiple-Arch Dam," by F. A. Noetzli, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 361.

C. H. HOWELL,* M. AM. SOC. C. E. (by letter).—The interest shown in this paper is appreciated. Mr. Jakobsen states "the authors assume that the arch dam is a continuous structure, not divided by contraction joints or cracks" and "to insure freedom from shrinkage cracks, the authors state that openings will be left in the dam and that these will be filled in the coldest weather."

The first statement is not quite correct. One of the fundamental concepts of the trial load method is the assumption of joints both horizontal and vertical. These joints are considered incapable of transmitting tensile stresses. In this respect this method of analysis differs from others. The writers did not state that closing plugs would be used to "insure freedom" from shrinkage cracks. The statement in the paper is "to compensate, to some degree, for the shrinkage of the concrete." The extent of compensation depends on the temperature of the dam at the time of closure, the age of the previously poured concrete, and the number of plugs.

The writers had no idea of suggesting that the plugs would completely offset shrinkage. Mr. Jakobsen states that "in time, when more is known about shrinkage, it can be (and, of course, should be) included in the calculations". This sentence expresses exactly the thought of the writers.

Mr. Jakobsen calls attention to the fact that on diagrams in Figs. 5 and 8 no load is shown on the arches at the abutments. He properly questions the correctness of this, as does Professor Cain. Fig. 59 shows final load diagrams for two Horse Mesa arches. It is apparent that, at the abutments, the arch loads vary within wide limits, as stated by Mr. Jakobsen and Professor Cain. Figs. 5 and 8 are for the earliest studies; Fig. 59 was omitted from the original paper.

The method of determining the proportional distribution at the abutments suggested by Mr. Jakobsen, is not quite general. For example, let Fig. 60 (*a*) represent a part of the profile where a sudden change in slope occurs. Consider three equal loads, p_1, p_2 and p_3. Using Mr. Jakobsen's notation and method, the distribution of shear stress for p_1 (see Fig. 60 (*b*)) is expressed by,

$$\frac{p_1 - c}{c} = \frac{\sin 30°}{\cos 30°} = \frac{0.5000}{0.866} = 0.577 \ldots\ldots\ldots\ldots (184)$$

for p_2 (see Fig. 60 (*c*)),

$$\frac{p_2 - c}{c} = \frac{\sin 30°}{\cos 60°} = \frac{0.500}{0.500} = 1.00 \ldots\ldots\ldots\ldots\ldots (185)$$

and for p_3 (see Fig. 60 (*d*)),

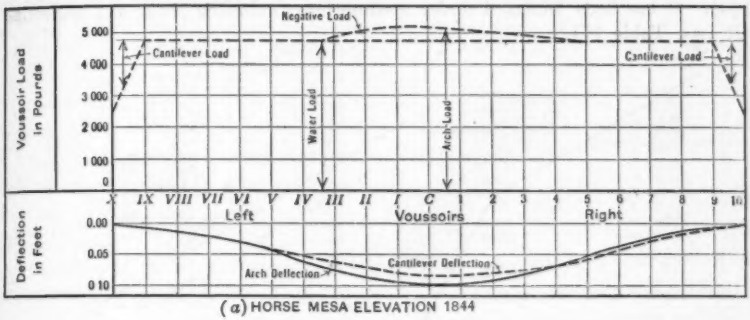
$$\frac{p_3 - c}{c} = \frac{\sin 60°}{\cos 60°} = \frac{0.866}{0.500} = 1.732 \ldots\ldots\ldots\ldots (186)$$

Because they are very close together, the loads must have approximately the same distribution and not the wide variation indicated in Equations (184), (185), and (186).

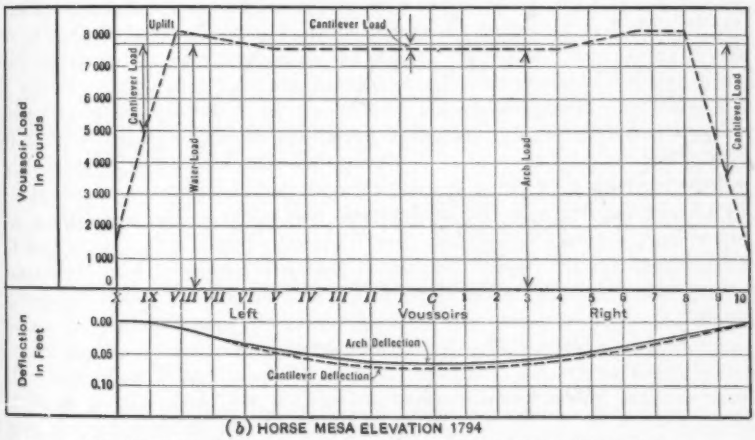
The writer thinks that Mr. Jakobsen misunderstands the application of Fig. 15. In computing the secondary arches, a new center line is drawn through the middle of the uncracked part of the original arch. The new

* Chf. Engr., J. G. White Eng. Corporation, S. en C., City of Mexico, Mexico.

analysis is then made on this new center line. Its length is divided equally and the moments of inertia computed on sections normal to it. No oblique sections are used. The lines in Fig. 15 are intended to show the division of the water load into portions tributary to the divisions of the axis.



(a) HORSE MESA ELEVATION 1844



(b) HORSE MESA ELEVATION 1794

FIG. 59.—FINAL LOAD DIAGRAMS FOR TWO ARCHES, HORSE MESA DAM.

Mr. Rich, as well as others, states that in short thick arches the deflections caused by shear are appreciable and should be considered. When such arches are assumed to be capable of resisting tension the effect of shear is considerable. However, if the area affected by tension is excluded and if the analysis is made on the more flexible interior arch the effect of shear has not been found to be important in such arches investigated by the writer. This has also been the case in regular arches entirely in compression. Shear is the thrust times the sine of the angle between the arch axis and line of thrust. If there is no tension in the arch the angles between the line of thrust and arch axis cannot be large because the latter is within the middle third at all points.

However, it is well to include the effect of shear since it is a factor, although not a serious one, and does not add materially to the work.

The writer has checked Equations (55), (56) and (57) and believes them to be correct. In accordance with Mr. Rich's request, a horizontal section of the arch at Elevation 1 980 of the Calles Dam is shown in Fig. 61 (*a*). It has been analyzed under assumptions including shear and neglecting it (see Table 17).

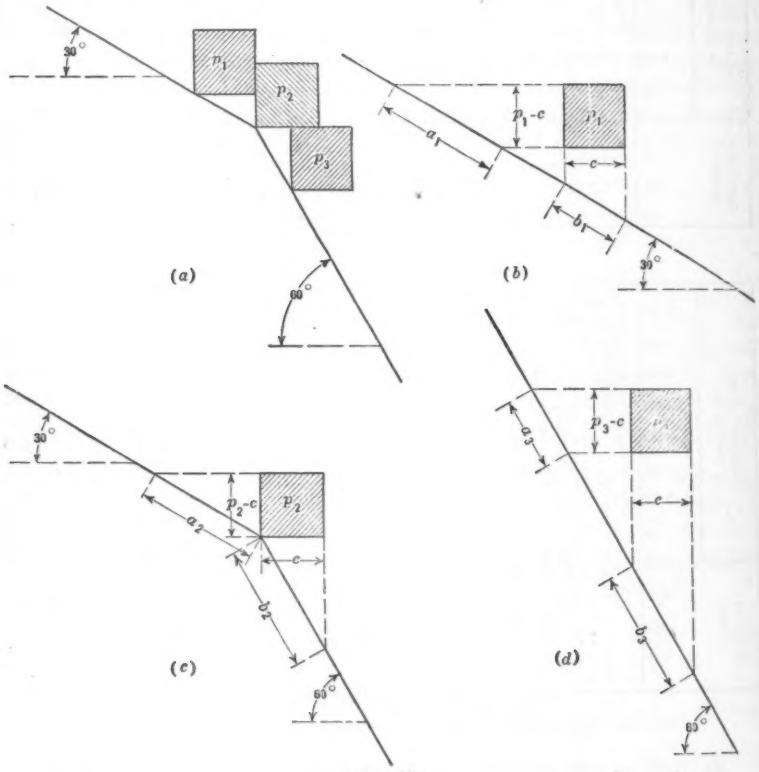


FIG. 60.

The area between the dotted lines and the theoretical extrados (Fig. 61 (*a*)) was found to be in tension in the first analysis. If shear had been considered in connection with tensile stresses the effect would have been considerable because the thrust line was far outside the middle third and formed large angles with the original axis.

Analysis of the "interior arch" (between the theoretical extrados and theoretical intrados) which is entirely in compression, shows that the difference between the positions of the thrust lines with shear and without it is too

small to be platted. The differences in computed deflections and eccentricities as shown in Table 17 are negligible.

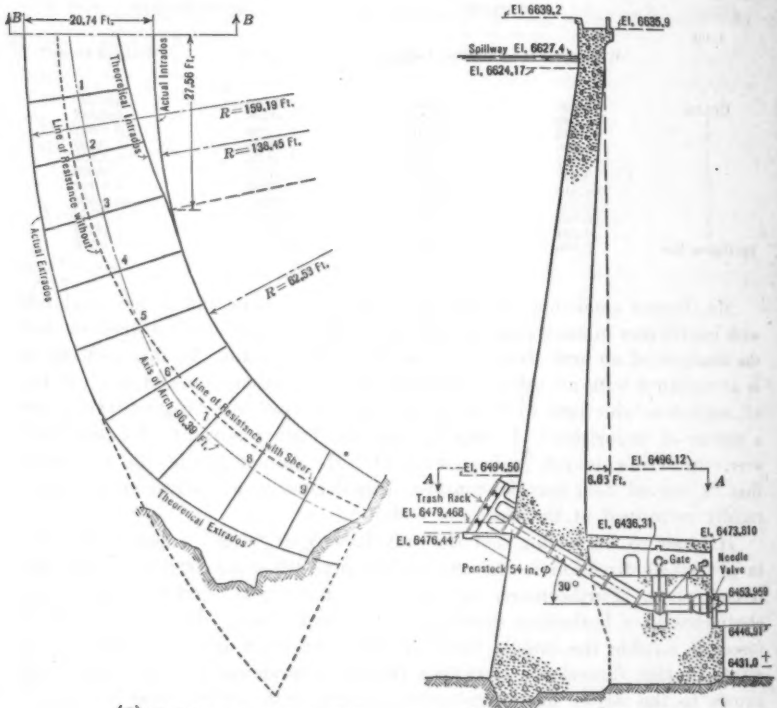
Mr. Turner condemns the conception of arches alone and arches combined with cantilevers in analyzing curved dams. He proposes as the correct method the analysis of an arch dam as if it were a curved plate. In this position he is at variance with all others contributing to the discussion and most, if not all, engineers who have written on the subject. However, "engineering is not a matter of majorities." It may be that Mr. Turner is right. Of this, however, the writer is yet to be convinced. He cannot accept the statement that "a curved dam may be considered analogous to a vertical curved plate rigidly restrained at the base and ends."

It seems to the writer that the only force that "fixes" a dam to its base in a vertical direction is its own weight plus whatever vertical water load it may carry. Furthermore, the only force that "fixes" a curved dam to the abutments in a horizontal direction is the arch thrust. If the resultant of forces is outside the middle third in either direction the dam will tend to rotate in that direction. It cannot then be considered as fixed. All dams known to the writer have construction joints, both vertical and horizontal. The entire base of the dam is a construction joint. The writer knows of no evidence to the effect that tension can be transmitted across ordinary construction joints unless reinforcement is used.

The student in the engineering school mentioned by Mr. Turner would be considered deficient in knowledge of the ordinary theory of concrete design and practice if he proposed to take advantage of the tensile strength of concrete in the design of a jointless concrete beam. Yet some post-graduate engineers with years of experience undertake to analyze unreinforced concrete dams with numerous vertical and horizontal joints as if tensile stresses could be transmitted across them.

Mr. Turner gives two diagrams, Figs. 18 and 20 for deflections of the Stevenson Creek Dam and states, "the graphic method determines relative, not actual deflections" and "the agreement between the relative theoretical and measured deflections [of Engineering Foundation] is sufficiently close to carry conviction."

A diagram of computed deflections which is merely similar in appearance to a diagram of observed deflections, but which is entirely lacking in quantitative data by which quantitative comparison can be made, cannot be accepted as a scientific proof of the method of computation.



(*a*) SECTION *A-A* AT ELEV. 1980. (*b*) SECTION *B-B* AT CENTER

FIG. 61.—CALLES DAM.

Furthermore, as far as the writer can see, Mr. Turner's method not only assumes tensile strength where it does not exist, but takes no account of the different radii of the different parts of a dam, the varying thickness, or of any temperature effect.

Fig. 19 (*a*) does not at all resemble the actual plan of Horse Mesa Dam. If it was used in Mr. Turner's analysis and if the results are correct it would seem that the plan of an arch dam has nothing to do with the analysis. As far as the writer can see, Mr. Turner's method will show the same "relative deflections" if the dam is straight, slightly curved, greatly curved, thin, or thick; if it acts under a drop in temperature or a raise; or if it is inclined or vertical.

For these reasons he cannot accept Mr. Turner's conceptions nor his conclusions. Some rational method may be devised in the future, by which

all the involved factors in the problem can be considered and the dam analyzed as a unit, but as yet this has not been done.

Professor Constant agrees with the first three conclusions in the paper. For the fourth he presents a method of analysis which entails the use of influence lines. For circular arches of constant thickness without tension this method should be more rapid than that given in the paper.

In all the dams thus far studied by the writer it has been thought advisable to increase the abutment thickness either because of pressure in uncracked arches or to provide for the formation of adequate interior arches where tension was indicated. In the case of non-circular or irregular shaped arches, the shapes of which change with each trial computation, the influence-line method may not be so advantageous.

Mr. Hanna, as did Mr. Rich, notes the neglect of shear and develops formulas for including it. He also calls attention to the fact that the arches do not deflect radially except at the crown and that the lateral cantilevers are affected by the torsional force required to twist them to the deflected arch, and *vice versa*.

Dr. Vogt states that this effect is not appreciable. This matter was also considered by the Committee of Engineering Foundation on Arch Dam Investigation which found the effect so small that it was neglected.*

Mr. Mensch gives a clear exposition of a circular arch under normal loads and an analysis for secondary arches. There are several excellent methods and Mr. Mensch has added to them.

He states, "* * * it is a mystery to the writer why arched dams are not designed in the first place in the shape of the future secondary arches, with enlargements at the dangerous sections." One reason why this has not been done is that the erroneous belief persists that unreinforced and jointed concrete can resist tension in arched dams. Another is that it usually results in overhanging sections and the public and the profession are not "up to" that as yet. The writer believes that it will certainly be done in the future when the advantages of highly curved and flexible arches are better understood.

In excavating for the Horse Mesa abutments it was found that the arches would be much longer than assumed in the original design, which is a condition frequently encountered. The dam was then laid out again and analyzed by the trial load method by the engineers of the Salt River Valley Water Users Association. In the lower arches the new design is a radical departure from ordinary practice. These arches were materially thinned down at the points of contraflexture so that all the voussoirs, instead of just those at the crown and abutments, carried approximately the maximum stress. This thinning at areas of low stress is analogous to Mr. Mensch's suggestion for thickening in regions of high stress.

This also resulted in reducing temperature and rib-shortening stresses materially because the arches were made more flexible. Furthermore, a saving of about 12 000 cu. yd. over the original design was made. The lengthening of the arches of the original design would have required about 13 000

* *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 153.

cu. yd. additional, so that a total saving of about 25 000 cu. yd. resulted. Moreover, the arches are more evenly stressed than in the original design.

In the Calles Dam, designed by Julian Hinds, M. Am. Soc. C. E., which was completed in 1928, a part of the concrete in the tension areas at the abutments of the lower arches was omitted, as shown in Fig. 61 (*a*). The rock was simply left in place and the upper arches, while overhanging the lower ones, were actually supported on the undisturbed rock. This resulted in an appreciable saving.

Savings similar to those made at the Horse Mesa and Calles Dams can and will be made in the future by omitting the unnecessary parts of the arches. The writer believes it is practical to support the overhang, if necessary, on piers or webs. He is in complete agreement with Mr. Mensch that it would be more satisfactory if cantilever action could be eliminated. This, however, cannot logically be done with vertical dams. A section of any vertical wall will carry some water load. This cannot be reasonably neglected in considering the arch loads. Vertical elements in inclined dams can carry no water loads; the arches take it all. The problem is thus simplified.

The writer believes that inclined arch dams with tension areas eliminated and with thinner sections in regions of low stress or thicker sections in regions of high stress, will be common in the future.

Professor Cain points out the fact that the method as described neglected the friction between the arches, and that this neglected factor contributes to their strength. Dr. Vogt also goes into this matter of tangential resistance in more detail and shows that in wide dam sites it is an appreciable factor.

It is pleasing to the writer that Professor Cain so strongly emphasizes the fact that tension cannot be transmitted across cracks and ordinary construction joints. This error has been most persistently retained in other methods of analysis. The statements of Professor Cain will go far in eliminating this fallacy in the future.

The writer is indebted to Messrs. Savage and Houk for their discussion. It clearly explains the latest development of the trial load method. He believes their discussion will extend the use of this method generally.

Returning for the moment to the effect of shear, attention may be called to Fig. 50. This arch has appreciable areas in tension. Both lines of thrust (with and without shear) are outside the middle third. If the shape of the arch were modified by increasing the abutment thickness so as to permit an interior arch to form, which would be entirely in compression, the line of thrust would be within the middle third. It would be more nearly parallel to the center line. Therefore, the effect of shear would be materially less than that indicated in Fig. 50.

It is reassuring to know that in the case of the Gibson Dam the refined methods indicated no substantial changes in the results given by the original computation. Horse Mesa is the only dam designed by the trial load method, as described in the paper, which is built and under full load. The water surface at Calles is about 50 ft. from the top. Horse Mesa is one of the very highest of dams and probably the thinnest, for its height, in the world. It shows no sign of distress and has carried its full load for several years.

The Stevenson Creek Dam was analyzed by the trial load method soon after it was first proposed. In this analysis (see Fig. 62) the effect of shear was not included in either arches or cantilevers. It was assumed that the concrete was incapable of taking tension; that the modulus of elasticity was 2 000 000; and that there was a temperature drop of 20° Fahr. The load tests on the actual dam were conducted in such a way that they did not include appreciable temperature changes.

The maximum arch stress computed by this analysis was 1 600 lb. per sq. in. The maximum given in the Report of the Committee of Engineering Foundation on Arch Dam Investigation* is about 1 100 lb. A change in temperature between 8° and 3.5° gave a stress of about 100 lb. per sq. in., or a total of 1 200 as against 1 600 as given by the analysis for a temperature drop of 20 degrees. It is seen that this crude analysis, based on assumptions considerably at variance with conditions at the time of testing, gave conservative results.

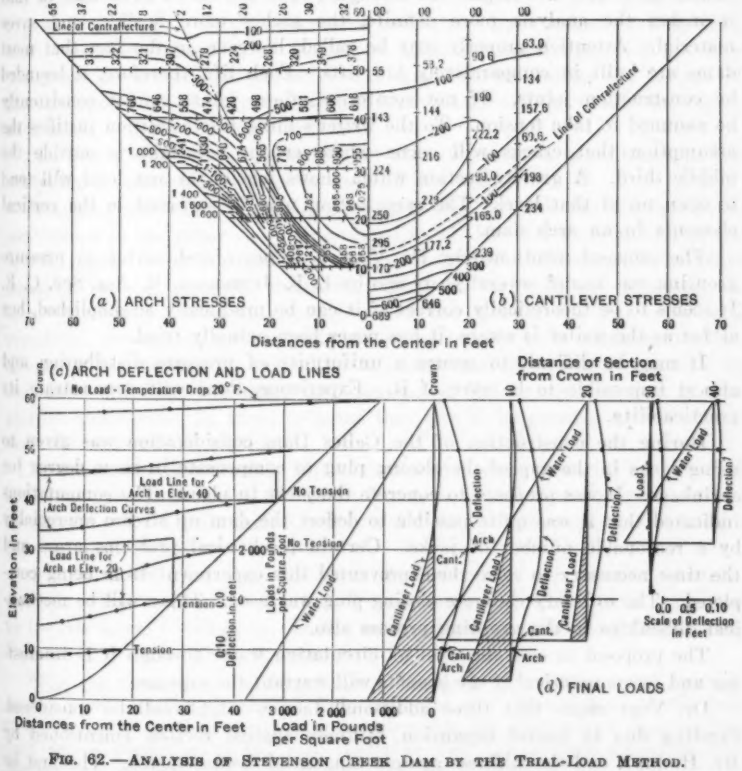


FIG. 62.—ANALYSIS OF STEVENSON CREEK DAM BY THE TRIAL-LOAD METHOD.

* *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 141.

Mr. Noetzli notes that the trial load method has been used in the design of the Horse Mesa, Gibson, and Owyhee Dams. To this list should be added the Calles Dam, previously mentioned. This is a very thin dam with a slight overhang in the central section, as shown in Fig. 61 (*b*).

Mr. Noetzli states:

"* * * it is perhaps indicated that future efforts should be directed toward alterations in the type of structure, such as would eliminate, in part at least, * * *, some of the uncertainties which are inherent in * * * the thick arch dam".

With this statement, the writer is in complete accord.

Dr. Vogt's discussion is constructive. He points out, as does Mr. Noetzli, that, once a crack has formed, the occurrence of adjacent cracks in the concrete is not probable. The writer thinks this point is well taken, and that it constitutes an uncertain element in considering "secondary arches". He also believes that removing the material down to the surface of the secondary arch does not impair the strength; it is a distinct advantage in that it makes the analysis more definite, the arches more flexible, and saves material. Attention properly may be called, however, to the fact that most dams are built in comparatively low lifts. Each lift, therefore, is bounded by construction joints. If not reinforced, these joints cannot consistently be assumed to take tension. To the writer's mind this condition justifies the assumption that cracks will occur whenever the resultant is outside the middle third. A gravity section which shows tension at any level will tend to open up at that level. The same action may be expected in the vertical elements in an arch dam.

The proposal mentioned by Dr. Vogt to improve arch action by pressure grouting was made* several years ago by L. R. Jorgensen, M. Am. Soc. C. E. It seems to be theoretically correct if it can be practically accomplished, but as far as the writer is aware, it has never been actually tried.

It may be difficult to secure a uniformity of pressure distribution and almost impossible to be sure of it. Experience alone will demonstrate its practicability.

During the construction of the Calles Dam consideration was given to using jacks in the gap of the closing plug to compensate in some degree for shrinkage. It was proposed to concrete the jacks in place. The computations indicated that it was quite possible to deflect the dam up stream appreciably by a reasonable number of jacks. Certain mechanical problems arose and the time necessary to solve them prevented this experiment from being completed. The ordinary concrete closing-plug was used. There will be mechanical difficulties in the grouting process also.

The proposal to cool the dam by circulating water through it is interesting and seems practical if the benefits will warrant the expense.

Dr. Vogt states that three additional factors might well be considered. Bending due to lateral expansion, stiffness against torsion (mentioned by Mr. Hanna), and the stiffness against tangential displacements. The first he

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 316.

believes will usually be negligible. In two cases he found that torsional resistance reduced the stresses slightly and he, therefore, recommends that this factor be neglected except perhaps for very thick dams. He states that resistance against tangential displacements is of considerable importance at wide dam sites, and gives mathematics for an approximate solution, together with the results of an interesting model test to confirm his conclusion.

His statement that multiple-arch dams may possibly be built without buttresses is startling. It is not evident to the writer how the usual multiple-arch section could be deprived of its buttresses, stood up vertically, and at the same time be safe from sliding even if the arch thrusts could be theoretically carried across the various units.

Regarding the cases in which gravity abutments failed and the arches stood, it should be stated that one of these dams, the Moyie, was completely reinforced by 20-lb. rails on 2-ft. centers, both horizontal and vertical.* The other, Lake Lanier, was reinforced for the top 12 ft.* of its total height of 60 ft.,‡ or 20 per cent. At the end of the arch where the abutment failed, these 12 ft. comprise about 45% of the height. The reinforcement could not help stiffening the arches against tangential displacement during the failure of the abutments. If the arches had not been reinforced the tangential resistance alone might not have saved them.

Mr. Floris expresses impatience that the writers gave some formulas for analyzing arches. He then gives some of his own.

Summing the results of the discussion it may be said that the first three conclusions in the paper are unquestioned by all but Mr. Turner. As to the fourth, nearly every one has pointed out omissions and suggested improvements in the mathematical treatment. This was expected and is welcomed. It was distinctly stated in the paper that the method was not considered complete. Several of the omitted factors were specifically mentioned. The discussion has shown how tangential resistance and shear effect may now be included. Dr. Vogt has dealt with foundation deformation so that it may also be considered. In time, it seems that it will be possible to include all pertinent factors.

In conclusion it is frankly admitted that at present the trial load method is tedious and cumbersome. However, it may be stated that a graphic method developed by Mr. Hinds indicates that a complete solution may be made in a fraction of the time now required.

It is believed that the trial load method gives a reasonably accurate analysis. The conception of vertical and horizontal elements is supported by the Stevenson Creek tests. In the report of the Committee of Engineering Foundation on Arch Dam Investigations,† it is stated,

"For the most part the directions of the principal strains were approximately vertical and horizontal. This indicates that the division of the dam into imaginary vertical and horizontal elements for purposes of analysis not only serves convenience, but also indicates that the stresses found in this manner will generally be close to the principal stresses."

* *Engineering News-Record*, Vol. 97, 1926, p. 616.

† *Proceedings*, Am. Soc. C. E., May, 1928. Pt. 3, p. 193.

An inspection of the plans of the dam designed by this method will show that they are economical in material. The discussion has shown that the method determines the maximum stresses conservatively. Further development of the method is expected to result in more accuracy and increased economy both in material and in time of designing.

For small thin dams with large central angles the application of the trial load method may not be necessary. For such dams the formulas developed by Professor Cain are thought to be adequate. For high thick dams and especially for those with small central angles and irregular profiles the writer thinks the use of the trial load method is advisable. His thanks are extended to those who discussed this paper.

Paper No. 1713

HYDROSTATIC UPLIFT IN PERVIOUS SOILS*

By H. de B. Parsons,† M. Am. Soc. C. E.

With Discussion by Messrs. F. R. Harris, J. C. Meem, Eugene E. Halmos, T. R. Lawson, J. Vipond Davies, Lazarus White, T. Kennard Thomson, Daniel E. Moran, Alexander V. Gallogly, Allen Hazen, Charles Terzaghi, Frank S. Bailey, Charles R. Gow, E. L. Chandler, Martin J. McPike, Jacob Feld, J. Albert Holmes, E. W. Lane, and H. de B. Parsons.

Synopsis

This paper describes an original research to determine the hydrostatic uplift on the base of a structure, founded on a pervious soil, when there is no loss of head due to velocity of flow. Engineers have not been in agreement on this question, some believing that the pressure due to the hydrostatic head acts on the full area of the base, and others that the pressure acts only on a portion of the area because the remaining portion is in intimate contact with the soil.

The paper records the results of 218 tests, not including trial tests, nor those made to standardize the apparatus. The soil materials used were sand, gravel, and clay. The tests were conducted with both low and high hydrostatic heads. The size of the base area, the head, and the unit loading on the soil were varied sufficiently to demonstrate that the results are independent of these factors. Shallow depth of soil under the test base, however, does affect the results.

The effective area, or that portion of the base on which the uplift acts, is stated in percentage of the total base area. The test results show that this effective area is approximately 90 to 100%, according to the test conditions.

* Presented at the meeting of May 2, 1928.

† Prof. Emeritus, Rensselaer Polytechnic Inst.; Cons. Engr., New York, N. Y.

The apparatus used and the methods of conducting the tests are fully described and illustrated.

Introduction

There is little information on record regarding hydrostatic uplift in pervious soils. Although some tests have been published,* a search revealed a paucity of data, but a desire for more knowledge on this subject.

Divergent opinions are held by engineers on the magnitude of the hydrostatic uplift force acting on the base of a structure built on pervious soils. When the head is relatively high, the resulting uplift becomes an important consideration in the design and construction of dams, piers, caissons, and similar structures.

Obviously, there is no hydrostatic uplift under a structure founded on rock when water cannot enter the joint between the base and the rock surface. However, should water reach the base of the structure through a fissure or water-bearing seam, there would be uplift on that portion of the joint to which water could obtain access. This uplift would act only on that portion of the base area where close physical contact with solid rock did not exist.

Engineers now give recognition to hydrostatic uplift, when making calculations for important dams founded on pervious soils, and various assumptions are made to insure the safety of the structure. Ordinarily, an engineer selects one of the following assumptions according to his idea of the conditions obtaining at the site:

1.—Allowance for uplift due to total head acting on the full width of base.
2.—Allowance for uplift due to total head at the up-stream edge, which is assumed to diminish uniformly to zero at the down-stream edge.
3.—Allowance for uplift due to a portion of total head (say, three-fourths, two-thirds, or one-half) at the up-stream edge which is assumed to diminish to zero at the down-stream edge.
4.—When the down-stream edge of the base is below tail-water level, the uplift at this edge is taken at tail-water head instead of at zero, as in Assumptions (2) and (3).
5.—When conditions are favorable for a tight joint at the up-stream edge, then uplift is assumed as constant over the width of the base due to the head at the down-stream edge.
6.—Modifications of these assumptions are made to comply with the designer's idea for safety, especially when drainage ducts are provided.

The question arises whether or not it is ultra-safe to assume the uplift pressure as acting on the total area of the base, both for uniform intensity of uplift and also for varying intensity due to a flow of water through the soil beneath the base. Some engineers have favored the hypothesis that water under head enters between the particles of a pervious foundation soil, and, in consequence, the uplift pressure acts only on that portion of the base which is exposed to water. Under this hypothesis, the remaining portion of the base area, being in direct contact with the particles of the foundation soil, is not

* *Transactions*, Am. Soc. C. E., Vol. LXX (1910), p. 352.

subject to uplift because the contact, between base and soil, prevents the water from reaching this portion; and, it is claimed, the effective area would have some relation to the voids in the foundation material.

In the opinion of other engineers, uplift pressure acts on the total area of the base. Under this hypothesis, the uplift pressure acting on the base of a structure is, first, a direct hydrostatic pressure on the base area exposed to the water; and, second, an indirect pressure through the soil particles in contact with each other and with the base.

The writer undertook some experimental research work in order to obtain information regarding these hypotheses, and this paper records the results of the tests made.

Some of the smaller tests were made in the writer's office. In collaboration with Thomas R. Lawson, M. Am. Soc. C. E., apparatus was made from designs prepared by the writer, and set up in a laboratory of Rensselaer Polytechnic Institute, Troy, N. Y. Funds for the tests at Rensselaer were made available through the kindness of the Trustees from the Laflin Fund for research work. The writer also designed other apparatus, built at his own expense, which was erected in a laboratory of Stevens Institute of Technology, Hoboken, N. J. There were two series of experiments—one with low heads and one with high heads.

Low-Head Tests

Tests were made with low hydrostatic heads acting on a glass jar and on metallic cans, embedded in sand. At the instant the jar or can commences to rise from the sand, the hydrostatic uplift, acting on the bottom, just equals the weight of the jar or can, plus the sand friction against its side. It was necessary, therefore, to determine this sand friction, which was done as follows: The can to be tested was placed on a support which rested on the bottom

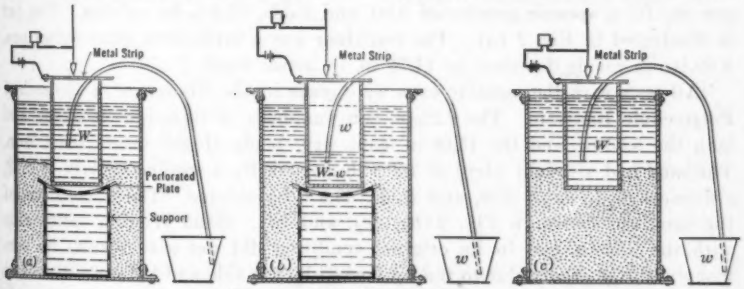

Fig. 1.—Sand Friction Tests.

of a containing vessel. This support had no top, and the can was placed on a perforated plate so that water could freely reach the bottom of the can. The supporting contact area between can and perforated plate was made small so as to be negligible (see Fig. 1 (*a*)). The support was filled with water, and wet sand was placed in the container to a predetermined height on the side of the can, and hand-packed. The can then was filled with water to give it additional weight, and afterward the container was filled with water to the

same level as the water inside the can. The outside head was carefully measured from water surface to bottom of can. To indicate the first movement of the can, a plumb-bob was suspended just clear of a metal strip across the top of the can, and wired through a battery and a buzzer. The water inside the can was slowly siphoned until the can commenced to rise (Fig. 1 (*b*)). The water siphoned from the can was weighed, to determine the weight of water left in the can at the instant of movement.

This procedure is expressed mathematically as follows:

Let U = hydrostatic uplift on the bottom of the can.
C = weight of empty can and metal strip.
C_1 = weight of water having same volume as submerged material of can.
W = original weight of water in can.
w = weight of water siphoned until can starts to float.
F = sand friction against side of can.

Then,

$$U < W + C + F$$

After siphoning w at the instant the can begins to float,

$$U = W - w + C + F$$

Also,

$$U = W + C_1$$

Equating the values of U and solving for F:

$$F = w - (C - C_1)$$

in which, $(C - C_1)$ is the weight of the can in water.

Sand Friction Tests.—All tests in the writer's office were made with a glass jar. Ordinary silica sand was used, having a weight (dry) of 112 lb. per cu. ft., a specific gravity of 2.80, and voids, 35.5% by volume. The jar is illustrated in Fig. 2 (*a*). The container was a cylindrical glass aquarium, 8.69 in. in inside diameter by 14.75 in. in inside depth.

All tests with the metallic cans were made in the laboratory of Rensselaer Polytechnic Institute. The 9.22-in. can was made of tinned sheet metal, and both the 5.53-in. and the 15.09-in. cans were made of galvanized sheet iron. The sand had a weight (dry) of 100.8 lb. per cu. ft., a specific gravity of 2.43, a fineness modulus of 2.09, and voids, 33.5% by volume. The dimensions of the cans are shown in Fig. 2 (*b*), (*c*), and (*d*). Sand friction tests made with the 9.22-in. can in its original condition did not give results in harmony with the others, due to the lip formed by the side and bottom. The tests always showed greater friction and were rejected as unreliable. The bottom recess then was filled with plaster of Paris as shown in Fig. 2 (*c*), and the recorded tests were made with the can in this condition. The container for all the cans was a steel cylinder, 36 in. in inside diameter by 32½ in. in inside depth.

Twenty-nine sand friction tests were recorded, consisting of six with the 3-in. glass jar, six with the 5.53-in. can, eight with the 9.22-in. can, and nine with the 15.09-in. can. Many other tests were not recorded because they were considered doubtful due to faulty manipulation or conditions of can that pre-

cluded accurate results. The results of the tests did not show any material difference in friction due to the materials of which the cans were made, namely, glass, tin, or galvanized iron.

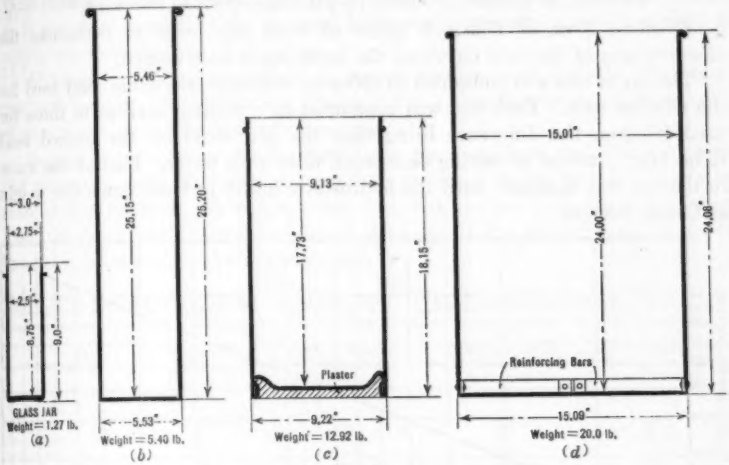

FIG. 2.

After determining the friction, the result was reduced to pounds per square inch of side surface of can embedded in sand. The results, as averaged for similar conditions, are given in Table 1.

TABLE 1.—AVERAGES OF TWENTY-NINE SAND FRICTION TESTS.

Depth that can was embedded in sand, in inches.	Friction, in pounds per square inch, of side surface of can in contact with sand.
0.5	0.01625
1.0	0.02338
2.0	0.03078
3.0	0.01616*
4.0	0.02636*
6.0	0.04700
8.0	0.04748
9.0	0.05655
12.0	0.05972
15.0	0.06790

* Doubtful.

The frictions were then platted on logarithmic paper (Fig. 3) and a mean line was drawn through the points, after omitting as doubtful the tests at 3-in. and 4-in. depths. The two discordant friction results were caused by a low one occurring at each depth, which made the averages too small. For all the uplift tests with the jar and cans, the friction was determined by reading the unit friction from the mean line (Fig. 3) and multiplying by the surface of the side in contact with the sand. This method eliminated slight irregularities due to manipulation. In order to find the mean line of friction (see Fig. 3), find the center of gravity, C, of all tests and the centers, A and B,

above and below C, respectively. The mean line passes through these three points. Tests at 3-in. and 4-in. depths of the can embedded in sand were omitted as doubtful results. The formula for the mean line is:

$$\text{Friction, in pounds} = 0.0227\ (\text{depth embedded, in inches})^{0.3977}$$

Effective Area of Base.—A series of tests was made to determine the effective area of the base on which the hydrostatic uplift acted.

The jar or can was embedded to different depths in the same sand used for the friction tests. Each test was conducted in a manner similar to those for sand friction, the difference being that the can stood on the packed sand (Fig. 1(*c*)), instead of resting on a stand filled with water. Part of the water in the can was siphoned until the hydrostatic uplift just overcame the weight and sand friction.

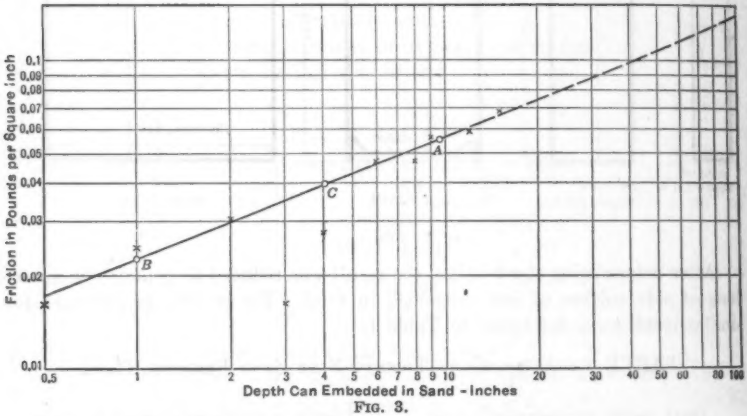

FIG. 3.

This procedure is expressed mathematically as follows:

Let A = outside area of base of can.
a = effective area of base on which hydrostatic uplift acts.
h = hydrostatic head on outside base of can.
W = weight of water in can.
w = weight of water siphoned until can just begins to float.
C = weight of empty can and metal strip.
F = sand friction against side of can.

All measurements were in inches and pounds, and the weight of 1 cu. in. of water was taken at 0.0361 lb. Then:

$$\text{Hydrostatic uplift} = 0.0361 \times h \times a$$

and,

$$\text{Resisting forces} = W - w + C + F$$

When the uplift just overcomes the resistance, these two expressions are equal. As all values are determined by the test measurements, except a, the effective area of base can be calculated. Then:

$$\frac{a}{A} \times 100 = \text{percentage of base area on which hydrostatic uplift acts.}$$

Thirty-three tests were made with wet sand, hand-packed in the container, namely, eight with the glass jar, six with the 5.53-in. can, ten with the 9.22-in. can having the bottom recess filled with plaster of Paris, and nine with the 15.09-in. can having the bottom reinforced on the inside with small angle-bars, as it was discovered that the external hydrostatic pressure caused a deflection which was measureable.

Although an effort was made to secure similar conditions in each test, the variations in the results are probably due to manipulation and difficulty of accurately recording the low pressures.

Results of tests under similar conditions were averaged, and Table 2 gives the summary, with the tests arranged in order of depth that the can was embedded in the sand. It will be noted that with the low hydrostatic pressures used, the depth of the sand bed below the base of the cans did not seem to have any influence on the effective area.

TABLE 2.—Effective Area of Base with Wet Sand Packed in Container.

Can tested.	Diameter of can, in inches.	Sand depth below base, in inches.	Depth can was embedded in sand, in inches.	Average effective area in percentage of base.
Glass jar	3.0	6.0	0.0	97.6
Glass jar	3.0	6.0	0.5	96.5
Glass jar	3.0	6.0	1.0	90.5
Glass jar	3.0	6.0	2.0	89.6
Metal can	15.09	7.5	3.0	98.2
Metal can	5.53	6.5	4.0	88.0
Metal can	9.22	11.0	4.0	99.7
Metal can	5.53	6.5	6.0	90.8

Metal can	9.22	11.0	9.0	82.5
Metal can	15.09	7.5	9.0	94.5
Metal can	15.09	7.5	12.0	92.7
Average of all tests				91.4
Average of tests omitting glass jar				90.6

A similar series of tests was made with the same sand hand-packed and tamped in a dry condition around the can. After filling the can with water, the container was filled on top of the dry sand to the same level and the test was conducted by siphoning water from the can as before. It was found that time had to be allowed for the water to saturate the sand, or the results would not be concordant.

The results are given in Table 3, being the averages of eighteen tests, namely, seven with the 5.53-in. can, six with the 9.22-in. can with plastered bottom, and five with the 15.09-in. can. The effective area in percentage is somewhat smaller than that obtained with the wet sand packing. It is possible that the results were affected by the time element mentioned.

High-Head Tests*

The apparatus consisted of a container made from a piece of extra heavy steel pipe, 12 in. in inside diameter, having a blind cast-iron flange screwed

* Made in laboratory at Stevens Institute of Technology, Hoboken, N. J.

on the bottom. A cast-iron companion flange was screwed on the top, to which was bolted a specially designed cover fitted with a stuffing-box and packing gland. A solid steel contact rod, 3.99 in. in diameter by 60 in. long, with the bottom end machined to a smooth surface at right angles to the axis, passed through the stuffing-box. The gland was packed with square-section steam piston-rod packing. There was an air-cock in the cover, and the container was tapped for a water-pipe connection and diametrically opposite for a pipe leading to a pressure gauge. The equipment is shown in Fig. 4. The contact rod weighed 216 lb., and had a base area of 12.53 sq. in. When supported by a soil, the unit load was, therefore, 17.24 lb. per sq. in., equivalent to 1.24 tons per sq. ft.

TABLE 3.—Effective Area of Base with Dry Sand Packed in Container.

Average of all tests				85.6

In these experiments, the soil to be tested was first put in the container and packed. The rod was then brought down into firm contact with the soil, and water was allowed to enter the container very slowly, while the air found exit through the cock in the stuffing-box flange. When the container was full of water and the air-cock closed, the pressure rose slowly. When the uplift was sufficient to balance the weight of the rod and to overcome the stuffing-box friction, the gauge pressure was recorded. This point was indicated by a buzzer wired to a plumb-bob and a copper strip lashed to the rod. The first movement of the rod could be detected before the buzzer sounded, by watching the light under the plumb-bob point. The device proved to be very sensitive.

Before each test, the difference in level between the base of the contact rod and the gauge center was measured. The gauge pressure, as registered, was corrected for this difference in head. The gauge also was calibrated before using, and care was taken to note that the contact rod was vertical by sighting along the plumb-bob cord.

Immediately after determining the hydrostatic uplift gauge pressure, a friction test was made. This was done by raising the contact rod just clear of the soil, so that its base was in complete contact with the water. The hydrostatic pressure required just to raise the rod was then recorded, as before.

Let A = base area of the contact rod.

a = effective area of rod, that is, the area on which uplift acts.

W = weight of rod.
F = friction of stuffing-box packing.
P = corrected hydrostatic gauge pressure when rod, resting on the soil, just commences to rise.
p = corrected hydrostatic gauge pressure when rod, being in complete contact with water, just commences to rise.

Then,

$$Pa = W + F = pA$$

or,

$$\frac{a}{A} = \frac{p}{P}$$

Then, the ratio of effective area to total base area, expressed in percentage, is $\frac{p}{P} \times 100$.

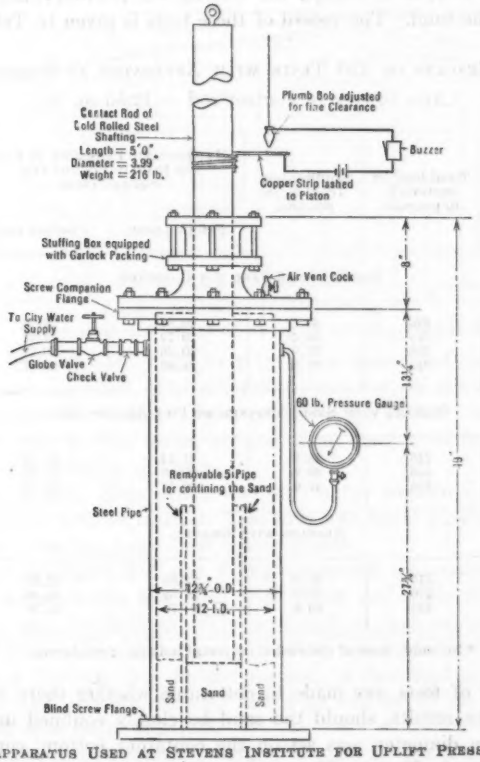

FIG. 4.—APPARATUS USED AT STEVENS INSTITUTE FOR UPLIFT PRESSURE TESTS.

Tests were made to determine not only the hydrostatic uplift, but also whether a variation in the depth of soil bed, beneath the base of the contact rod, would cause any change in the uplift pressure.

Contact Tests with Sand.—The first test was made without sand, but with the contact rod resting directly on the cast-iron bottom of the container. Although the base of the rod was machined smooth and the surface of the cast-iron bottom was rough, there was direct contact between the metals. Therefore, the effective area recorded was that portion of the area of base exposed to water. After this test, the contact rod and container head were removed. Wet sand was then put in the container to the required depth, leveled, and packed by hand. After the head was replaced, the sand was further packed by ramming with the contact rod.

The sand was brown silica building sand, having a weight (dry) of 107 lb. per cu. ft., a specific gravity of 2.5, and voids, 31.2% by volume.

The tests were made by varying the depth of the sand bed below the base of the rod, from about 1 in., then to 6 in., and then to 12 in. They were conducted to find, first, the hydrostatic uplift when the rod base was in contact with the sand bed; and, second, the stuffing-box friction when the rod was just clear of the sand. The record of these tests is given in Table 4.

13.5	216	56.6	21.76	21.57	100.0

*No sand; base of rod rested on metal bottom of container.

Another set of tests was made to determine whether there would be any difference in the results, should the sand be closely confined under the rod. A pipe, 5 in. in diameter, was set on the container bottom, concentric with the rod, as shown in Fig. 4. Wet sand to the required depth was put in this pipe and packed by using the rod as a ram. The area of the base of the contact rod is 12.53 sq. in. These tests also are recorded in Table 4.

Contact Tests with Gravel.—Gravel was put in the container and tested in a similar manner. The gravel consisted of smooth, rounded, quartz pebbles, varying in size from ⅛ to ½ in., with an occasional stone ¾ in. in longest dimension. It had a weight of 97 lb. per cu. ft., a specific gravity of 2.62, and voids, 40.76% by volume. Thirty-seven tests were made. The results are recorded in Table 4.

The relation of the records is made clearer by inspection of Fig. 5, in which the results given in Table 4 are platted and curves drawn through the points. It will be noted that the hydrostatic uplift acted on practically the full area of the base when the sand depth beneath the base exceeded 17 in. Also, as the depth of the sand bed was decreased, the effective base area became less. It will be noted, also, that the confinement of the sand, by the 5-in. pipe placed around the 4-in. rod, did not materially affect the results. With gravel, the effective area of base was larger for shallow depths of bed than with sand.

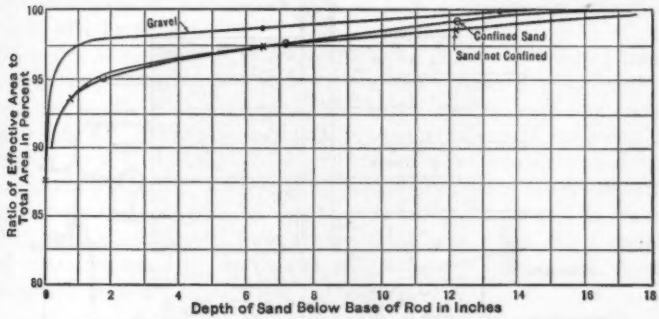

FIG. 5.—RELATIVE RESULTS OF TESTS AT STEVENS INSTITUTE.

Every test was repeated from four to seven times, and the averages of similar tests were recorded. The differences, however, in the gauge pressure readings of similar tests, were slight, as shown in Tables 6 and 7. There were 110 tests made in this series, not including many trial tests to see that the apparatus was working properly.

Contact Tests with Clay.—Clay was put in the container, and an effort made to test it in a similar manner. The clay was fairly pure in quality and of the kind used for top dressing of tennis courts.

In a damp condition, the clay firmly supported the contact rod, but it flowed when the container was filled with water and while the contact rod was used as a ram for packing. The rod sank at each ram, until its base touched the bottom of the container. An effort was made to confine the clay closely by using the 5-in. pipe around the rod, as described previously. The result was the same, namely, the clay flowed up and out of the 5-in. pipe and acted like sand with quick behavior.

When tested with hydrostatic pressure, the rod always sank into the clay bed (whether confined or not) below its original starting point as soon as the pressure was released. The results (such as they were) indicated that the effective area was nearly a 100% of the base area.

Tests Made at Rensselaer Polytechnic Institute

The apparatus consisted of a riveted steel cylinder, 36 in. in diameter by 32½ in. deep, as shown in Fig. 6. The bottom was stiffened by 2-in. angle-bars and the sides were reinforced by steel bands 3¼ in. by ⅜ in. The cover, fitted with a stuffing-box and gland, was bolted to the cylinder, and could be removed for placing sand in the container. The contact rod was a piece of 12-in. extra strong pipe, turned to 12½ in. in outside diameter and filled with concrete. A 3-in. pipe extended above the 12-in. pipe for centering the concrete weights. Three concrete weights were made, each approximately 3 by 3 ft. by 9 in. thick, with projecting steel reinforcement bars to facilitate handling. The container was tapped for a water pipe, to which was fitted a pressure gauge.

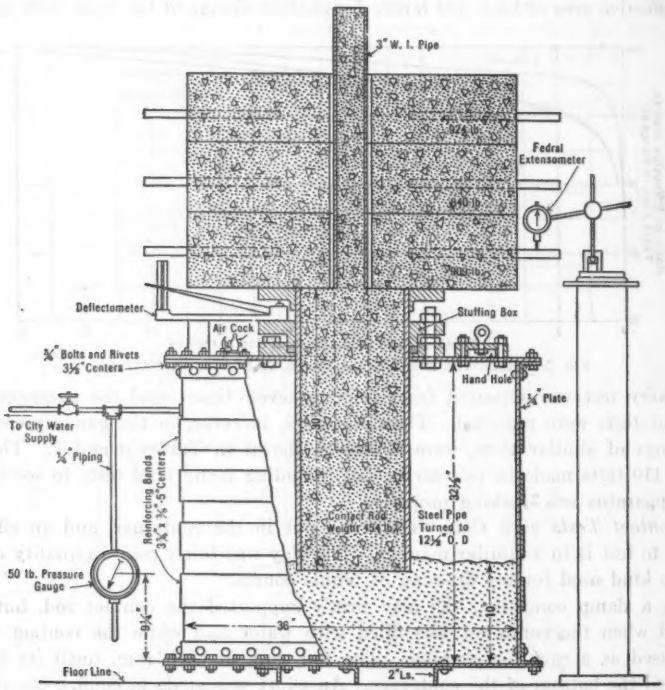

FIG. 6.—APPARATUS USED IN UPLIFT PRESSURE TESTS, AT RENSSELAER POLYTECHNIC INSTITUTE.

The contact rod weighed 454 lb. and had a base area of 122.7 sq. in. The concrete weights were 909, 840, and 924 lb., respectively. When resting on the sand for testing, the unit loadings were, therefore, 533 lb. per sq. ft. without the weights; 1 600 lb. with the lower weight; 2 585 lb. with the two lower weights; and 3 669 lb. with all three weights.

The tests were conducted in a manner similar to those made at Stevens Institute, and the mathematical formula was the same. The pressure gauge was calibrated, and the readings as corrected were recorded. An extensometer was used to indicate the first movement of the contact rod, and a deflectometer to record any change in position of the cover of the container due to the heavy internal hydrostatic pressure.

Tests were made to determine, not only the hydrostatic uplift, but also whether a variation in soil loading would cause any change in the uplift pressure.

Contact Tests with Sand.—Wet sand was put in the container to a depth of about 10 in., leveled and hand-packed. The contact rod, when loaded with weights, settled into the sand; but prior to each test, the depth of sand directly under the contact rod base was measured.

The sand was smooth or water-worn silica sand, having a weight (dry) of 116.7 lb. per cu. ft., a specific gravity of 2.83, a fineness modulus of 2.50, and voids, 34% by volume.

The record of the tests is given in Table 5. It should be noted that the loading in these tests was heavy, under the three weights, being more than 1.8 tons per sq. ft. of bearing area. While the greatest care was exercised to secure accuracy, the results may seem to have unwarranted variation in the stuffing-box friction. This variation in friction was probably caused by the centers of gravity of the heavy concrete weights not being always directly in the axis of the contact rod. Any slight eccentricity would tend to make the rod bind in the stuffing-box. As the recorded results are the averages of several tests (confirmed by trial tests), the percentage of base area found to be effective is no doubt close to the true figure.

TABLE 5.—Results of Twenty-Eight Tests with Apparatus at Rensselaer Polytechnic Institute.

9.25	3 127	619.0	30.53	30.39	100.0

The data given in Tables 1 to 5 are averages of the results found by repeating similar tests. The results of a few tests are given in more detail in Table 6, with low heads, and Table 7 with high heads.

The observations recorded in these tables show the closeness of repeated tests, which were not always made on the same day. The closeness of similar tests also shows the fairness of using averages to eliminate personal variations in manipulation and observation. Furthermore, the personnel of the

test parties was changed, and the results obtained by the various parties were in harmony.

SUMMARY

The preliminary testing disclosed that the "time element" entered the problem when dry sand was used. It required several hours for the sand to become saturated, and for the full hydrostatic pressure to be evenly transmitted. When using the large container at Rensselaer, as long as 18 to 24 hours was allowed for saturation. An experiment was made by having one end of a rubber tube embedded in the sand under the test base, and noting the time required for the water in the tube to reach the same level as that in the container.

To avoid inaccuracy caused by the time required for saturation, the sand used in the tests at both Stevens and Rensselaer was packed in a saturated condition.

By not embedding the base of the contact rod, the problem of sand friction was eliminated in the high-head tests. The experiments showed that:

1.—In pervious soils the area of base on which uplift acts is always a large percentage of the total base area. Although the results are generally between 90 and 100% of the total base area (with a few below the lower limit), it would not be safe to estimate an uplift in pervious soil of less than full pressure head acting on the total area of base, when there is no flow of water through the soil; nor less than the full pressure head indicated by the hydraulic gradient when there is flow through the soil.

The hydrostatic pressure acts, not only on that portion of the base area to which the water has access, but also on each particle of the soil material. Therefore, a part of the uplift pressure is transmitted to the base through the points of contact of the particles with one another and of the particles with the base.

1363	Sand not confined..	122.7	13.99 13.99 13.99	13.99	14.51 14.51 14.26 14.76	14.51	96.5

In a bed of pervious material the hydrostatic pressure acts on the portions of the surfaces of the particles which are exposed to the water. A base prevents hydrostatic pressure from acting on the top surfaces of the particles in contact with it. Consequently, the resultant of the forces on all the particles beneath the base is upward. The sum of this resultant pressure acting through the particles plus the hydrostatic pressure due to the water acting directly on the base constitutes the total uplift on the base. With sufficient depth of soil, the effective area of the base is found to approximate 100 per cent. Therefore, the portion of the total uplift acting through the particles

directly on the base is equal to the hydrostatic head at the plane of the base times that part of the base area in contact with the soil. At shallow soil depths the aggregate of the uplift forces acting through the particles fails to equal the hydrostatic head at the plane of the base times the area of the base in intimate contact with the soil.

2.—The uplift is reduced when the depth of the pervious soil is shallow. The tests at Stevens showed this reduction commencing at about 16 or 17 in. of soil. These tests also showed that the uplift is less with finer soil particles at corresponding depths of soil within the limit named. The experiments made at Stevens (Table 4 and Fig. 5) were the only ones in the series designed to record the effect of variable depth of soil beneath the base. The results of tests at Rensselaer (Table 5), in which the area of base of the rod was about ten times greater than that at Stevens, showed that the average effective area in percentage of base was approximately 98.8 when the sand depth below the base was a little more than 9 in. At a corresponding depth for the tests at Stevens (Fig. 5), the effective area was about 98.0% for sand not confined, 98.3% for confined sand, and 99.2% for gravel.

3.—The variation in sizes of base areas, from 7.07 sq. in. for the 3-in. jar to 178.84 sq. in. for the 15.09-in. can, or twenty-five times, does not alter the result.

4.—The variation in hydrostatic uplift pressure per unit of area, from 0.29 lb. per sq. in. to 30.39 lb. per sq. in., or one hundred times, does not alter the result.

The profession would be benefited if engineers would report data on magnitude of uplift pressures observed in construction work.

Acknowledgments

The writer expresses his thanks to Thomas R. Lawson, M. Am. Soc. C. E., Philip D. Joynt, Jun. Am. Soc. C. E., and Messrs. C. E. Rose and E. R. Wiseman for their help in conducting the tests at Rensselaer; to Mr. George L. Quigley for his help with all the tests and especially for his aid in revising the manuscript; to Eugene E. Halmos, M. Am. Soc. C. E., for suggestions made during the work; and to Mr. Warren R. Bentley, his Office Assistant.

The writer also acknowledges his obligation to the Trustees of both Rensselaer Polytechnic Institute and Stevens Institute of Technology for space in the testing laboratories.

DISCUSSION

F. R. HARRIS,* M. AM. SOC. C. E.—The speaker notes that in his "Introduction", Mr. Parsons states that there is little information on record regarding hydrostatic uplift in pervious soils and was impressed with this as far back as 1909. However, in connection with the design and construction of Dry Dock No. 4 at the Brooklyn Navy Yard, there was considerable discussion on this subject.

It is apparent that a dry dock structure is one in which the hydrostatic uplift is of primary importance. In fact, it is the outstanding condition which influences the entire design of the work. In all dry dock structures built previous to 1909, with which the speaker is familiar, the full hydrostatic pressure incident to extreme high tide, or even in excess of this, if the apparent ground-water elevation was higher than extreme high tide, was calculated. There was considerable discussion at that period as to whether or not such uplifts were present and active. One of the theories in vogue then, which Mr. Parsons mentions, is that this pressure was lessened by a reduction in the area of the sub-grade surface in contact with water and subject to water pressure; that is, the surfaces of the subsoil in contact were thought to consist of fine particles of materials pressing against the under side of the structure which served to reduce the area subject to water contact and hydrostatic pressure. It was considered that this, in turn, reduced the total hydrostatic uplift and that this condition obtained so long as the weight of the structure was in excess of such uplift.

The speaker had some doubts as to the correctness of this theory, in fact, he did not agree with it and, therefore, the dry dock was designed to take full hydrostatic uplift. For future information, devices for recording the actual uplift were placed in the dock floor at several places. These consisted of cylinders with a lead diaphragm, the under side of the diaphragm being at sub-grade. The cylinder projected up into the concrete floor and was embedded in it. A plunger or piston with sufficient clearance so as not to bind in the cylinder, was held against the upper side of the diaphragm by a shaft with a capstan screw. On completion of the dock structure observations were made on the uplift, the piston being released for this purpose. In every case practically full hydrostatic pressure was recorded on the diaphragm. In connection with these observations there was provided, through the dock floor, pipes fitted with pressure gauges and the observed water pressure on the gauges was checked against ground-water and tidal observations, the gauges indicating full hydrostatic pressure, fluctuating with tidal changes.

Observations on the diaphragm followed the pressure-gauge observations on the pipe connections so closely that the speaker was convinced that the hydrostatic uplift was 100 per cent.

The speaker regrets that it has not, as yet, been possible to arrange these data in a suitable form for publication. The results were, nevertheless, very convincing, in indicating undoubted full hydrostatic uplift.

J. C. MEEM,* M. AM. SOC. C. E.—The author is to be commended highly for the painstaking care with which he has endeavored to solve one of the difficult problems of applied engineering. The speaker has made somewhat similar experiments, although not, perhaps, so exhaustively, with similar apparatus, and has also co-operated with the author, at least in the early stages of this experimental work. He believes, however, that the results of the author's experiments are not conclusive as to the reduction of area of uplift pressure through soil.

The principal reason for this belief is that in order to determine the reduction of area definitely, it is necessary to establish a specific area of contact, and this contact does not appear to have been established in any of the author's experiments, due to the small area of the can or piston, compared with the relative size of the grains of sand or gravel, and to the shallow depth—especially in the case of the hydraulic piston—at which it was subjected to pressure. For instance, under a microscope this piston would have appeared as if resting on a few pinnacles rather than on a flat area. Furthermore, if the author was unable to get more than 15% contact (see Table 4) between the bottom of the piston and the bottom of the container, it is reasonable to suppose that he would not be able to establish a larger area of contact on loose, irregular particles. In the four experiments which the speaker made with hydraulic apparatus similar to that used by the author, he was able to establish a much higher percentage of contact by plunging the piston into the sand, pressing it well down, and leaving it for varying intervals until normal conditions resulted.

In order to give a better understanding of this experiment, a section of the apparatus is shown in Fig. 7(*b*). It consists of a hydraulic chamber with the piston actuated hydraulically by a pump connected by copper pipe to the chamber and carrying a gauge reading to pounds. It was found that it took about 4 lb. of pressure to raise the piston when plunged into water alone.† A table was then placed in the chamber so that sand could be packed around the piston, leaving the bottom free, and it was found that the additional pressure required to raise the piston did not register on the gauge; and frictional resistance due to this sand was assumed to be negligible or less than 25 lb. per sq. ft.

The table was then removed, the chamber was partly filled with sand, and the piston pressed into it, where it was allowed to remain for periods varying from a few minutes to 2 hours. The pump was started and the pressure required to lift the piston varied from 17½ to 25 lb. (averaging about 22 lb.), which gradually dropped to 4 lb., when the piston came out of the sand.

Even if the friction on the piston due to surrounding sand is determined by using the coefficient found by the author, it is seen that the pressure required to lift the piston from sand with which it has made contact is three or four times that required to lift it in clear water.

It should be noted that if there is 100% contact of water or pressure on the base of the piston there should also be 100% of water pressure around

* Chf. Engr. and Secy., F. L. Cranford-C. H. Locher, Inc., Brooklyn, N. Y.

† *Transactions*, Am. Soc. C. E., Vol. LXX (1910), p. 367.

the piston; in which case, friction should be negligible under the author's theory. When a piston rests in the sand, or is only slightly depressed into it, the reaction of the pressure from the piston to the sand voids under it tends to depress the sand further and the action is wedge-like around and under its edges, gradually depressing the sand away from the piston until it has established an area sufficient to lift it. Proper contact may be established in many ways, but those most nearly approximating conditions of practice are: Plunging the piston to a sufficient depth and pressing it firmly into the sand; placing a layer of cement mortar between the piston bottom and the sand; or placing a layer of stiff clay, so that in the latter two cases the action of the water will be through the voids of the sand or gravel against the mortar or clay, raising the latter and, consequently, raising the piston. Careful distinction should be made between structures resting on soil and those resting partly on piles or caissons. In the latter cases the soil may tend to settle away from the structure and leave the area not supported exposed to the full pressure over the remaining area. This accounts for the fact that gauges

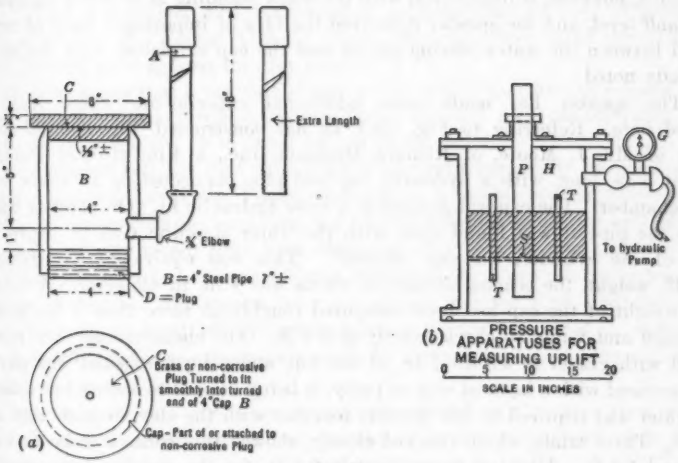

FIG. 7.

through submerged and buried structures may register full pressure, even if there may not be full area pressure, on the bottom, top, or sides of the structure. Water under pressure must eventually open up a lead if openings or outlets are caused to exist, even if the adjoining areas may be excluded from pressure by contacts extending beyond the sphere of influence. Where the structure rests on soil, however, any settlement of the soil results in a settlement of the structure, so that the ratio of uplift area is not changed.

Nevertheless, whether the structure rests on caissons, piles, rock, gravel, or soft ground, it must either be floating or supported. Where the supporting areas are of sand, gravel, or other soil, there must be areas of contact between the bottom of the structure and the soil, extending beyond the influence of

uplift, and, while the minimum sections of these areas of contact may be in various planes, the cross-section through the minimum areas represents in sum those excluded from uplift or buoyant pressure. This cannot be other than a definite fact. The author states that even if there may be areas of soil in contact with the piston or bottom of the structure, other areas of soil are pressed against these, tending to give full pressure over the whole area. This is not in accordance with actual conditions; that is, a structure, together with the soil beneath it, is either floating or it is supported; both conditions cannot be present at the same time.

It does not appear to the speaker that the question in this case, as to whether or not the pressure through soil is static or dynamic, is as important as the question whether or not the water pressure exerts itself against or through compact masses of soil.

It is obvious that if an absolute contact is made between the soil and the hydraulic cap (in the experiment referred to), the problem of relative uplift can be solved in the laboratory as well as in the field.

This, however, is impractical with the water standing at or above the gravel or sand level, and the speaker conceived the idea of imposing a layer of moist sand between the water-bearing gravel and the cap or piston, with the result already noted.

The speaker has made some additional experiments which may be noted here. Referring to Fig. 7(*a*), he has constructed, through the courtesy of Mr. J. Moore, of Richard Dudgeon, Inc., a 4-in. circular chamber about 5 in. long, with a hydraulic cap and pipe connected by an elbow with the chamber. The cap was ground to a loose hydraulic fit. On pouring water into the pipe it was found that, with the water standing 0.55 ft. above the top of the cylinder, the cap "floated". This was equivalent to lifting a 2.8 lb. weight, the bearing surface of which was 4 in. in diameter. Although the weight of the cap had been computed roughly at more than 3 lb., it was weighed and found to check exactly at 2.8 lb. The chamber was then partly filled with gravel to within $\frac{3}{4}$ in. of the top, and a layer of sand was put in and covered with a layer of clay or putty, it being desired to show what column of water was required to lift the cap, together with the clay, or both clay and sand. Three trials, which checked closely, showed this column to be between 1.1 and 1.2 ft. Allowing approximately 0.1 ft. for the weight of the sand, a column of 1.2 ft. would be exactly double the clear water column, showing 50% reduction of area due to the gravel.

In some of the later experiments with the apparatus shown in Fig. 7(*a*), there was 4 in. of sand below the cap. It would require a water column of 6 in. approximately to lift this, and about 6 in. more to lift the cap, that is, 1 ft. in all. It is not believed that friction need be considered in so small a layer of soil, with the inside faces greased, and it is thus seen that, if the water stood at 8 in. above the top of the chamber, plus the 4 in. below, this 1-ft. head should lift the sand and cap, or that a 6-in. head above the chamber should lift the cap alone, from clear water.

As a minimum of 1 ft. 8 in. was required to do this, it would seem to indicate a reduction of the pressure area of 70% on the cap alone, or 50% on the

cap and sand; that is, if the cap alone had lifted from the sand, it would appear that the pressure acted through 30% of the voids of the sand, or through 50% of the gravel voids in lifting the sand cap—which is almost certainly what happened.

Since these experiments were made, the speaker's assistant, J. C. Fisher, Jun. Am. Soc. C. E., has made several additional experiments. His findings are as follows: When the water-bearing gravel was placed within 1 in. of the top of the chamber and ½ in. of moist sand was placed over it, covered to the top by a clay cap, with the inside of the chamber greased to prevent friction and leakage, this clay cap was lifted (apparently) by a column of water 0.165 ft. above its bottom plane. The column required to lift from clear water was approximately ¾ in., so that 1⅛ in. would show 60% reduction of area pressure, or 40% effective area pressure. This experiment was repeatedly made with approximately similar results. If, as may have been the case, the sand lifted from the gravel, then the column of water, acting ½ in. lower, would have been approximately 0.20 ft., or 2.4 in., of which 1½ in. was required to lift sand and clay. This would show 40% reduction of pressure area, or 50% of pressure area effective. Mr. Fisher thinks, however, that the water acted through the thin layer of sand against the clay cap.

He also found that a can forced into a thin bed of mortar and pressed into sand to insure contact, would not rise (after setting) until its buoyancy was approximately doubled by drawing off the inside water.

The speaker believes that this latter experiment can easily be made on a large scale, and that if Mr. Parsons had gotten a mortar contact between the bottom of his can and the sand, and had allowed time for setting up and adjustment, his results would have been different. He believes also that the best way to make the uplift experiment on a large scale is to use a large piston in a hydraulic chamber and plunge the piston deeply into the sand, giving it time for settlement and adjustment before putting on pressure; that is, repeating the hydraulic chamber experiments made by the speaker* with a much larger piston and apparatus.

In each case, care was taken to get contact and, at the same time, to see that the cap or piston was as free to turn as in the case of the clear water trial.

It is probable, however, that full contact cannot be established in small areas such as this; but this experiment is believed to prove definitely that the uplift area is greatly diminished by the presence of sand, gravel, or soil of any kind.

The speaker is now practically convinced (*a*) that the area of uplift pressure on a submerged structure, buried or partly buried in soil, is reduced below the percentage of voids rather than equalling it, or tending toward 100% of the whole area; (*b*) that the pressure of water is against a mass of soil rather than through it, unless leads, orifices, or artificial voids occur; and then (*c*), unless such leads or artificial voids are made to exist, that the flow of water through soil is rather by seepage than by pressure head and, although this

* *Transactions*, Am. Soc. C. E., Vol. LXX (1910), p. 364.

head influences the flow, the influence is incidental rather than direct, and in proportion to the void characteristics of the soil.

Daugherty states:*

"Thus, in the case of a ship, for example, sunk in the mud at the bottom of a body of water, the pull, T, necessary to raise the ship is not only the weight of the ship, but also the entire volume of water on top of it."

This is probably true of all structures buried or partly buried in submerged soils which do not contain a large percentage of voids natural or artificial.

The speaker believes that pressure is rapidly dissipated when it has no outlet, just as it has been found impossible to force grout or pea gravel under pressure into natural voids; but when it has an outlet, grout soon opens up a lead and can be forced into artificial voids long distances away from the pump.

Here it may be interpolated that rust, too, will fill artificial voids rapidly, but when these are filled it will cease to function, except as a protective coating for the remaining steel or iron.

Returning to the matter of pressure through voids, the speaker, through his assistants, continued the experiments with the apparatus shown in Fig. 7(*a*) and found that when gravel was placed in the bottom of the chamber and sand to a depth of 4 in. was pressed down compactly above it, with a contact cap of grease between the sand and the piston cap, the sand was forced out of the chamber under a column equal in head to from 1.8 to 2.1 ft. This finding showed two things definitely: It took from 75 to 100% more head of water acting through gravel to raise the sand column from a gravel contact than was theoretically required to lift its own weight, together with that of the cap. That is, the weight of the cap and sand together was 2.6 + 2.8 = 5.4 lb., which, distributed over 12.56 in. of area, equalled 0.43 lb. per sq. in., or approximately a column of water of 1 ft., which would indicate a contact of from 40 to 50% between the sand and gravel. It further showed that the line of least resistance was not through the voids to lift the lighter cap which would raise in clear water at 6½ in. of column, but rather against the heavy body of sand requiring a column of from 1.8 to more than 2 ft. This, and a previous experiment,† proves definitely that where there are no artificial voids, uplift pressure is greatly diminished or absent on partly buried submerged structures.

The history and record of such structures are full of such evidence. Among typical examples may be cited: (*a*) A structure concreted to solid rock in which there are no fissures and, consequently, no uplift; (*b*) dredges flooded and sunk which do not rise when pumped out and have to be "hydraulically mined" to raise them; (*c*) hulks half buried in sand which cannot be raised through buoyancy alone; (*d*) tunnels and structures which do not rise after the soil is stabilized around them, although difficulties are sometimes experienced in holding them down during the exigencies of construction; and numberless others. This is definite evidence that theory and

* "Hydraulics," p. 33.

† A photograph of the sand column lifted in a similar experiment made by the speaker is shown in *Transactions*, Am. Soc. C. E., Vol. LXX (1910), p. 364, Fig. 22.

practice must here be in accord. Sometimes the instances cited are noted as due to suction, but there can, of course, be no suction unless the pressure is almost or entirely excluded from the otherwise buoyant area.

It is generally known that the Holland Tunnel rose more than 12 in. due to the hydraulic envelope caused during construction by the agitation into a soupy condition of the surrounding soil, and that it had to be partly back-filled to prevent flotation; and yet it cannot be doubted that when this hydraulic envelope had been replaced by grout and the surrounding soil stabilized, there could no longer be any possibility of the tunnel rising.

Light back-fill, or friction grip, even if it may be more considerable than found by the author, will not hold down a structure which has a water-jacket, or is under what may be called full buoyant pressure. The speaker agrees with the author that it is always safest to design, where practicable, against full pressure area, particularly in structures subject to heavy vibration, shallow submergence, or shallow cover. This is equivalent, however, to saying that steel structure designs should have a factor of safety; but it does not militate against the theory that there cannot be pressure and contact in the same area. The speaker wishes to thank F. L. Cranford and C. H. Locher, Members, Am. Soc. C. E., and their staff for assistance in making the experiments noted.

Eugene E. Halmos,* M. Am. Soc. C. E.—The speaker had the privilege to be in constant touch with the work done by the author in devising and making the tests and in the interpretation of the results. He believes that the method of approaching the problem and the manner of conducting the tests will be found to be above criticism and that the author's conclusions will meet with the approval of the profession.

What Mr. Parsons did not state but of which the speaker knows, is the large amount of labor and the considerable time the author has devoted to these tests and the substantial sums of money which he has expended in order to find the answer to a question the solution of which he considered of commensurate importance for the benefit of the Engineering Profession. Moreover, there was the agony of suspense lasting for days and often for weeks at a time when, due obviously to errors in technique somewhere, results contrary to reasonable expectation were recorded. These errors could not be easily detected on account of the complexity of the elements which, by the nature of the problem itself, go to make up the results of the tests. The whole apparatus and every step of the experiment had to be re-examined with painstaking care many times before all sources of error were eliminated.

Most of the experiments were conducted at Stevens Institute and at Rensselaer Polytechnic Institute. It was found that the engineering colleges, perhaps with very few exceptions, are not properly equipped to make tests of a variety of practical problems in their hydraulic laboratories. In the case under discussion, the efforts and the money of a private individual had to be utilized in the solution of a problem which is of interest to all engineers. The speaker believes that this is another instance that indicates the

* Chf. Engr., Parklap Constr. Corporation, New York, N. Y.

necessity of installing modern hydraulic laboratories in American institutions of learning.

As to the paper itself, the speaker wishes to comment on one point only which has not been emphasized by the author, probably because it is somewhat of a by-product.

In making the tests to determine the friction on the sides of the cylinders, the author has found a formula which shows that the average friction per unit of surface is proportional to the 0.4 power of the depth to which the cylinders were embedded. The total friction per linear unit of perimeter, therefore, would be proportional to the 1.4 power of the depth. It is an accepted principle in mechanics that within the limits of the pressures here considered, the friction is proportional to the pressure exerted against the surface. Therefore, the pressure of the sand around the cylinder has been shown to be proportional to about the 1.4 power of the depth, contrary to the formulas used in the design of retaining walls, dock walls, etc., which assume that the pressure of both dry and saturated earth-fill is proportional to the square of the height of the backing. In other words, the author's formula gives a much smaller pressure than that of Rankine. It seems that the difference, which is very substantial, is due to cohesional forces acting between the particles of sand used for the tests. These forces are neglected in the formulas derived to determine the pressure on retaining walls. On the other hand, when sinking caissons in saturated ground to substantial depths, practical constructors assume uniform friction along the outer surface of the caisson, the value of which they find to be independent of the depth, in other words, proportional to the zero power of the depth. The author's formula, therefore, gives values greatly in excess of the friction experienced in such cases.

In view of the foregoing, the speaker believes that it is well to emphasize the fact that the formula given by the author, while correct within the limits of his experiments and for the material utilized in his tests, should not be used for the purpose of designing retaining walls, caissons, or similar structures.

T. R. Lawson,* M. Am. Soc. C. E.—Emphasis should be placed on the care taken by the author to eliminate all possible variables and to secure conditions which will approximate those of actual practice. The 12-in. plunger used in the apparatus at Rensselaer Polytechnic Institute was a hollow cylinder filled with concrete, thereby giving a contact between a concrete base and the sand, thus simulating the actual conditions under the base of a concrete dam.

In order to prevent any trouble from settlement, no readings were taken until after the full load had been applied through the concrete weights, and a sufficient interval of time had been allowed between loading and readings until all possibility of settlement had ceased. This time interval extended from 24 to 48 hours.

When these experiments were first begun, some difficulty was experienced from the expansion of the large cylinder from internal pressure. The difficulty

* Head, Dept. of Civ. Eng., Rensselaer Polytechnic Inst., Troy, N. Y.

was made apparent by observing that, under pressure, the piston settled into the sand instead of rising. The difficulty was overcome by heavily reinforcing the outside container with steel bands. No trouble was experienced after this up to pressures of 30 lb. per sq. in.

The series of experiments were repeated a number of times under different loads on the piston, and in each instance the upward motion of the piston began at a load approximately equal to the friction of the sand on the side of the piston plus the product of the area of the piston and the pressure per square inch indicated by the pressure gauge.

This apparatus is still available for further tests, and should it appear desirable as a result of the discussion of this paper, other experiments will be attempted.

If the upward pressure on a pervious soil is 100%, as indicated by the experiments, considerable attention must be paid to cut-off walls not only on the heel to take care of the seepage under the base, but also at the toe where the full static pressure from the tail-bay will act on the base.

The results from these experiments bring forcibly to mind another very important research on which there is but little reliable data; that is, the thrust due to a saturated fill on the back of a retaining wall. While retaining walls are designed with a fairly accurate knowledge as to the thrust due to a dry fill, very little information is available to the engineer as to the effect of saturating this fill with water. Information of this character would be particularly useful in the design of harbor and dock walls where the effect of tide on the back of the wall is an important factor.

J. Vipond Davies,* M. Am. Soc. C. E.—The speaker notes with interest that engineering investigators differ on the matter of hydrostatic uplift in soil. When he first came in touch with the question of the construction of tunnels under the Hudson River, he was told that there were two schools of engineering thought on the subject. One was that any tunnel built under the Hudson must of necessity float up to the surface by uplift, and then float down the river. Members of the other school insisted that it was absolutely certain that any tunnel built under the river would sink in the comparatively soft silt and that would be the end of it.

So far as the speaker knows, every tunnel built under the Hudson River has been weighted, at some time or other during its construction period, to keep it from lifting. The Hudson and Manhattan Tunnels were all weighted by the excavated silt. This was left on the floor of the tunnel until such time as the superincumbent load or flow of the soil, comprising the river silt, squeezed in on the tunnel lining and gave weight enough to resist the buoyancy of the tunnel itself. Subsequently, the tendency was toward a downward settlement notwithstanding that the tunnels are much less in weight than the displaced soil.

It is a fact that any dredging in the bed of the river causes uplift in the tunnel below. There is no doubt about that; it is a perfectly measurable quantity. During the recent dredging of the 2 000-ft. channel in the Hudson

* Cons. Engr.; Pres., Jacobs & Davies, Inc., New York, N. Y.

River to a 40-ft. depth plane, there was a very definite uplift in all the tunnels under the river, caused by the removal of that superincumbent load.

Many engineers are familiar with the fact that all tunnels in Hudson River silt pulsate with the daily rise and fall of the tide, sinking as the tide rises and the pressure on the silt bed increases, and lifting as the tide falls and the pressure on the bed of the river reduces.

It is equally certain that any tunnel under the Hudson can be lifted bodily by pumping stiff puddled clay, or some material like clay, through the invert. The tunnels normally remain stable and stationary under the river; but there is no doubt that a tunnel can be lifted if that were desired for any reason. It can be raised and uplifted by high-pressure pumping of a solid material.

As to the distribution of the pressures over areas, the speaker has never had the assurance to do otherwise than consider 100% of the hydrostatic uplift pressure uniformly distributed over the entire area of structures that were likely to be in contact with water.

As an example, in the Hoboken Terminal of the Hudson Tunnel System, a station structure was designed as a box with complete arched inverts, partly in silt and partly in sand. In that case the entire structure was designed to give 100% loading against hydrostatic uplift. There were parts in which the weight of the structure itself would have been less than the aggregate load necessary; and in those sections the speaker had the space under the platforms filled with concrete to increase the loading against uplift. These localized areas were (*a*) at the east end of the station where the silt was very soft, being near the water-front; and (*b*) where the concourse floor above the main structure reduced the amount of back-fill forming part of the superincumbent load.

Any man would be quite brave who attempted to design structures of this character, without allowing fully for the entire hydrostatic uplift, uniformly distributed over the whole area.

Lazarus White,* M. Am. Soc. C. E.—As a result of experiments performed in 1910,† the speaker was rather inclined toward the belief that there was not 100% hydrostatic uplift on structures built in pervious soils. Mr. Parsons' tests were made with the expectation of rather confirming the same views and when the results were found to be inconsistent with his ideas they were studied very carefully. The speaker has been unable to find flaws in these later experiments.

The question arises, How can one reconcile the older tests with those made by the author? They were both honestly made and they are radically different in their conclusions. The speaker believes that the latter were conducted under truly static conditions and the former under dynamic conditions. In the older experiments there was a flow of water in the sand and a great loss of pressure.

As Spencer has said "there is some truth left in every error". However, because there is an uplift on 100% of the area it does not follow that there

* Pres., Spencer, White & Prentis, Inc., New York, N. Y.

† *Transactions*, Am. Soc. C. E., Vol. LXX (December, 1910), p. 352.

is 100% pressure, except in the case of a truly static condition, which does not usually exist in construction work. It is, therefore, necessary to multiply a 100% area by a pressure which is less than the full hydrostatic pressure.

Suppose, for instance, that there is 100% pressure on a concrete floor in a coffer-dam. Through leakage there is a great reduction of head, so that the total uplift is much less than the maximum which can be computed. For that reason those who have constructed coffer-dams incline to the belief that uplift does not act on the full area. The true explanation is that it is acting on the full area, but not with an intensity corresponding to 100% of the difference of head between the inside and outside water levels.

It is well known that 20 ft. of head can be supported by 1 ft. of concrete, provided the foundation material is well under-drained and the leakage is pumped away. Of the concrete, 1 ft. will suffice because allowing that flow gives a tremendous loss of head between inside and outside. In quite a number of cases the need of allowing for 100% uplift has been obviated by permanent under-drains and pumps. This is a natural condition as much as anything else of which the engineer may take advantage if he sees economy in it.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—It seems to the speaker that when subsoil materials are taken into a laboratory they are no longer subsoil materials. They can never again be put into a condition duplicating that in which Nature had placed them or giving similar test results. For instance, in each and every case there is a difference in the arrangement of the more or less natural cementing material, and there is no way of telling how many thousands of pounds of pressure Nature may have exerted during the placing, or shortly thereafter.

In Western New York State the speaker has seen hardpan, or glacial drift, that in some former age had been placed under an unknown depth of water, at an elevation of more than 1 200 ft. above sea level. One might almost as well pulverize concrete and then expect it to act in a laboratory as if it still were concrete.

An accident in one of the Hudson River tunnels would be appalling. However, the fact remains that all these tunnels are lighter than water and are subject to slight daily variations in level, rising and falling inversely as the tide; although, of course, the theoretical hydrostatic uplift should depend entirely on the difference in elevation between the top and bottom of the tunnel and not on the total depth of the water.

What probably happens is that the effect of the tide re-acts more quickly on the roof than on the bottom of the tunnel, allowing the water to be squeezed away from the base, so that when the tide rises the tunnel is forced down into the silt, reversing the process as the tide falls. While no one can prove that the tunnels will ever be wrecked, no one can prove that they will not. It would be worse than foolish to make this statement—except as a warning against constructing future Hudson River tunnels on the same basis as the present tubes. Beyond a peradventure of a doubt, perfectly safe tunnels can be built, and for much less money, in the Hudson River.

* Cons. Engr., New York, N. Y.

A circular caisson, carried to hardpan in Lower New York, with concrete 4 ft. above the cutting-edge in the working chamber, was lifted by the water pressure and had to be removed, at a considerable loss. On another occasion a large rectangular caisson resting on rock—at a depth of 19 ft. of water in the Susquehanna River, with the 6-ft. working chamber filled with concrete and concrete also placed above the deck—was lifted by an unusually high tide and had to be towed away and destroyed. In that case if there had been 1 ft. more of concrete on the deck, the mass would have been heavier than the water displaced. Each and every foundation is apt to have certain conditions not found elsewhere and all the laboratory tests in the world would not eliminate the necessity of using one's best judgment. It would appear, therefore, that the only safe rule for uplift is to use 100% of the hydrostatic head.

DANIEL E. MORAN,* M. AM. SOC. C. E.—The speaker would like to emphasize two points. When water is moving through sand there are static conditions and dynamometric conditions, and they must not be confused. Moreover, there is capillary action. If the base of a layer of fine sand is wet, the water will rise in the sand by capillary action. In laboratory experiments on sand there are radically different conditions than those found in a natural deposit.

The second point is that in making various tests in the laboratory it became very evident to the speaker that if he loaded sand in a cylinder, the forces transmitted from the loaded piston to the platen went partly through the sand and partly through the cylinder. He then substituted for the platen two pistons, one on the top and one on the bottom, with only a relatively small volume of sand in the cylinder.

When the speaker applied the load on the top piston and tried to measure it on the bottom piston, part of the load was being transmitted through the sand and part through the walls of the cylinder containing the sand. Therefore, he had to be very careful in reaching any conclusions.

The author's experiments were undoubtedly accurate and designed to secure accurate results. The only mystery to the speaker is that he did not get 100 per cent.

ALEXANDER V. GALLOGLY,† ASSOC. M. AM. SOC. C. E.—Some years ago the speaker was engaged in the construction of an earthen dam. The reservoir was formed by cutting off the top of a hill and depositing the excavated material around the edge to form an enclosure about ¼ mile wide and ½ mile long. The excavated material was ideal, consisting of about two-thirds sand and one-third clay and boulders.

The dam was built in 8-in. layers and rolled with a 10-ton grooved roller. No stones larger than 8 in. in thickness were included. The resulting material had nearly the nature of concrete. This part of the dam (which formed the inner portion) was called the "impervious embankment", and it proved to be quite impervious. It was about 180 ft. thick at the base, 30 ft. at the

* (Moran, Maurice & Proctor), New York, N. Y.
† Care, Carpenter & Duffy, Mamaroneck, N. Y.

top, and it had a maximum height of 42 ft. Excavated material, including boulders, was placed around the outside in 2-ft. layers without rolling.

About four years after the reservoir had been filled with water, the work of cutting through the dam for the purpose of tapping the lake was undertaken. The material was found to be dry and acted like concrete, there being no curve of leakage, such as that described in textbooks. This condition continued until the original ground surface was reached and passed. When the bottom of the trench had been excavated to a point about 1 ft. below the original surface, a small pool of water about 2 ft. in diameter appeared. This was bailed out, and the material was excavated with a shovel until the water began coming through the fine sand lenses in a manner similar to that observed in the excavations outside the reservoir. The level at which this water appeared was 21.5 ft. below the surface of the water in the lake. As the excavation proceeded, this condition gradually developed over the entire area of the bottom and sides of the trench below the level of the original surface under the dam.

As the trench was being excavated and just before the water appeared, a peculiar hissing sound was heard. This was found to be caused by air which was being forced out ahead of the water. If upward pressure was present to any extent, why did it not push up the soil in the bottom of the trench? Did not the presence of the trapped air cause an additional weight to act against the hydrostatic head? During the construction of the gallery, the seepage into the trench amounted to only 300 gal. in 24 hours. This was removed by bailing.

The speaker believes that the conditions surrounding a foundation placed in water-bearing material, can be compared to a U-tube closed at one end, in which the water in the open leg is balanced by the foundation itself, together with that portion of the material under the foundation in which air is trapped. It is known that all water contains small air-bubbles which tend to collect under a flat surface.

In the experiments described by the author, the apparatus seems to illustrate the conditions surrounding a river caisson only. In such a case the upward pressure would equal the full hydrostatic head plus the upward pressure caused by the weight of the semi-liquid material penetrated by the caisson. The experiments do not seem to cover all the cases of foundations constructed in pervious materials below ground-water level.

ALLEN HAZEN,* M. AM. SOC. C. E. (by letter).—This paper presents a careful experimental investigation of one of the fundamental conditions of dam construction. It is no less valuable because it affords a complete confirmation of ideas long held by many members of the Society. It should lead to the discard of all less complete allowances.

The effect of uplift from water pressure is not confined to material below the base of masonry dams. It may also exist in any part of the structure where the masonry is pervious unless adequate interior drainage is provided. In cold climates frost may cause a temporary sealing of outlets at the lower

* Cons. Engr. (Hazen, Everett & Pirnie), New York, N. Y.

face of the masonry and this, in turn, may result in development of full pressure in the full thickness of a dam.

The effect of uplift is to reduce the stability and strength of the dam. It tends first, to overturn it, and, second, to take off weight and reduce the friction and resistance to sliding.

The resistance of natural materials to sliding is not known with any satisfactory degree of definiteness. There is reason to think that with some softer rocks, such resistance is not in proportion to height and weight; and for high structures it may be much less than has sometimes been assumed. The Panama Canal slides furnish an illustration, from an entirely different field, of the low coefficient of friction of soft rocks at high pressures. Experience with harder materials and lower unit stresses may not be a safe guide for soft rock. Masonry dams have failed by sliding more frequently than by overturning.

Looking at the matter broadly, the problem of dam design needs to be managed with a strong hand. Dams and reservoirs must play an important part in the future development of this country. They must be made strong enough and safe enough so that the people who live near them as well as those who build them and benefit by them will be assured of their safety.

In the past, some dams have been built of ample proportions strong enough for all contingencies. There are many dams in the United States that would stand if filled with a liquid twice as heavy as water. These dams are safe. Even earthquakes do not seriously shake or touch them. On the other hand, there are many dams that would not stand such a test. Too many dams have failed to reach the point of actual stability.

Engineers speak of a factor of safety, but the term needs to be defined more closely. In a steel structure the factor of safety may mean the ratio between the stresses at the assumed loading and the ultimate strength of the steel, but no one thinks that a load corresponding to the ultimate stress could be safely applied. Engineers speak of a factor of safety of 4, but really they believe that something like double the assumed load would probably be held.

It may be somewhat the same with dams. When a designer states that a factor of safety of 2 was used—based no doubt on some rather arbitrary assumptions—it may mean that the real factor of safety is much less than 2. It may turn out that it is little, if any, more than 1. It certainly does not mean that a liquid twice as heavy as water could be safely held.

It may be earnestly hoped that some one will set up an authoritative policy of dam design that will lead to the construction of dams that would be stable and safe if subjected to pressure from a liquid much heavier than water. If this could be done, it would tend to restore confidence in dam design and construction; and even if some of the works to be presently constructed, should cost somewhat more than they otherwise would, some such policy is needed and will tend to the ultimate benefit of all concerned.

CHARLES TERZAGHI,* M. AM. SOC. C. E. (by letter).—The hydrostatic uplift acting through sands on the bottoms of seals, cellar floors, and other

* Prof., Foundation Eng., Mass. Inst. Tech., Cambridge, Mass.

structures, is so simple and clear an hydraulic phenomenon that it is far more difficult to account for the attitude of engineers toward the uplift than it is to compute its intensity.

The theoretical aspects of hydrostatic uplift acting through sands were convincingly presented in 1912 by A. Franzius,* and it is almost inconceivable that the opponents of Mr. Franzius† could fail to realize the weight of his arguments. Gaede, in 1917,‡ and Engesser, in 1919,§ computed the intensity of the uplift acting through sand, assuming that the area of contact between the individual sand grains is determined by the Hertz formula (area of contact between curved surfaces pressed against each other). The computation led to the conclusion that the hydrostatic uplift acting on a surface in contact with the sand should range between 97% and almost 100% of the hydrostatic uplift exerted by water, provided the modulus of elasticity of the sand grains ranges between 100 000 and 500 000 kg. per sq. cm., and that the pressure acting on the sand does not exceed 10 tons per sq. ft. The fraction of the area over which the hydrostatic uplift does not act should, according to theory, be independent of the size of the grains. These theoretical results agreed with the results of the experiments performed in 1886 by Brennecke,‖ in 1887, by Forchheimer,¶ in 1916, by Schaper,** and in 1917, by Busemann.†† They also are in very good agreement with the results of the tests performed in 1926 by Mr. Tsin Hsiao, at the Massachusetts Institute of Technology, under the supervision of the writer, and in moderately satisfactory agreement with those now published by the author.

All the tests, including those of Mr. Parsons, were based on the same principle, namely, measuring the hydrostatic uplift at the instant when the forces acting on the submerged body balanced those acting downward. Because of this fact, Busemann claimed in 1917 that the test results thus obtained do not represent the hydrostatic uplift which acts on the base of a pier before an actual uplifting occurs. However, his arguments can be considered conclusively invalidated by the results of Gaede and the computations of Engesser.

As a matter of fact, the data and assumptions on which the theory is based, are so plain and the range of possible error associated with theory is so small (if compared with the importance of the errors which are apt to be connected with laboratory tests in that particular field), that in all cases where the test results are in conspicuous contradiction with theory, investigators should first direct their attention toward finding errors in the testing method. It should be kept in mind that a real contradiction between test results and theory—that is, a contradiction which cannot be accounted for by errors of observation—would mean that there is an error in the fundamental principles of hydrostatics, and there are not many sciences which rest on so stable a foundation.

* *Zentralblatt der Bauverwaltung*, 1912, p. 583; 1913, p. 617.
† *Loc. cit.*, 1912, pp. 522 and 617; and 1913.
‡ *Loc. cit.*, 1917, p. 501.

¶ *Zentralblatt der Bauverwaltung*, 1887, p. 314.
** *Loc. cit.*, 1916, p. 514.
†† *Loc. cit.*, 1917, p. 205.

There is such a contradiction, for instance, between the results of the Engesser theory and the conclusions reached by Mr. Parsons concerning the effect of the depth of the permeable stratum on the intensity of the hydrostatic uplift. According to theory, the thickness of the layer of sand between the base of this structure and the impermeable bottom below the sand should be without any effect on the hydrostatic uplift, provided it is at least equal to several times the diameter of a sand grain. According to Mr. Parsons, the uplift is reduced when the depth of the pervious soil is shallow. The writer believes that the apparent influence of the thickness of the layer was due to the air content of the sand beneath the base of the can. Undoubtedly, Mr. Parsons has done his best to exclude this source of error, but every one who has had experience with sand experiments knows that it is almost impossible to exclude the air entirely. Thus, for instance, when saturating a sand by allowing the water to enter through a permeable base, thus giving the air a chance to escape freely in an upward direction, it was found by weighing and by computation that, within the saturated space, more than 30% of the voids remained filled with air and the degree of saturation increased very slowly as time passed. If it has no possibility of escaping in an upward direction because of the presence of the bottom of the can, it is hardly to be expected that the air will ever disappear completely. One of the possible effects of the air content on the hydrostatic uplift, if measured by high-head tests, can be explained by Fig. 8. The dotted line indicates the size of an air bubble at the outset of the test. As soon as the water pressure goes up, the bubble becomes smaller and this, in turn, requires the water to flow toward the bubble. Then the head required to overcome the resistance against flow causes an apparent increase in the pressure required to lift the can, because the true resistance consists of both the weight of the can and the head required to direct the flow toward the shrinking bubbles.

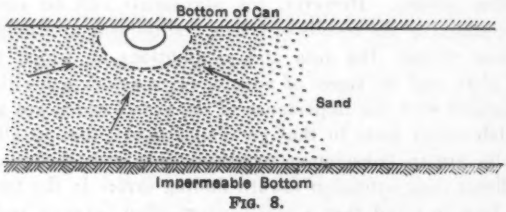

FIG. 8.

In the tests which were performed in 1926 by Mr. Tsin Hsiao, at the Massachusetts Institute of Technology, the diameter of the can was 5 in. In order to reduce the effect of any trace of air on the test results, the sand was placed on top of a layer of coarse sand (grain size, from 2 mm. to 6 mm.), so that the distance between the bottom of the can and the top of the coarse sand was nearly equal to 1 in. The results of the tests were as follows:

Grain size, in millimeters.....	2.00	1.41	0.84	0.35	0.10
Effective area, in percentage....	99.25	99.85	99.50	98.50	99.25

Considering these figures and the fact that the results obtained by Mr. Parsons are as far from being as consistent with each other as those obtained by

Brennecke in 1886 and by Forchheimer in 1887, the writer hesitates to accept his conclusions concerning the effect of the thickness of the layer on the intensity of the hydrostatic uplift. The writer is inclined to consider this effect exclusively as a result of various imperfections of the testing method. However, as a whole, Mr. Parsons' tests furnish figures that are at least of the same order of magnitude as those which ought to be obtained according to the laws of hydrostatics. Hence, it is hoped that they will serve their purpose of demonstrating to the skeptic members of the Engineering Profession (for the sixth time since 1886) that the uplift acting through sand really is very nearly 100% of the uplift acting through water, provided the underground consists of almost cohesionless sand. If Mr. Parsons succeeds in achieving this purpose, his efforts will certainly have been well worth while.

Far more difficult is the question concerning the hydrostatic uplift acting through fine silt and clay. For measuring the uplift in such materials, no satisfactory experimental method has been found thus far—Mr. Parsons' method included. The theory of Engesser also loses its validity because every soil grain is surrounded with a layer of adsorbed water which has, for all intents and purposes, the properties of a solid. No hydrostatic uplift can be transmitted through this layer, the thickness of which is certainly not more than $\frac{1}{20\,000}$ mm.; it may be thinner. For sand grains, the presence of this layer can be neglected. Hence, for such materials, Engesser's theory is accurate enough. However, for grains the size of very fine silt and clay particles, these layers are apt to become an item of increasing importance.

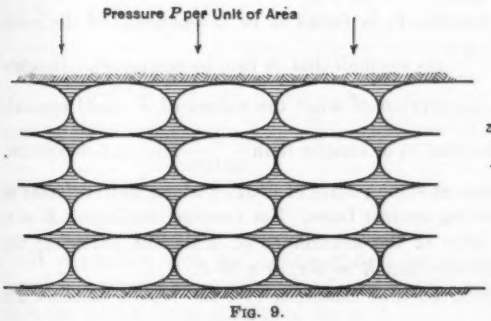

FIG. 9.

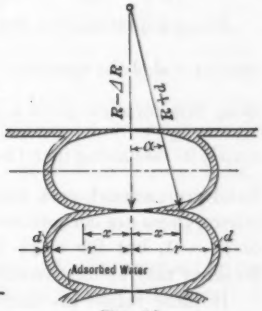

FIG. 10.

For evaluating the influence of the layers of adsorbed water on the hydrostatic uplift, assume that the bottom of a can is supported by lens-shaped grains arranged as shown in Fig. 9. The grains touch each other at their flat sides. Each grain is surrounded with a skin of adsorbed water with a thickness, d (Fig. 10). Since, at the bottom of the can, the area exposed to the uplift is smaller than that between the grains, the computation must be made for a section beneath the first row of grains (Fig. 10).

Let E = the modulus of elasticity of the grains;
r = the radius of their vertical projection;

n = the shape factor;
$R = n\,r$ = the radius of curvature of their surfaces of contact;
P = the pressure per point of contact;
p = the downward pressure exerted by the can on the sand (including hydrostatic uplift);
x = the radius of the area over which no hydrostatic uplift can act;
F = the proportion of a unit of area of the base upon which no hydrostatic uplift can act; and,
ΔR = the shortening of the radius of curvature, R, due to the pressure, p.

The number of points of contact per unit of area of the base is $\frac{1}{4r^2}$. Since the angle, α, is very small, the radius, x, is almost equal to,

$$2\,R\,(d + \Delta R) = 2\,n\,r\,(d + \Delta R)$$

For R, the formulas of Hertz give the term:

$$\Delta R = 0.77\,\sqrt[3]{\frac{P^2}{E^2\,R}} = 1.94\,r\,\sqrt[3]{\frac{p^2}{n\,E^2}}$$

The area over which the hydrostatic uplift cannot act is,

$$F = \frac{x^2}{4\,r^2} = \frac{1.57\,n}{r}\left(d + 1.94\,r\,\sqrt[3]{\frac{p^2}{n\,E^2}}\right) = 1.57\left(\frac{d\,n}{r} + 3.05\,\sqrt[3]{\frac{n^2\,p^2}{E^2}}\right)$$
$$= 1.57\,(C_1 + C_2) \qquad (1)$$

in which, $C_1 = \frac{d\,n}{r}$ and $C_2 = 3.05\,\sqrt[3]{\frac{n^2\,p^2}{E^2}}$.

From Equation (1) the value, F, is found to be independent of the grain size, provided the quantity, $\frac{d\,n}{r}$, is so small that it can be neglected. In addition, this formula gives a conception of what the values of F could approximately be, assuming that d is equal to or smaller than $\frac{1}{20\,000}$ mm. = 0.000005 cm. Sand grains touch each other at some points of contact along flat surfaces; at others, there are corners resting against faces. For average conditions, $R = r$, or $n = 1$, but for clays (due to the abundance of scale-like particles) the designer may assume tentatively that $R = 5\,r$, or $n = 5$.

If these values are introduced into Equation (1), the results obtained are as shown in Table 8.

The figures assembled in Table 8 (A) show that there is no possibility of accounting for an effect of the presence of sand or gravel on the hydrostatic uplift in excess of about 1%, provided the laws of hydrostatics are valid. The differences between 0.99 and Mr. Parsons' figures can safely be considered a measure for the efficiency of his testing arrangement.

In connection with the figures quoted in Table 8 (B) it should be remembered that the films of adsorbed water which exclude the transmission of hydrostatic uplift, also produce an adhesive bond between the particles. In other words, the greater the pressure-reducing effect of the films, the greater should

be the cohesion of the material. This conclusion agrees with the empirical fact that a microscopic sand ($n = 1$, with small values of F) has very little cohesion if compared with a clay ($n = 5$, with large values of F). Hence, the greater its cohesion, the greater should be the pressure-relieving effect of the presence of the substratum on the hydrostatic uplift. Absence of cohesion is a safe indication for almost 100% uplift.

TABLE 8.

In connection with the sealing of foundation pits, prior to unwatering the sealed space, there is still another factor which requires serious consideration. It is the relative permeability of the seal.

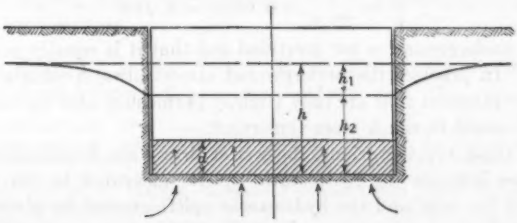

Fig. 11.

Fig. 11 represents a cross-section through a round or a square foundation pit surrounded by a water-tight enclosure and sealed by a somewhat permeable bottom slab with a thickness, d.

Let F = the area of the bottom of the pit;
k_1 = the coefficient of permeability of the seal;
k_2 = the coefficient of permeability of the underground;
h = the hydrostatic head which would act on a perfectly impermeable seal; and,
h_1 = the loss of head due to percolation through the seal.

According to the law of Darcy the quantity of water, Q, which percolates through the seal is equal to,

$$Q = F\, k_1 \frac{h_2}{d}$$

On the other hand, the loss of head, h_1, due to the quantity, Q, flowing through the underground toward the seal is (according to Forchheimer) approximately equal to,

$$h_1 = \frac{Q}{4\, k_2 \sqrt{\frac{F}{\pi}}}$$

Since $h_1 + h_2 = h$,

$$F\, k_1 \frac{h - h_1}{d} = 4\, k_2\, h_1 \sqrt{\frac{F}{\pi}}$$

The relative loss of head, $\frac{h_1}{h}$, that is, the apparent decrease of the hydrostatic uplift due to percolation, is therefore, equal to,

$$\frac{h_1}{h} = \frac{1}{2.26\, d \frac{k_2}{k_1} \frac{1}{\sqrt{F}} + 1}$$

Suppose that the seal is ten times less permeable than the underground; that is, $k_1 = 0.1\, k_2$; that F_1, the area of the pit, is 100 sq. m. (about 1 100 sq. ft.); and $d = 1$ m. (3.3 ft.). Under these conditions, the drop in head due to percolation would be,

$$\frac{h_1}{h} = \frac{1}{3.26} = 0.307 = 30.7\%$$

For $k_1 = 0.01\, k_2$,

$$\frac{h_1}{h} = \frac{1}{23.6} = 0.0425 = 4.25\%$$

provided the underground is not stratified and that it is equally permeable to a great depth. In practice the underground almost always contains layers and seams of silty material that are only slightly permeable, and the corresponding drop of head would be much more important.

From all these considerations, the writer draws the following conclusions: The difference between the hydrostatic uplifts measured by Mr. Parsons on the bottom of the cans and the hydrostatic uplift exerted by plain water may essentially be due to various imperfections of the testing method. The same

seems to be true for the apparent effect of the depth of the pervious soil on the intensity of the hydrostatic uplift. The apparent contradiction between theory, according to which practically 100% of the hydrostatic uplift should act through cohesionless materials, and engineering practice which shows that the uplift through such materials is sometimes very much smaller, may essentially be due to the pressure-relieving effect of seepage through the seal, seepage through joints in the enclosure, and the adhesion between the seal and the enclosure of the pit. On the other hand, if the underground has an appreciable cohesion, the low value of the uplift may be due, wholly or partly, to the physical character of the water enclosed in very narrow spaces.

Knowing by experience the great amount of time and painstaking labor required to perform an investigation of the type described by Mr. Parsons, the writer wishes to express his appreciation, and it is hoped that the paper will serve its purpose of clearing up the prevailing misconceptions concerning hydrostatic uplift.

FRANK S. BAILEY,* ASSOC. M. AM. SOC. C. E. (by letter).—The author's researches have provided a welcome addition to the fund of engineering knowledge. The experiments were repeated so many times and the results interpreted so carefully that there seems to be no question as to the reliability of the conclusions. They should bring to an end the uncertainties and differences of opinion which may have hitherto existed.

Now that Mr. Parsons' experiments have been published, it is to be expected that records of similar experiments or of measurements of uplift pressures on various structures will be added. By coincidence some records of this nature have appeared,† describing uplift measurements made by the U. S. Bureau of Reclamation on several dams. Two of these records—the Colorado River Dam, on the Grand Valley Project in Colorado, and the Percha Dam, on the Rio Grande Project in New Mexico—show upward pressures under dams which are founded on gravel.

Records of uplift pressures on the Pinhook Dam, at Maquoketa, Iowa, and on the Island Park Dam at Dayton, Ohio, show that both dams rest on sand and gravel foundations.‡ These experiments showed that, unless the bed of the stream or reservoir above the dam was sealed by silt, the uplift pressure on the bottom of the dams on sand and gravel foundations varied from nearly full head at the up-stream end to the tail-water head at the lower end, diminishing more or less closely according to the "line-of-creep" theory. Considering the results of the author's experiments and the corroborative evidence recently published, it appears that his conclusion as to full hydrostatic head in pervious soil is entirely justified.

CHARLES R. GOW,§ M. AM. SOC. C. E. (by letter).—While it may be true that the author's conclusions are not entirely new, they are so definitely

§ Pres., The Gow Co., Inc., Boston, Mass.

confirmatory of previous experience along similar lines that there is no longer any valid reason for the assumptions frequently made that ground-water pressures exert substantially less than 100% of the theoretical pressure due to their heads.

A question in this connection which may be entitled to consideration is that of the reduced pressure applied by a structure on the soil due to this hydrostatic uplift. A building with a water-tight basement situated below water level would apparently suffer a reduction in the amount of weight normally applied to the soil by the quantity of water displacement represented and, in many instances, this may be a considerable factor justifying somewhat higher load values than would ordinarily be used.

Likewise, it is to be noted that account is frequently taken of the weight of soil removed in the process of excavating a deep basement in determining the net increase in unit loading which the structure imposes on the supporting stratum. The usual practice has been to calculate the weight of material removed according to its weight in free air. If, however, the excavated material in its natural state is in whole or in part below the ground-water level, it may be assumed that the actual weight removed in the process of excavation is less than this amount due to its immersion in water. Of course, if hydrostatic uplift is assumed to reduce the weight of the structure this factor need not be considered since the two effects offset one another.

While the title of the paper refers especially to pervious soils, the author discusses briefly some of his experiments with clay instead of sand. As a matter of fact, it is doubtful if there are in Nature any actually impervious soils. Experiments which have been made seem to indicate that even the densest clays will permit some passage of water, although at an extremely low velocity rate. Under these circumstances there would seem to be no good reason for differentiating between the so-called pervious and impervious soils with respect to the ultimate effect of hydrostatic uplift. There are, however, certain aspects of the problem as it relates to the so-called impervious soils which are entitled to mention.

When a basement is constructed within an excavation made in a clay soil, there is danger that surface water may be admitted into the porous back-fill around the outside of the basement walls which may upon occasions supply temporarily a pressure at the level of the under side of the basement floor-slab equal to that of a water-head of the full depth of excavation. Usually, it is assumed that a more or less water-tight connection is made between the floor masonry and the supposedly impervious soil upon which it rests and to a certain extent this is probably true. One can never be definitely sure, however, that water pressure from such a source as that referred to will not find its way into the seam between the masonry and earth and thereby exert its full uplifting influence.

An instance of this sort occurred a few years ago in connection with a mercantile building in Boston, Mass. The basement floor was laid directly on a soil of the type generally recognized as impervious in character. The space surrounding the basement wall was back-filled as is more or less customary with material of porous character consisting of waste plaster, bricks,

and the like, with the result that when a heavy rain occurred shortly after the completion of the building, the voids in this loose back-fill were completely filled with water up to the surface of the ground. A few days later the basement floor which had not been designed against uplift was forced upward over the greater part of its area as a consequence of the admission of water operating under this head.

On another occasion the clear-water basin of a large filtration plant in the vicinity of Boston was founded on a stiff blue clay which showed no observable evidence of water percolation through it. After the completion of the structure a heavy downfall of rain occurred leaving a number of deep pools of water in some of the unfilled trenches around the outside walls. No especial thought was given to the matter until a day or so later it was observed that the center portion of the structure was gradually rising and that the area affected was constantly extending in a lateral direction around the point of initial movement. Ultimately, an area 100 ft. or more in diameter was affected with a maximum rise at the center of 3 ft. Holes were then drilled through the floor of the basin allowing the water pressure to relieve itself by flowing into the interior of the structure. Thereupon the raised portion gradually settled back into its former position without any damage other than a few slight cracks in the concrete.

Upon investigation it was learned that during the preliminary stages of construction a shallow sump had been excavated at this particular location and lateral drains had been made in the clay to lead into this sump any water that might collect. Prior to placing the concrete floor the sump and open drains had been filled with gravel, thus furnishing a blind drain through which water was admitted from the pools pocketed behind the high walls of the basin, thus permitting its uplifting influence to exert itself.

According to eye-witnesses the upward motion of the structure was very slow and as it increased the affected area widened. This would seem to indicate that the water pressure first forced itself under a sufficient area adjacent to the sump to cause a very slight upward motion which, in turn, raised the adjacent floor-slab sufficiently to enlarge the area of pressure application and thereby the movement became progressive.

Whereas it is customary to design floor-slabs of sufficient strength to permit them to transmit the upward pressure to column and wall supports, it is sometimes found to be economical to anchor the slabs into the soil by means of piles or caissons.

About 1921 a 1 000 000-gal. crude-oil reservoir was constructed in South Boston immediately adjacent to the harbor and at a depth considerably below high-water level. As there was no earth covering over the roof of the tank it was absolutely essential to prevent flotation by establishing some form of anchorage. In this instance the underlying soil was clay and a series of concrete caissons were sunk to a considerable depth below sub-grade. They were belled out at their bases while vertical reinforcing rods were embedded for the full length of the caissons and bonded into the floor of the tank. In this manner the necessary resistance against uplift was provided. The same method has frequently been used by the writer to provided intermediate reac-

tions against uplift in floor spans of considerable extent so as to permit of a more economical type of floor-slab design.

The whole subject of hydrostatic uplift has been an extremely troublesome one for many years, and it is a source of gratification to the writer to have so authoritative an expression regarding its influence as that presented by the author.

E. L. CHANDLER,* M. AM. SOC. C. E. (by letter).—The large number of experiments conducted, the very considerable range in the magnitude of the tests, and the painstaking methods followed by the author in assembling the data for this paper, serve to render his conclusions authoritative in treating a subject that heretofore has brought forth much diversity of opinion. Proper allowance for upward pressure acting on a structure founded on pervious material is a feature of design that has been poorly understood, and the information set forth in this paper is most welcome.

The total pressure developed under any structure depends, of course, on two factors: First, the effective area over which the pressure acts; and, second, the intensity of pressure. As for the first, the author's experiments seem to prove that, for a pervious soil, the area subjected to pressure is so nearly 100% of the total area that it would be unwise to assume any lesser value.

The writer has been interested in experiments to determine values for the second factor, by means of apparatus installed in dams during construction. The best data obtained were in connection with the Pinhook Dam at Maquoketa, Iowa. An account of the work done there, with an analysis of the results, has already been given in a discussion by the writer,† and details will not be repeated here. However, it is believed that the subject matter of that discussion may properly be considered in connection with Mr. Parsons' paper.

From a study of those experiments, the writer concludes that, under a dam on a pervious foundation, uplift due to the full hydrostatic head developed should be assumed at the up-stream edge, and that uplift at the down-stream edge should be taken as equal to tail-water if the apron is submerged, or to zero in the absence of submergence. At any intermediate point the uplift should be determined in accordance with the "line of creep" theory, the pressure diminishing uniformly from the up-stream to the down-stream edge in proportion to the total distance between the two edges when measured along the line of contact between the under side of the structure and the underlying material. Such measurements should take into account all cut-off walls and should follow down the up-stream face of the cut-off and then upward along the down-stream side.

It would seem, therefore, that for structures of the type under consideration, the practice of assuming uplift equal to only a fraction of the full up-stream head, or of considering the upward pressure to act on only a part of the base area, is apt to lead to unstable designs. Although it is true that the pressure may not quite reach 100% of the head, and that the effective

* With Price Bros. Co., Dayton, Ohio.

† See his discussion of the paper by Julian Hinds, M. Am. Soc. C. E., entitled "Upward Pressures Under Dams: Experiments by the U. S. Bureau of Reclamation," in this volume of *Transactions*.

area for uplift may not be quite 100% of the total base area, it appears unsafe, in the light of information given, to proceed on any lesser assumptions. This would apply only in a modified form for structures on semi-pervious materials, whereas the question of pressures acting on structures on rock must be approached in a different manner.

MARTIN J. MCPIKE,* ASSOC. M. AM. SOC. C. E.—Previous to the construction of Dry Dock No. 4 at the U. S. Navy Yard, Brooklyn, N. Y. (1908-12), some difference of opinion was found regarding the amount of hydrostatic uplift which would have to be considered in the analysis of the dry-dock design. As the hydrostatic uplift, if considered, would be a factor of prime importance and an item of some monetary significance, the question of its amount was given quite extensive thought.

Frederick R. Harris, M. Am. Soc. C. E., was at the time in charge of this project, and his experience on structures in water-bearing soil had led him to the opinion that the full hydrostatic head would have to be considered.

In view of the varied opinions expressed at that time and in order to have something tangible on which to base the design of future structures of this type, Admiral Harris had designed and placed at several positions in the floor of this dock, pressure indicators, or, as they were called, dynamometers, of the type shown in Fig. 12.

These pressure indicators were of bronze and consisted of an extra heavy pipe, 4 in. in diameter and approximately 5 ft. 8 in. long, connected to castings at the upper and lower ends. The lower casting was bell-shaped and had a diaphragm of lead, 12 in. in diameter, weighing 5 lb. per sq. ft., attached to its bottom by a bolted ring. Bearing against the upper side of this diaphragm and capable of being backed away from the face thereof by a capstan screw extending to, and operated at, the extreme upper end of the dynamometer, was a platen plate with a vertical and horizontal movement that was limited by three lugs into which set-screws, threaded into the bottom casting proper, projected.

The top casting contained a stuffing-box or gland, to prevent leakage of the pressure-transferring fluid with which the dynamometer was filled, and formed a connection for the pressure-reading gauge and a pipe for filling the dynamometer.

When it was desired to obtain a reading on any particular one of the dynamometer gauges, the capstan screw was turned, thereby withdrawing the platen plate from the face of the diaphragm and permitting it to become operative. This, in turn, through the medium of the pressure-transferring liquid (in these particular dynamometers, a light-grade oil), indicated a pressure on the gauge.

As regards location in the completed structure, the dynamometers were cast in the concrete floor of the dry dock during its construction, the lead diaphragm being placed in line with the bottom line of the dock floor, the main body of the dynamometer projecting up through the floor, about 8 ft., with the top ending in a pocket just below the upper level of the finished concrete.

In order that the readings on the gauges at the top level of the floor would be truly representative of the pressures encountered at the diaphragm level, approximately 8 ft. below, it was necessary to adjust the gauges used in the final installation to take care of this difference in head; hence, a series of tests was run on the dynamometers to determine as accurately as possible the "instrument factor" of each, and what loss, if any, would have to be considered in the transmission of the pressure from this lower level to the upper level.

The tests consisted in applying a variable pressure on the bottom of the diaphragm by placing a plate (see Fig. 12) below it, into which was tapped a 1-in. pipe connected to a hand-operated booster pump at the other end. The diagram gives a general idea of the arrangement of pump, gauges, etc., for the tests.

A standard gauge was used in conjunction with a commercial gauge, one being located on the pump (Gauges Nos. 2 and 3), the other being located on the dynamometer (Gauge No. 1), and at every 5-lb. increment from 0 lb. to 30 lb. and every 5-lb. decrement from 30 lb. to 0 lb. indicated on the booster-pump gauge, an observation was taken on the dynamometer gauge.

Each test consisted of ten individual runs, the readings on the dynamometer gauge were recorded, and the averages of each test were used for the final graduation of the dynamometer gauges.

Both lead (5 lb. per sq. ft.) and copper (No. 27 B.w.g.) diaphragms were used in the tests, but lead diaphragms were selected for the completed structure, owing to the most consistent results being obtained therefrom in the tests.

A typical test run is indicated in Table 9. In order that the final results should be consistent under all conditions likely to be encountered in the field, a great deal of care was exercised in running the tests, the position of the gauges varying for the different tests and indicated in Fig. 12 and Table 10. The averages of all tests run, as well as the variation in readings in the dynamometer gauge under the different conditions of gauge location and diaphragm material, are also given in Table 10.

After the completion of the dry dock in 1912, observations were taken on these dynamometer gauges four times daily for a period of several months, and their readings, plotted in conjunction with tidal observations, indicated practically 100% hydrostatic uplift fluctuating with tidal changes.

After the dynamometers had served the purpose for which they were installed, the gauges were removed and the pockets filled with concrete. In 1918, two of the dynamometers were uncovered, and observations taken thereon were consistent with the results previously obtained. On June 15, 1928, the speaker again had the opportunity of testing the effectiveness of two of these dynamometers, and they indicated a pressure of exactly the same intensity as they did in 1918.

JACOB FELD,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper should settle, once and for all, the disputed question of the transmission of hydrostatic pressure through pervious soils. The contentions of some engineers

* Cons. Engr., New York, N. Y.

that the area of a wall covered by grains of soil was not affected by the pressure of the water surrounding such grains had no theoretical basis and was never previously tested. The sole basis of the contention was the fact that dams and other structures built on such an assumption had not failed. These experiments prove definitely that the hydrostatic pressure against a surface cannot be decreased by placing a granular material against that surface.

The method of drawing conclusions from the first set of tests is open to criticism. Table 1, giving averages of friction tests, in pounds per square inch, on the side of the can in contact with sand, is purely an arbitrary set of figures which cannot be applied to any other case. A factor which will influence these values is the height of water overlying the top of the sand. The friction of the can embedded in sand, occurring as it does at the point of motion, is a function of the pressure of the sand against the can. The amount of this pressure depends on the depth and the nature of the sand, and the latter depends on the water overlying it. As a result the use of Fig. 3 to determine the percentage of base area on which hydrostatic uplift acts, gives results which are not quite consistent. In analyzing the data in Table 2 it is interesting to note that the average percentage of effective area on which hydrostatic uplift acts is 95.7 for the metal can 15.09 in. in diameter, 88.5 for the 9.22-in. can, and 86.7 for the 5.53-in. can. This is for the condition of wet sand packed in the container. The other set of experiments in the first part, enumerated in Table 3, shows a number of low values for the 9.22-in. can when the sand is packed dry in the container with, later, an addition of water. This can had a plaster-coated bottom and it is highly probable that there was a considerable quantity of air trapped on the surface of the bottom. However, the data from the other two sets of tests are so conclusive that there is no doubt of the validity of the results.

The author states that he found no appreciable difference in friction due to the materials of which the cans were made, namely, glass, tin, or galvanized iron. The writer believes that in all work on sand and similar soils the same conclusions can be drawn, because the friction between materials like glass, tin, galvanized iron, or wood and sand, is practically the same as the friction of sand against sand. As a result, the true frictional value measured is practically that of sand against sand since a thin layer of the filling material adheres to the test surface and true motion is not between the filling material and test surface, but is a shearing deformation in the filling material itself. Similar results and conclusions were obtained by the writer in his experimental work on the determination of the lateral pressure of soil against walls made of wood, glass, and sheet metal.* Similar results were also obtained by Müller-Breslau in 1906 in his experimental work in earth pressures. Certainly the friction between sand and the ordinary concrete or stone used for dams is greater than the friction between sand and such test materials, and the conclusion therefore applies to all actual conditions.

In reference to the tests with clay, the lack of results is explained in the paper by the fact that the clay became liquid in nature. Under such condi-

* *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), pp. 1472, 1476, and 1477.

tions the pressure exerted is given by the formulas in hydrostatics and the same conclusions given for sand then apply to clay. That liquid materials, such as a concrete mix, obey the laws of hydrostatics has been proved by the experimental work of Messrs. F. R. Schunk* and E. B. Smith.†

Referring to the experiments of the first set, the amount of friction measured is an indication of the total lateral force acting against the submerged can. The ratio between the vertical force (resistance measured in the tests) to the horizontal pressure of the saturated sand against the can must equal the coefficient of friction between saturated sand and the material of which the can was made. This coefficient can be experimentally determined and is quite constant for all the usual materials, even for such unlike materials as wood, tin, and glass. The results are then directly applicable to the design of walls, quays, or docks acted upon by saturated soils and also to dams against which silt has accumulated to considerable heights. The writer would like to know whether any designer of dams has investigated the change in pressures sustained by a dam because of silt accumulation in the reservoir.

J. Albert Holmes,‡ M. Am. Soc. C. E. (by letter).—The author, after careful experimentation, prolonged study, and weighing of evidence, has placed before the Engineering Profession the data in a problem which he has ample reason to believe embodies a correct interpretation of the facts. Still, considering the weight of the evidence in earlier experiments,§ he probably hesitated long and re-weighed the evidence with great care before reaching so divergent a conclusion.

Mr. Parsons states that his research was made "to determine the hydrostatic uplift on the base of a structure, founded on a pervious soil, when there is no loss of head due to velocity of flow". This is static head, acting by mere weight without motion. There was some replacement by water when pistons were actuated in the apparatus used by Mr. Parsons. The pressure, when applied to the water above the sand, must necessarily build up throughout the whole body of the sand, not only to the depth of the piston end, but to the bottom of the chamber, before actuating the piston.

The soil particles in a bed of pervious material must have appreciable size, otherwise the material will be impervious. Mr. Parsons refines the matter minutely when he states that the resultant of pressure of a particle of soil in contact with the base of a structure is upward. This is so, especially when the contact is but a point, since it could not be much more than a point. Rather than any considerable part of the base of a structure being in contact with the pervious soil particles, it would seem more likely to be in contact with water.

The writer's interest in the problem of hydrostatic uplift relates to dams, and more particularly to earth dams where there is flow through the soil and a hydraulic gradient.

* *Professional Memoirs*, U. S. Corps of Engrs., Vol. 1, No. 3, 1909, pp. 247-260.

§ *Transactions*, Am. Soc. C. E., Vol. LXX (December, 1910), p. 364.

In all hydraulic experiments with soils, the presence of air is a disturbing factor affecting flow. Air is also present in the ground under dams and, of course, affects seepage rates there. An instance is recalled where air escaping upward through the water from an isolated mound of original ground, kept ice from forming just above on the core pool of an earth dam during a cold winter.

E. W. LANE,* M. AM. SOC. C. E. (by letter).—The profession is greatly indebted to the author for giving to it the results of such thorough experimentation on a subject which is of great importance, but of which so little is known. The application of the experiments is not confined to dams, because, judging from the number of cases which have come to the writer's attention of buried tanks, cisterns, and even septic tanks, being lifted from their positions by upward pressure of the water acting through the surrounding soil, the costly accidents resulting from a neglect of this pressure must be legion.

For many years the writer has been interested in the effect of upward pressure on dams on porous foundations. Some information was available on the unit pressure beneath dams, but the writer could find only one attempt to determine the area on which the pressure acted.† The writer did not regard these experiments sufficiently conclusive, and, therefore, made a few of his own. The method used was very similar to that used by Mr. Parsons in his low-head tests. The bottom of a large vessel (Fig. 1) was filled with sand. A conical depression, the size of a smaller vessel, was scraped in the sand and filled with paraffin, which had been heated just above melting temperature, in order that it would make a contact with the sand similar to concrete poured on a gravel base, without running deeply into the voids. The depression was made conical to prevent the entraining of air beneath the smaller vessel. While the paraffin was still liquid, a smaller vessel with vertical sides was set into it, and the paraffin allowed to harden in contact with the inner vessel. This vessel was then filled with water nearly to the top, and water was added slowly to the outer vessel until the inner one floated.

The results were not developed quantitatively, since the height of water in the outer vessel (with respect to the inner one) which was necessary to lift the inner vessel, was very little more than that necessary to float the inner one after being lifted free from the sand. It was evident, therefore, that the pressure through the sand acted on practically the entire area of the base of the inner vessel. The slight difference in height in the two cases might easily be due to friction in breaking the contact of the paraffin and the sand adhering to it and the main body of sand. This difference also includes the discrepancy, if any, due to a time element in the transmission of pressure through the sand as the water was poured into the outer vessel. If the writer were to repeat the experiments, he would adopt Mr. Parsons' method, and siphon the water from the inner vessel, instead of adding it to the outer one, as the former method eliminates all question regarding a possible time of transmission of pressure through the sand. However, error from this source could

† "Pressure, Resistance, and Stability of Earth," by J. C. Meem, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXX (1910), p. 352.

not have been appreciable, since both it and the friction in breaking contact with the bottom are included in the very slight amount the inner vessel was lifted when the contact with the sand bed was broken.

H. DE B. PARSONS,* M. AM. SOC. C. E. (by letter).—A full and frank discussion increases knowledge, and this is especially true when the subject is one of experimentation and research. The writer, therefore, thanks those who have criticized his paper. Some of the discussions require no comment, and consideration of the others will be as brief as the facts will permit.

Mr. Meem infers that the pistons or contact rods were not pressed or forced into the sand beds so as to secure full contact, but were simply rested on the sand. The experimental rods were forced down firmly, and their unit loading was as heavy as that under many buildings. The cans were pressed down by hand to compress the sand beneath their bases and establish definite areas of contact. In some of the tests made at Rensselaer Polytechnic Institute, the apparatus was allowed to stand, heavily loaded, for 18 to 48 hours, but the results were substantially the same as when the tests were made (with saturated sand) shortly after arranging the apparatus. Mr. Meem's experiments are interesting, but seem, to the writer, to embody dynamic rather than strictly hydrostatic conditions. Professor Terzaghi's discussion should be read with Mr. Meem's contribution.

Mr. Gallogly stated that the apparatus seemed to illustrate the conditions surrounding a river caisson only, and that the tests do not seem to cover all the cases of foundations constructed in pervious soils below ground-water level. The writer would like to call attention to the fact that his tests were made to determine whether the hydrostatic uplift acted on the full area of the foundation base, or only a part, called the "effective area". This being so, it would seem that the results apply to any kind of structure founded below water level.

The discussion by Professor Terzaghi is both instructive and constructive. The writer was unaware of any tests published in the English language before his paper, and he undertook this research because repeated demands were being made for information by American engineers.

He found, at the beginning, the difficulty of excluding the air content from the sand; and it was one of the causes which delayed the final tests for about nine months, as the air produced erratic results. A test was made by inserting a rubber tube in the sand bed, one end being against the base of a can and the other joining a glass tube having the open end above the water level. The water level in the containing vessel was then raised, and the time noted for the water in the glass tube to come to the same level. It took many hours for the water in the tube to rise, and it frequently did not quite reach the level of the water in the container. The writer and his aides recognized this as air, and the technique was changed to saturate or try to saturate the sand.

The tests made at Stevens Institute of Technology for gravel, confined sand, and sand not confined, appeared to show that the depth of material below

* Prof. Emeritus, Rensselaer Polytechnic Inst.; Cons. Engr., New York, N. Y.

the base of the contact rod had an influence on the effective area, as shown in Fig. 5. This result appears to have been substantiated by the high-head tests at Rensselaer Polytechnic Institute.

All tests were repeated under similar conditions, and the results averaged. (See Tables 1 to 7.) The results with the gravel confirmed those with the sand, as regards the influence of the depth of the material. The gravel was put in the container with water, and the rod pounded down, like a battering ram, on the gravel, to compact it before completely filling the container with water. On account of the relatively large voids between the pebbles, and the manipulation used, it would seem that air was practically excluded. In view of the cases cited by Professor Terzaghi, the writer can reply only by saying that the conclusion, regarding the depth of material required under the base to get substantially 100% uplift, was in accordance with the results as found.

An explanation of the phenomenon may be somewhat as follows: Under the load applied by the contact rod, or by that of a base of an ordinary structure, there can be no appreciable deformation of the sand or gravel particles, although the particles are firmly pressed together in close contact. The weight is supported on the contact areas between the base and the top layer of the particles. There was no hydrostatic head on these areas, as the contact excluded the water. The top layer (that is, the one next to the base) was supported by other layers of particles, between which there were contact areas on which the hydrostatic head also did not act. If the particles had been arranged in perfect alignment, uniform in size, and of oval form, as in Fig. 9, the effective area would be less than the area of the base by an infinitely small amount, corresponding to the elastic deformation of the particles, as stated by Professor Terzaghi; if, with a similar arrangement, the contact areas of the particles were flat and of measurable extent, the effective area would be less than the total area of the base, since the head would act only on that part between the contact areas, no matter how deep the sand was under the base.

The fact is that the particles varied widely in size and shape, and were in every conceivable position relative to one another; and the contact areas on the top and the bottom of a particle would not be always in the same vertical line. The head, acting on the top half of a particle exposed to the water, would give a downward resultant, to which force would be added the weight of the particle. Likewise, the head acting on the bottom half would give an upward resultant, the head being greater due to the vertical thickness of the particle. This increase in head would be extremely small for one particle, but would be measurable as the layers increased. It would seem reasonable that some depth of material would be required before the exposed areas on the bottoms of the particles, with their hydrostatic heads, would be sufficient to overcome the exposed areas on the tops with their heads, so as to transmit the uplift to the base through the points of contact. While appreciating Professor Terzaghi's criticism, it is conceivable that an analytical treatment might not be as accurate as the results of high-head tests.

Mr. Feld is correct instating that the sand friction tests, given in Table 1 and shown graphically in Fig. 3, are not to be applied to other work. The condition of the sand is described in the paper. The water levels for the can tests (low-head tests) were within a few inches of the top edges of the cans.

Mr. Holmes states that in the high-head tests there was "some replacement by water when the pistons were actuated". The pistons were stationary during the test. When a piston commenced to move, the test was over.

The water pressure in the sand or gravel body built up as the head was increased, but without movement, as the water can be considered as incompressible under the pressures used. The only chance for "flow" was entrapped air, and this has been discussed in the writer's reply to Professor Terzaghi.

CONTINUOUS BEAMS OVER THREE SPANS*

By I. Oesterblom,† M. Am. Soc. C. E.

With Discussion by Messrs. Frank S. Bailey, Clyde T. Morris, A. Lincoln Hyde, Harold E. Wessman, Robert M. Wilder, W. F. Way, H. M. Hadley, T. F. Hickerson, John I. Parcel, R. A. Caughey, John B. Snethlage, T. D. Mylrea, and I. Oesterblom.

Synopsis

The matters of accessibility, natural light, and fresh air combine to make three-span construction more prevalent than any other series of multiple spans for buildings.

In the colder, and even in the temperate, climates, office buildings, schools, hospitals, hotels, clubs, etc., generally provide for corridors in the center with rooms on either side. In the tropics the same classes of buildings, and also the dwellings, have rooms in the center with verandas on either side. Thus, the problems of two long side spans with a short center span, or two short side spans with a long center span, are constantly offered to the engineer for solution.

For continuous construction, particularly prevalent on account of the increasing use of reinforced concrete, the proper solution of the moment equations is a most tedious task. It has come to be a very frequent custom, therefore, to neglect such important matters as the effect on moment factors of variability in spans, loads, and sections.

This erroneous custom is sometimes very serious in its consequences. It reaches to all divisions of engineering—design, control, and execution; consultants, municipal authorities, and manufacturers of specialties, all are affected. Even engineering committees and technical schools seem to have avoided the problem or condoned the errors.

* This paper was published in March, 1928, *Proceedings*.
† Structural Engr., St. Louis, Mo.

In textbooks from Continental Europe, the problem is usually covered by the evolution of formulas which may be used in good faith and with good results, although they are generally tedious to apply.* Tables to facilitate the use of the formulas are generally missing, or are so elaborate as to be of no use for the most common problems of variable spans in commercial engineering work. The economic significance of the variables affecting the moment factors is also overlooked.

This paper aims to provide the necessary tables showing moment factors for all the most common conditions, so that the moments may be found with the expenditure of less effort and time. It also shows the significance of the variables and the seriousness of the usual conventional errors. By the use of correct methods, safety and economy of materials are obtained simultaneously.

The Three-Moment Equation

The "three-moment equation" is presented in many different forms, one of which is the following:

$$(M_1 + 2\,M_2)\,\frac{l_{12}}{I_{12}} + (2\,M_2 + M_3)\,\frac{l_{23}}{I_{23}} = -\,\frac{6\,A_{21}}{I_{12}} - \frac{6\,A_{23}}{I_{23}} \ldots\ldots (1)$$

The symbols have the usual significance:

M_1, M_2, etc. = bending moments (at supports).
l_{12}, l_{23}, etc. = spans.
I_{12}, I_{23}, etc. = moments of inertia.
A_{21}, A_{23}, etc. = moment area reaction for simple span conditions.†

The proper meanings of the subscript indices in relation to supports and spans are shown on Fig. 1, according to the following system:

(1) Supports are numbered 1, 2, 3, and 4.
(2) Spans are numbered 12 between Supports 1 and 2; 23 between Supports 2 and 3; etc.
(3) Reactions are numbered as the supports.
(4) Unit loads and moments of inertia are numbered as the spans.
(5) Concentrated loads are numbered as the spans, with subscript numbers for each span to indicate locations, as 121, 122, 123, etc., for loads on Span 12.
(6) The area moment reactions take the first subscript number from the support and the second from the adjacent support on the contributory side. For example, A_{32} is the reaction at Support 3 due to the moment area between Supports 3 and 2.

The form of Equation (1) is "universal" in so far as it takes into account a different section for each span of the beam and any condition of loading. It is not completely universal, however, in so far as it neglects the effects of settlement of supports, or changes due to temperature or similar causes. For purposes of ordinary construction the form is sufficiently comprehensive, as variations in span, section, and load are the only factors that ordinarily affect the stresses.

* See, especially, formulas in "Beton Kalender," pub. by Wilhelm Ernst & Sohn, Berlin, Germany, which contains some of the equations derived by the writer.

† That is, the reaction of the area under the moment curve considered as a load, the moment curve being obtained for simple span conditions.

In the left side of Equation (1) are all the "moment terms"; in the right side are the "load terms". The reasons for these designations are obvious.

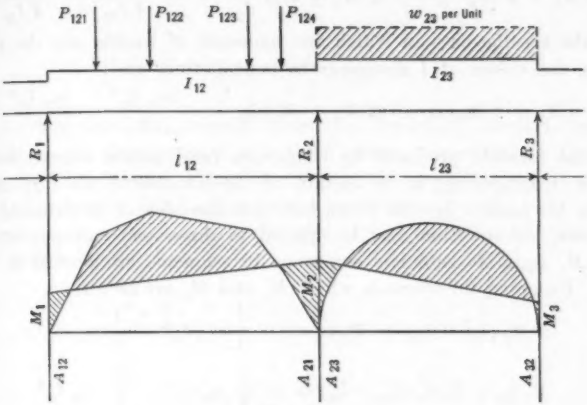

FIG. 1.

Methods of Solution.—For a two-span construction with no end restraints, the end moments, therefore, being equal to zero, the moment at the center support can be found by means of one moment equation only. For each additional span under similar conditions as regards end restraint, one additional equation will be required. The solution of several equations of this type is an elaborate task. Determinants will have to be resorted to for three or more equations. This simplifies the task of solution, but it still requires a great deal of time. For several spans it is customary to use graphic methods, by means of which results can be obtained quickly and accurately. The methods now in use take into account all the usual variables—spans, loads, and moments of inertia.

The graphic method may be the only practical method for five spans or more—even for four spans, it may prove to be the best. For three spans, however, and especially for commercial "repeat work" involving merely minor variations, it would be desirable to have a method developed in detail with moment factors available for immediate use. It is the object of this paper to provide these moment factors.

For commercial work, uniform loads or concentrated loads at equal spacing are especially significant. Other cases may be considered as unusual and for them no moment factors need be developed; they should be treated individually. Moments due to equi-distant concentrated loads are so nearly equal to uniform loads that the same moment factors would apply. Consider, therefore, the significance of the area-moment reactions and the need of making the "load terms" more definite.

CLAPEYRON'S THEOREM

The moment area for a uniform load is parabolic, and, therefore,

$$2A = \frac{2}{3} \times \frac{w l^2}{8} \times l = \frac{w l^3}{12} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Hence, the three-moment equation in more definite form would be,

$$(M_1 + 2\,M_2)\,\frac{l_{12}}{I_{12}} + (2\,M_2 + M_3)\,\frac{l_{23}}{I_{23}} = -\,\frac{w_{12}\,l_{12}^{\,3}}{4\,I_{12}} - \frac{w_{23}\,l_{23}^{\,3}}{4\,I_{23}} \quad \ldots\ldots(3)$$

For the specific case in which the moments of inertia are the same for all spans, the values of I disappear by cancellation, and:

$$(M_1 + 2\,M_2)\,l_{12} + (2\,M_2 + M_3)\,l_{23} = -\,\frac{w_{12}\,l_{12}^{\,3}}{4} - \frac{w_{23}\,l_{23}^{\,3}}{4} \quad \ldots\ldots(4)$$

This is the formula produced by Clapeyron (and almost simultaneously by two other investigators) in the middle of the Nineteenth Century and since known by his name. In this form, but with the idea of introducing amendments later, the equation may be applied to three-span construction. With M_1 and M_4 equal to zero two equations in sequence are needed to find M_2 and M_3. Dropping the terms in which M_1 and M_4 are factors,

$$2\,M_2\,(l_{12} + l_{23}) + M_3\,l_{23} = -\,\frac{1}{4}\,w_{12}\,l_{12}^{\,3} - \frac{1}{4}\,w_{23}\,l_{23}^{\,3} \quad \ldots\ldots(5)$$

$$M_2\,l_{23} + 2\,M_3\,(l_{23} + l_{34}) = -\,\frac{1}{4}\,w_{23}\,l_{23}^{\,3} - \frac{1}{4}\,w_{34}\,l_{34}^{\,3} \quad \ldots\ldots(6)$$

Support Moments.—For further operations a symbol, K, for an oft-occurring expression is introduced as follows:

$$K = 4\,(l_{12}\,l_{23} + l_{12}\,l_{34} + l_{23}\,l_{34}) + 3\,l_{23}^{\,2} \quad \ldots\ldots(7)$$

Solving for $M_3\,l_{23}$ in Equation (5) and introducing the values of M_3 in Equation (6):

$$M_3\,l_{23} = -\,\frac{1}{4}\,w_{12}\,l_{12}^{\,3} - \frac{1}{4}\,w_{23}\,l_{23}^{\,3} - 2\,M_2\,(l_{12} + l_{23}) \quad \ldots\ldots(8)$$

$$-\,K\,M_2 = \frac{1}{2}\,w_{12}\,l_{12}^{\,3}\,(l_{23} + l_{34}) + \frac{1}{2}\,w_{23}\,l_{23}^{\,3}\left(\frac{1}{2}\,l_{23} + l_{34}\right) - \frac{1}{4}\,w_{34}\,l_{34}^{\,3}\,l_{23} \quad \ldots\ldots(9)$$

Equation (9) now will give all the support moments, M_2, and after these are found all the support moments, M_3.*

First, considering Span 12 only loaded with w_{23} (w_{34}, therefore, being equal to zero),

$$-\,K\,M_2 = \frac{1}{2}\,w_{12}\,l_{12}^{\,3}\,(l_{23} + l_{34})$$

and,

$$M_2 = -\,\frac{w_{12}\,l_{12}^{\,3}}{2\,K}\,(l_{23} + l_{34}) \quad \ldots\ldots(10)$$

For the second span loaded, and with w_{12} and w_{34} equal to zero, in like manner,

$$-\,K\,M_2 = \frac{1}{2}\,w_{23}\,l_{23}^{\,3}\left(\frac{1}{2}\,l_{23} + l_{34}\right)$$

and,

$$M_2 = -\,\frac{w_{23}\,l_{23}^{\,3}}{4\,K}\,(l_{23} + 2\,l_{34}) \quad \ldots\ldots(11)$$

* The term, "support moment," refers to the moment at a support as distinguished from "span moment," within the span itself.

Finally, with Span 34 only loaded, and with w_{12} and w_{23} equal to zero,

$$-K M_2 = -\frac{1}{4} w_{34} l_{34}^3 l_{23}$$

and,

$$M_2 = \frac{w_{34} l_{34}^3}{4 K} l_{23} \quad \ldots\ldots (12)$$

Thus, have been found the moment effects for the second support due to uniform loads on the first, second, and third spans, respectively. The expressions for M_2 being found, Equation (8) may be used, together with Equations (10), (11), and (12), to find similar expressions for M_3.

Setting w_{12}, w_{23}, and w_{34} equal to zero in like manner, the equations for Span 12 loaded will be,

$$K M_3 l_{23} = -\frac{1}{4} K w_{12} l_{12}^3 + w_{12} l_{12}^3 (l_{12} + l_{23}) (l_{23} + l_{34}) = \frac{1}{4} w_{12} l_{12}^3 l_{23}^2$$

and,

$$M_3 = +\frac{w_{12} l_{12}^3}{4 K} l_{23} \quad \ldots\ldots (13)$$

Similarly, for Span 23 loaded:

$$K M_3 l_{23} = -\frac{1}{4} K w_{23} l_{23}^3 + \frac{1}{2} w_{23} l_{23}^3 (l_{12} + l_{23}) (l_{23} + 2 l_{34})$$

$$= -\frac{1}{4} w_{23} l_{23}^3 (2 l_{12} l_{23} + l_{23}^2)$$

and,

$$M_3 = -\frac{w_{23} l_{23}^3}{4 K} (2 l_{12} + l_{23}) \quad \ldots\ldots (14)$$

Finally, for Span 34 loaded:

$$K M_3 l_{23} = -2 M_2 (l_{12} + l_{23}) = -\frac{1}{2} w_{34} l_{34}^3 (l_{12} + l_{23}) l_{23}$$

and,

$$M_3 = -\frac{w_{34} l_{34}^3}{2 K} (l_{12} + l_{23}) \quad \ldots\ldots (15)$$

Span Moments.—From the expressions for the support moments one may proceed to find equations for the span moments through the medium of expressions for the reactions. The relations between support moments and reactions for any one span are given by the equation,

$$R_L l_{12} = M_2 - M_1 + \frac{1}{2} w_{12} l_{12}^2 \quad \ldots\ldots (16)$$

In like manner the relations between span moments and the reactions will be,

$$M_x = M_1 + R_L x - \frac{1}{2} w_{12} x^2 \quad \ldots\ldots (17)$$

R_L indicates the reaction at the left end of the span and M_x, the span moment at a distance, x, from the left support. $M_{x\,\max.}$ is expressed by M_{12}, M_{23}, and

M_{34}, respectively. Differentiating M_x in regard to x, and setting the derivative equal to zero, gives for $M_{x\,\max.}$:

$$x = \frac{R_L}{w_{12}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

and,

$$M_{x\,\max.} = M_1 + \frac{{R_L}^2}{2\,w_{12}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

Solving for R_L in Equation (16) and using that value in Equation (19):

$$M_{12} = M_1 + \frac{1}{2\,w_{12}}\left(\frac{M_2}{l_{12}} - \frac{M_1}{l_{12}} + \frac{w_{12}\,l_{12}}{2}\right)^2 \quad \ldots\ldots\ldots\ldots (20)$$

Equations (18) and (19) are useful and important; but Equation (20) is the one to be used for the specific purpose of finding maximum span moments. All three equations obviously are good for any span with proper modifications of the indices for M, w, and l. Therefore, the following equations hold for Spans 23 and 34:

$$M_{23} = M_2 + \frac{1}{2\,w_{23}}\left(\frac{M_3}{l_{23}} - \frac{M_2}{l_{23}} + \frac{w_{23}\,l_{23}}{2}\right)^2 \quad \ldots\ldots\ldots\ldots (21)$$

$$M_{34} = M_3 + \frac{1}{2\,w_{34}}\left(\frac{M_4}{l_{34}} - \frac{M_3}{l_{34}} + \frac{w_{34}\,l_{34}}{2}\right)^2 \quad \ldots\ldots\ldots\ldots (22)$$

It should be noted that for the particular cases under investigation all terms containing M_1 and M_4 disappear, as these two moments are always zero.

Moment Effects from Adjacent Spans

As may be noted, Equations (20), (21), and (22) will give expressions for the maximum bending moments in the loaded spans, but obviously will not give any results for adjacent spans. This is on account of the presence of the zero load element, w, as a divisor in the second term of the equations, which makes the expressions indefinite. To find the meaning of this indefinite feature the three-moment diagrams may be considered in sequence, as shown in Fig. 2.

As previously, the supports are indicated by the numerals, 1, 2, 3, and 4; the spans by the numbers, 12, 23, and 34; and the conditions of loading by the letters, A, B, and C. In Fig. 2, A shows a diagram for Span 12 loaded; B, for Span 23; and C, for Span 34. The quantities, M_{f12}, M_{f23}, and M_{f34}, would be the moments at points of maximum effect for the loaded spans if they were freely supported and not continuous; and M_{12}, M_{23}, and M_{34}, the actual maximum moments for the loaded spans.

It is obvious from Fig. 2 that there can be no maximum span moments in the interior of spans adjacent to the loaded spans. This, therefore, is the interpretation of the indefinite feature of Equations (20), (21), and (22).

Combination of Moment Effects.—For purposes of analysis the individual diagrams are instructive. As the ultimate aim of this paper is practical, however, the results from the combination of the three are more interesting. It is not desired to know the maximum effect in the unloaded spans, but rather the effect where the combined moments will be a maximum.

In individual cases it is easy to establish the points of maximum effect for loaded spans due to the loads on these spans. Equations (16) and (18)

will give these with little effort after the negative moments have been found. After the addition of secondary effects from adjacent spans the points of maximum moment will not be quite the same. The combined moments at the two points would be substantially the same, however, as the change of curvature between the points is insignificant.

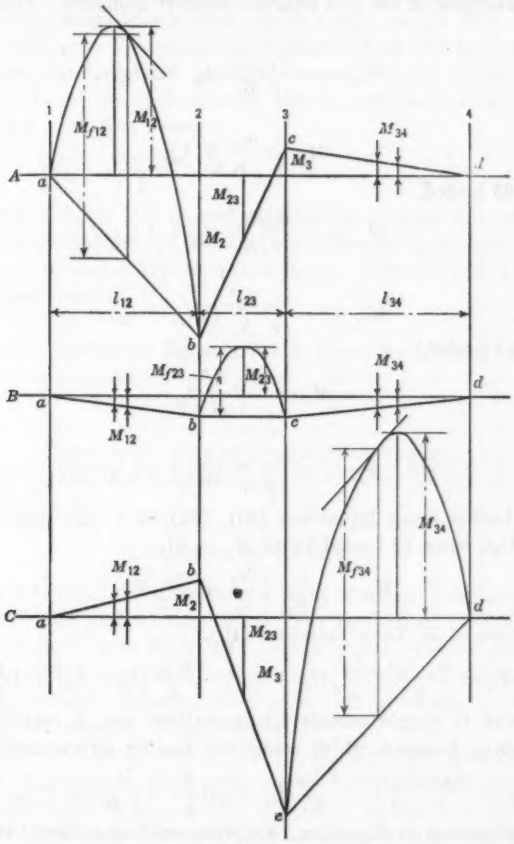

FIG. 2.

It is intended finally to establish definite moment factors for given ratios of span lengths. It would lead too far afield to establish without error the secondary moment effects from loads in adjacent spans. Instead it is necessary to introduce an approximation, by assuming that the secondary effects at the mid-spans will give results close enough to be added to the two principal moments. An inspection of Fig. 2 will show that for the totals this is substantially correct. On all the spans the lines representing the two unloaded effects are compensating, and the resultant of the two is almost hori-

zontal. In the outside spans the secondary effects are generally small, while in the center spans the mid-points in most cases of reasonable design are truly points of maximum combined effect. All these considerations combine to make the proposed approximation almost equal to definite accuracy.

On this basis the secondary mid-span moment effects can now be written directly as averages of the two adjacent support moments. Then, with Span 12 loaded,

$$M_{23} = -\frac{w_{12}\, l_{12}^{\,3}}{8\, K}\,(l_{23} + 2\, l_{34}) \qquad (23)$$

and,

$$M_{34} = \frac{w_{12}\, l_{12}^{\,3}}{8\, K}\, l_{23} \qquad (24)$$

With Span 23 loaded,

$$M_{12} = -\frac{w_{23}\, l_{23}^{\,3}}{8\, K}\,(l_{23} + 2\, l_{34}) \qquad (25)$$

and,

$$M_{34} = -\frac{w_{23}\, l_{23}^{\,3}}{8\, K}\,(2\, l_{12} + l_{23}) \qquad (26)$$

With Span 34 loaded,

$$M_{12} = \frac{w_{34}\, l_{34}^{\,3}}{8\, K}\, l_{23} \qquad (27)$$

and,

$$M_{23} = -\frac{w_{34}\, l_{34}^{\,3}}{8\, K}\,(2\, l_{12} + l_{23}) \qquad (28)$$

For the loaded spans Equations (20), (21), and (22) may now be used. Assuming, first, Span 12 loaded (with $M_1 = 0$),

$$M_{12} = \frac{1}{2\, w_{12}}\left(\frac{M_2}{l_{12}} + \frac{w_{12}\, l_{12}}{2}\right)^2$$

and with values of M_2 from Equation (10),

$$M_{12} = \frac{w_{12}\, l_{12}^{\,2}}{8}\left\{\frac{l_{12}^{\,2}}{K^2}\,(l_{23} + l_{34})^2 - \frac{2\, l_{12}}{K}\,(l_{23} + l_{34}) + 1\right\} \qquad (29)$$

This expression is simple enough for immediate use; it may be written in a different form, however, which sometimes has its advantages,

$$M_{12} = \frac{w_{12}\, l_{12}^{\,2}}{8}\left\{1 - \frac{2\, l_{12}}{K}\,(l_{23} + l_{34})\left[1 - \frac{l_{12}}{2\, K}\,(l_{23} + l_{34})\right]\right\} \qquad (30)$$

If the square bracket in Equation (30) were omitted entirely, the remainder would represent the mid-span moment, which has been suggested by some authorities as sufficiently accurate. For a loaded end span the error is considerable, as may be seen if the expression inside the omitted bracket be evaluated.

For Span 34 loaded, the span moment equations can now be written directly on account of the symmetry of the case. Substituting Indices 12 for 34 and 34 for 12 in Equations (29) and (30),

$$M_{34} = \frac{w_{34}\, l_{34}^{\,2}}{8}\left\{\frac{l_{34}^{\,2}}{K^2}\,(l_{23} + l_{12})^2 - \frac{2\, l_{34}}{K}\,(l_{23} + l_{12}) + 1\right\} \qquad (31)$$

and,

$$M_{34} = \frac{w_{34}\, l_{34}^2}{8} \left\{ 1 - \frac{2\, l_{34}}{K} (l_{23} + l_{12}) \left[1 - \frac{l_{34}}{2\, K} (l_{23} + l_{12}) \right] \right\} \ldots\ldots (32)$$

For moment effects in the center span due to loading in that span, again it is possible to write an approximation with a considerable accuracy and thereby eliminate long calculations, which would hardly add anything of practical significance. The maximum moment effect will be found so close to mid-span and the disturbing negative moment line for all reasonable span conditions will be so nearly horizontal that a mid-span expression for M_{23} is fully justified. On this basis,

$$M_{23} = \frac{w_{23}\, l_{23}^2}{8} \left\{ 1 - \frac{2\, l_{23}}{K} (l_{12} + l_{23} + l_{34}) \right\} \ldots\ldots\ldots\ldots (33)$$

To ascertain directly and immediately useful moment factors for all the most frequently occurring span and load conditions in three-span construction all the necessary formulas have now been found. Table 1 gives a summary of those expressions required.

TABLE 1.—SCHEDULE OF EQUATIONS FOR VARIOUS MOMENTS AND SPANS.

Load on:	M_{12}.	M_2.	M_{23}.	M_3.	M_{34}.
Span 12.....	Equation (30)	Equation (10)	Equation (23)	Equation (13)	Equation (24)
Span 23.....	Equation (25)	Equation (11)	Equation (33)	Equation (14)	Equation (26)
Span 34.....	Equation (27)	Equation (12)	Equation (28)	Equation (15)	Equation (32)

CONDITIONS OF SYMMETRY

Clearly it is impracticable to make a table of moment factors for all possible and reasonable span combinations. For increments of 6 in. and with a range from 8 ft. 0 in. to 30 ft. 0 in., which would cover all common cases, there would be no less than 2 025 combinations, for each of which there would have to be 15 moment factors. Neither is this necessary, as the moment factors are merely matters of span ratios.

This analysis will be limited to conditions of perfect symmetry or slight asymmetrical variations, as these cases are the only ones of frequent practical occurrence. First, let $l_{12}=l_{34}=l$ and $l_{23}=xl$, in which, x is the span ratio. Then moment factors may be established for all span ratios between 0.20 and 2.50 in increments of 0.10. Finally, it will be pointed out how these moment factors may be used to ascertain correctly moments for cases of asymmetric span relations.

For this purpose the equations enumerated in Table 1 will be used, with the span designations as noted and with the loads for the loaded spans equal to unity in proper sequence. The moment factor formulas (Table 2) are merely simplifications as outlined on the basis of the equations noted in Table 1. The table of "Moment Factors" (Table 3) is a further development for given span ratios.

TABLE 2.—MOMENT FACTOR FORMULAS FOR THREE-SPAN CONSTRUCTION.
(Two outside spans alike and equal to unity; middle span equal to x.)
$(K = 8x + 3x^2 + 4)$

Loading.	M_{12}.	M_2.	M_{23}.	M_3.	M_{34}.
Span 12 loaded.	$\frac{1}{8} - \frac{x+1}{4K}\left(1 - \frac{x+1}{2K}\right)$	$-\frac{x+1}{2K}$	$-\frac{x+2}{8K}$	$+\frac{x}{4K}$	$+\frac{x}{8K}$
Span 23 loaded.	$-\frac{2x^3 + x^4}{8K}$	$-\frac{2x^3 + x^4}{4K}$	$\frac{x^2}{8} - \frac{2x^3 + x^4}{4K}$	$-\frac{2x^3 + x^4}{4K}$	$-\frac{2x^3 + x^4}{8K}$
Span 34 loaded.	$+\frac{x}{8K}$	$+\frac{x}{4K}$	$-\frac{x+2}{8K}$	$-\frac{x+1}{2K}$	$\frac{1}{8} - \frac{x+1}{4K}\left(1 - \frac{x+1}{2K}\right)$

Dead and Live Load Effects.—It has come to be a practice among American designers to combine dead and live loads in computing moments. This is a very unfortunate practice, because the live load effects vary greatly, whereas the dead load effects do not. To endeavor to produce total load moment factors, comprehensive enough to cover every possible ratio of dead to live load, is merely to accept a crude method, when a correct method is equally simple. In Table 3, therefore, no attempt has been made at moment-factor summation, which the writer considers incorrect in principle, inaccurate as regards results, and leading to waste in materials of construction. In addition, both dead and live loads may vary from span to span, which makes the separation of moment factors necessary. Finally, there may be variation in moments of inertia, for which case, as will be seen, separated factors are essential.

MOMENT FACTORS

In Table 3 are given the coefficients, ϕ, of the moments for any given set of dimensions and conditions of loading. To find any moment, first find the ratio, x, of the center span to the end span, then multiply the moment factors, ϕ, for spans and load conditions, by $w l^2$. Both dead and live loads for all spans must be used in this computation and the results added. Always use the outside span in the formula as all moment factors have been computed on the basis of the outside span being equal to unity.

A comparative review of the moment factors in Table 3, particularly in comparison with conventional moment factors for equal span construction, is very instructive. It is especially noteworthy that negative moments occur in the center spans whenever these are short comparatively; also, in the end spans, when they are short. Indeed, the center spans are very severely punished by the end span loads, and the span ratio has to reach 0.60 before the danger of negative moments is avoided. This point is especially significant in view of the universal custom of computing moments as positive through an erroneous use of the conventional moment factors for equal spans.

Application of Factors—Symmetrical Spans.—An example will show the practical working of the formulas and tables.

TABLE 3.—MOMENT FACTORS, ϕ, FOR MAXIMUM BENDING MOMENTS IN THREE-SPAN CONSTRUCTION.

FORMULA, $M = \phi\, w\, l^2$

(Symmetrical span arrangement; x = ratio of middle to side spans; all moment factors are computed on basis of outside spans.)

Example 1.—A 9-ft. corridor span and two outside spans, 22 ft. 6 in. each; dead load, 67 lb. per sq. ft.; live load, 60 lb. per sq. ft for outside, and 80 lb. per sq. ft. for middle, spans; and span ratio, $x = 0.40$. From Table 3 directly:

Dead Load Bending Moments:

First and Third Spans (equal):

First span load..... $+ 0.084 \times 67 \times 22.5^2$
Second " " ..... $- 0.003 \times 67 \times 22.5^2$
Third " " ..... $+ 0.007 \times 67 \times 22.5^2$
Total effect ..... $+ 0.088 \times 67 \times 22.5^2 = + 2\,980$ ft-lb.*

Middle Span:

First span load..... $- 0.039 \times 67 \times 22.5^2$
Second " " ..... $+ 0.015 \times 67 \times 22.5^2$
Third " " ..... $- 0.039 \times 67 \times 22.5^2$
Total effect ..... $- 0.063 \times 67 \times 22.5^2 = - 2\,130$ ft-lb.

Middle Supports:

First span load..... $- 0.091 \times 67 \times 22.5^2$
Second " " ..... $- 0.005 \times 67 \times 22.5^2$
Third " " ..... $+ 0.013 \times 67 \times 22.5^2$
Total effect ..... $- 0.083 \times 67 \times 22.5^2 = - 2\,800$ ft-lb.

* The writer prefers the notation, "lb. ft." to distinguish units of moment from "ft-lb.," as units of energy.

Live Load Bending Moments:

First and Third Spans (equal):

First span load.....	+ 0.084	×	60	×	22.5^2	=	+ 2 550	
Second " "	− 0.003	×	80	×	22.5^2	=	− 120	
Third " "	+ 0.007	×	60	×	22.5^2	=	+ 210	
Maximum effect							+ 2 760	ft-lb.

Middle Span:

First span load.....	− 0.039	×	60	×	22.5^2	=	− 1 180	
Second " "	+ 0.015	×	80	×	22.5^2	=	+ 610	
Third " "	− 0.039	×	60	×	22.5^2	=	− 1 180	
Maximum effect							− 2 360	ft-lb.

Middle Supports:

First span load.....	− 0.091	×	60	×	22.5^2	=	− 2 770	
Second " "	− 0.005	×	80	×	22.5^2	=	− 200	
Third " "	+ 0.013	×	60	×	22.5^2	=	+ 395	
Maximum effect							− 2 970	ft-lb.

Total Bending Moments:

First and third spans (equal)	+ 2 980	+ 2 760	=	+ 5 740	ft-lb.
Middle span	− 2 130	− 2 360	=	− 4 490	ft-lb.
Middle supports	− 2 800	− 2 970	=	− 5 770	ft-lb.

The example is instructive in many respects. It shows how the moment factors may be summarized, when the load is equal for all spans and constant; and how they may be used separately for variable loads or loads of different magnitude. It shows that the load effects from the outside spans predominate in the middle span, so that the negative moments overbalance the positive moments. It shows how in the first span the moment from the second span load must be omitted to obtain the maximum effect and how in the middle span for the same reason its own load must be omitted. It shows, finally, that even with the outside span live loads omitted, the center span load will not be sufficient to cause a positive moment effect in the middle span as against the dead load effect from the outside spans. About most of these very important matters, conventional methods of design give no information.

Different Moments of Inertia

This leads to a consideration of three-span construction having a different moment of inertia in each span. For this purpose take Equation (3) and multiply by I_{12}; then,

$$(M_1 + 2\,M_2)\,l_{12} + (2\,M_2 + M_3)\,l_{23}\frac{I_{12}}{I_{23}} = -\frac{w_{12}\,l_{12}^3}{4} - \frac{w_{23}\,l_{23}^3}{4} \times \frac{I_{12}}{I_{23}}. \quad (34)$$

or in a more useful form, letting $q = \dfrac{I_{12}}{I_{23}}$,

$$(M_1 + 2\,M_2)\,l_{12} + (2\,M_2 + M_3)\,q\,l_{23} = -\frac{w_{12}\,l_{12}^3}{4} - q\,\frac{w_{23}\,l_{23}^3}{4}. \quad (35)$$

Expressed in words, Equation (35) means that if the moment of inertia varies from span to span, the moment factors already found may still be used, provided certain adjustments of spans and loads be introduced; that is:

(1) One span should be selected as the principal span to remain without change and with the original loads applied.

(2) The other two spans should be transformed (lengthened or shortened) in the ratio of the moments of inertia; the slenderer beams should be increased, and the heavier beams decreased, in length.

(3) The loads of the same two spans should be divided by the square of the same figure with which the spans were multiplied; or, in other words, for an increased span there should be decreased load and *vice versa*.

Application.—For purposes of demonstration and comparison take Example 1 as before, but with the moment of inertia for the middle span only a fraction of that for the outside span.

Example 2.—Same span conditions as in Example 1. Dead load, 67 lb. per sq. ft. for outside spans and 60 lb. for middle span; live loads, 60 and 80 lb., respectively; moments of inertia ratio (outside to middle spans), 4:1; middle transformed span, therefore, $4 \times 9 = 36$ ft.; span ratio, $\frac{36}{22.5} = 1.60$; modified dead load, $\frac{60}{16} = 3.75$ lb. per sq. ft.; and modified live loads, $\frac{80}{16} = 5$ lb. per sq. ft. With the original information, and with spans and loads modified, the moment factors can now be applied directly.

Dead Load Bending Moments:

First and Third Spans (equal):

First span load...	+ 0.100	×	67	× 22.5^2	=	+ 3 390	
Second " " ...	− 0.075	×	3.75	× 22.5^2	=	− 140	
Third " " ...	+ 0.008	×	67	× 22.5^2	=	+ 270	
Total effect						+ 3 520	ft-lb.

Middle Span:

First span load...	− 0.018	×	67	× 22.5^2	=	− 610	
Second " " ...	+ 0.170	×	3.75	× 22.5^2	=	+ 320	
Third " " ...	− 0.018	×	67	× 22.5^2	=	− 610	
Total effect						− 900	ft-lb.

Middle Supports:

First span load...	− 0.053	×	67	× 22.5^2	=	− 1 800	
Second " " ...	− 0.151	×	3.75	× 22.5^2	=	− 290	
Third " " ...	+ 0.016	×	67	× 22.5^2	=	+ 540	
Total effect						− 1 550	ft-lb.

Live Load Bending Moments:

First and Third Spans (equal):

First span load...	+ 0.100	×	60	× 22.5^2	=	+ 3 040	
Second " " ...	− 0.075	×	5	× 22.5^2	=	− 190	
Third " " ...	+ 0.008	×	60	× 22.5^2	=	+ 240	
Maximum effect						+ 3 280	ft-lb.

Live Load Bending Moments (Continued):

Middle Span:

First span load...	— 0.018	× 60	× 22.5²	= —	550
Second " " ...	+ 0.170	× 5	× 22.5²	= +	430
Third " " ...	— 0.018	× 60	× 22.5²	= —	550
Maximum effect				= —	1 100 ft-lb.

Middle Supports:

First span load...	— 0.053	× 60	× 22.5²	= —	1 610
Second " " ...	— 0.151	× 5	× 22.5²	= —	380
Third " " ...	+ 0.016	× 60	× 22.5²	= +	485
Maximum effect				= —	1 990 ft-lb.

Total Bending Moments:

First and third span (equal)....	+ 3 520	+ 3 280	= + 6 800
Middle span	— 910	— 1 100	= — 2 010
Middle supports	— 1 550	— 1 990	= — 3 540

Asymmetrical Span Arrangement

Thus far, only symmetrical cases have been examined. It would extend the discussion too far, and without particular value, to cover the full range of asymmetrical arrangements. The universal case may be solved without much difficulty by applying the formulas scheduled and introducing at the same time—if need be—span and load modifications as already described for variable moments of inertia.

There are numerous cases in which the span arrangement is almost symmetrical, the outside spans differing in length by a few feet only. In a moderate climate a school building, for example, may have a 10-ft. corridor in the center and 20 and 22-ft. rooms on the sides; or, in warmer climates, a 20-ft. room in the center with 12 and 14-ft. verandahs on the sides.

A survey of the moment factors in Table 3, particularly for the supplementary load effects from adjacent spans, will make it plain that such minor variations from true symmetry will not cancel the usefulness of the tabular figures. Each end span, with its inner support, may be computed quite accurately as if the opposite side were the same and, then, the middle span, assuming the end spans to be equal to an average of the two.

Assume, for instance, spans of 20 ft. 0 in., 9 ft. 0 in., and 22 ft. 0 in. The spans ratios are then 0.45 and 0.41, respectively. For these differences the variations in the load effects are visible to a small extent in the third decimal only. A simple example using a larger asymmetry would readily show further approximation.

Conventional Errors

In usual designing practice the solution by the graphical method or the three-moment theorem is not very common; instead, conventional moment factors are ordinarily applied. These factors were never intended to apply except for equal spans. How dangerously incorrect the use of these factors

is, may be shown by continuing the foregoing examples in accordance with the conventional method as follows:

$$\text{Outside spans} \quad \frac{127 \times 22.5^2}{10} = +\ 6\ 430 \text{ ft-lb.}$$

$$\text{Middle spans} \quad \frac{140 \times 9^2}{12} = +\ 940 \text{ ft-lb.}$$

$$\text{Middle supports} \quad \frac{-133 \times 15.75^2}{12} = -\ 2\ 750 \text{ ft-lb.}$$

A comparison of these results with those previously obtained is enlightening. A summary of the three methods is shown in Table 4.

TABLE 4.—COMPARISON OF MOMENTS, IN FOOT-POUNDS, BY VARIOUS METHODS.

Location.	By Three-Moment Theorem:		By conventional moment factors.
	Equal values of *I*.	Unequal values of *I*.	
Outside spans	+5 740	+6 800	+6 430
Middle spans	−4 490	−2 010	+ 940
Middle supports	−5 770	−3 540	−2 750

PRACTICAL CONSEQUENCES

Obviously, for the example chosen—and it represents a very common case—the moments for both the middle span and its support are most erroneously calculated. This is true not only with the rough conventional moment factors, but also when the three-moment theorem is applied without allowance for the change in cross-section.

The middle span moment by the conventional method is positive, whereas it should be decidedly negative and increase by a parabolic curve until the still larger support moment is reached. By the conventional method the support and outside span moments are also incorrect, but in this example not dangerously so. In regard to the use of the three-moment theorem it should be noted that modification for the change of section is most necessary, as the differences in results are very large—for the middle span and support moments, 55% and 49%, respectively. In this case, it is true the error is on the safe side, but with other span proportions it would be the reverse.

At any rate a question of economy or strength has been raised: Who would advocate using carelessly large quantities of materials when they are not needed, or leaving them out when they are required for strength? The question might also be asked: What chance, for instance, has a slender slab of concrete, proportioned for a moment of 940 ft-lb., to resist a negative moment of 3 540 ft-lb.?

Careless Designs.—The ignorance or lack of care in this matter would have brought disastrous results in reinforced concrete construction, had it not been for compensating features. When the two outer spans are long and the middle spans short, or *vice versa*—the cases where conventional methods are

most in error—the heavier spans with their supports generally act as independent units and as such are strong enough to stand of themselves. The slenderer spans also act independently, and are able somehow to hang on to the supports even in spite of numerous cracks, which are not as large as they might be (on account of generous load compensations) and are efficiently concealed by laitance, dust, floor coverings, partitions, base-boards, and the like.

Revision of Current Practice Essential.—This general subject has been taboo both to university and to municipal authorities. Consulting engineers likewise seem to be unable to spare the time to design correctly. The large reinforcement bar distributors, "pioneers and consultants in reinforced concrete," are possibly the worst offenders. Their various "tin pan systems", most excellent for long-span construction, are lagging behind in details suitable for a correct computation of continuity.

Perhaps even the Joint Committee on Concrete and Reinforced Concrete is somewhat to blame. It would have been consistent and quite in order for this Committee to omit all reference to moment factors, which are not truly subject to regulation by anything akin to a code; but to write several pages about moments for equal spans and then to state* merely that "continuous beams with unequal spans * * * shall be designed for actual moments", is surely inconsistent and only invites others to "escape from an unpleasant reality".

One effect on bureaucratic minds has been to make the conventional moment factors universal for almost all spans and conditions. Indeed a competent designer is sometimes forced to do what he knows to be wrong, because some one in authority has spoken with the appearance of great understanding. Possibly, and conceivably, this paper may bring some of these hazy or incorrect ideas to a proper focus.

Bibliography

The following bibliography on three-span construction has been prepared by the writer. Each reference was selected for one of three reasons: (*a*) The information is fundamental and classic; (*b*) the accepted theories have been expressed; and (*c*) the theories have been carried to practical results, with working formulas and tables.

DISCUSSION

FRANK S. BAILEY,* ASSOC. M. AM. SOC. C. E. (by letter).—Continuous beams have been studied so extensively in the past that the writer wondered when seeing the title of the author's paper what new treatment of the subject was possible. A reading of the paper, however, is sufficient to convince any designer of its value in eliminating the necessity for laborious computations in many cases.

Table 3, giving moment factors for maximum bending moments in three-span construction, should be a very real labor saver. A table giving the moment factors for three spans with fixed ends, would also be useful.

In a short paper entitled "Diagrams for Continuous Beams of Unequal Spans,"† the writer presented several curves of shears and moments for two and three-span beams, with supported and also with fixed ends, and generally carrying a uniform load over all spans. It is interesting to check the results in Table 3, with those found by the writer. The moment factors check with each other almost exactly for the case where all three spans are loaded. It should be noted that Table 3 gives factors for maximum bending moments but, while it gives a negative moment of $0.05\ w\ l^2$ as the maximum for the middle span in the case where the value of x is 0.50, this is really the minimum value of the moment, and occurs at the center of the span, as shown on Fig. 4 of the writer's paper previously mentioned, a negative moment extends entirely across the middle span and is a maximum adjacent to the supports.

In comparing Fig. 3 of the writer's paper referred to, with the author's Table 3, it was found that the moments at the center of the middle span and at the two supports check very closely, but as a matter of fact, the maximum moment in the middle span does not occur at the center, but adjacent to the supports, where it is negative. This fact, of course, would be obvious by using Table 3 and plotting a diagram showing the moments at the supports as well as in the spans.

The maximum positive moment in the end span as shown on the writer's Fig. 3 is equal to $+\ 0.024\ w\ l^2$, whereas Table 3 shows a maximum moment of $-\ 0.014\ w\ l^2$ in the end span, for all spans loaded. Here, again, the location of the maximum moment is really adjacent to the interior support.

The writer found a small positive moment in the end span while Table 3 gave a small negative moment as the maximum. On further reference to the paper the writer read that, "it is necessary to introduce an approximation, by assuming that the secondary effects at the mid-spans will give results close enough to be added to the two principal moments." It is likely, therefore, that this approximation may account for the rather unimportant discrepancy.

It is to be hoped that the author's criticisms of existing building codes and other standard rules for moment factors, will have beneficial effects. Sponsors of the various codes undoubtedly wish them to be as trustworthy as possible, and defects when found will be corrected sooner or later.

* Structural Designer, New England Power Constr. Co., Boston, Mass.

† *Journal*, Boston Soc. of Civ. Engrs., Vol. 4, No. 8, October, 1917.

Despite the best of building codes, accidents will happen if building inspectors and other officials and contractors are not extremely vigilant and perhaps sometimes even if they are. For several years the City of Boston has had a building code which will probably stand comparison with any other, and yet, because of some unforeseen weakness, a building in which a dance was being held a few years ago, suddenly collapsed, with shockingly tragic results.

. CLYDE T. MORRIS,* M. AM. SOC. C. E. (by letter).—It is with gratification that one sees the tendency of designing engineers in recent years to calculate stresses with greater precision. This tendency has been especially marked in reinforced concrete design, probably due to the fact that its basic theory is comparatively new and has been developed in connection with tests in university laboratories, by research workers skilled in this type of investigation. The uncertainties of the physical properties of concrete, namely, modulus of elasticity, time yield, and ultimate strength, would not seem to call for as careful theoretical computation of stresses as might be advantageous in the older material—steel—which has well known and constant physical characteristics. In spite of this, steel structures are still designed on assumptions of simple beams, girders, and trusses, connected by hinged joints. There is no doubt in the writer's mind that the steel frame of a modern, well-designed office building is just as much a monolith, as the building with a reinforced concrete frame. In fact, the effect of time yield of concrete upon the negative dead load moments at the joints of a reinforced concrete frame must be to relieve them to a considerable extent and to increase the positive moments at the mid-spans.

Therefore, it would seem that careful consideration of continuity in a steel frame with well-designed joints is just as important as in a reinforced concrete frame. Usually, the joints of steel frames must be designed to resist wind moments, and if properly designed will also care for the joint moments caused by dead and live loads.

It has been the writer's practice, in designing steel frame buildings, to make use of the same diagrams and methods developed for calculating the moments at the joints of rigid frames, which are published in the various texts on reinforced concrete construction.

Mr. Oesterblom illustrates well the fallacy of designing by rule-of-thumb methods. The writer would go even further and take into account the restraining effect of the supports. It is seldom that a continuous beam is supported on joints which are free to turn. It is usually rigidly connected to the columns, and the bending moments in both must be calculated and the design proportioned accordingly.

In a bent, with equal or nearly equal story heights, the slope deflection equations for any one floor may be written independently of the other floors, by assuming that the angles of rotation of the joints immediately above and below are equal to those at the floor under consideration. This is equivalent to assuming a hinged-end condition in all the columns at the mid-story heights. In a symmetrical three-span bent, such as that described by the

* Prof. of Structural Eng., Ohio State Univ., Columbus, Ohio.

author, this results in two equations and two unknown slopes when the loads are symmetrical, as they are for maximum span moments and for dead load.

A. Lincoln Hyde,* M. Am. Soc. C. E. (by letter).—The author is to be commended for his efforts to simplify, for practicing structural engineers, the frequently occurring problem of continuous beams over three spans, symmetrical with respect to end spans, but with the middle span varying from 0.2 to 2.5 times the end span. The limits of his values of x seem to be well chosen. For office buildings, hotels, hospitals, etc., they will fall well below 1.0, but for highway bridges in locations where it is desired to provide wide middle channels, the values of x may approach 2.5.

The writer feels that some designers will be saved considerable work by the use of the author's table of moment factors (Table 3), but designers of reinforced concrete are vitally interested in maximum shears and in the location of inflection points as well as in maximum bending moments.

For his own use the writer has prepared tables of reaction coefficients for beams continuous over three spans, the end spans being equal, and the middle span varying from 0.2 to 2.5 times the end span. With these tables the designer with little labor, may compute maximum bending moments and maximum shears, and may also locate inflection points. Tables 5 and 6 are herewith submitted with the hope that they may supplement Table 3, and prove of value to other designers. They were developed from the well-known Merriman formulas for a symmetrical span arrangement; x is the ratio of the middle spans, and all coefficients are computed on the basis of outside spans.

To find any reaction, first find the ratio, x, of the middle span to the end span, and then multiply the reaction coefficient, θ, by $w\,l$. The value, w, must be the dead load or the live load per linear foot as the case may be, and the value, l, must be the length of the end span, in feet. The dead and live load effects must be added for total effect.

Application of Reaction Coefficients.—Using the data of the author's Example 1, and dealing with Span 12: For full uniform dead load, and uniform live load over both end spans,

$$R_1 = 0.417 \times 67 \times 22.5 + 0.4218 \times 60 \times 22.5 = 630 + 570 = 1\,200 \text{ lb.}$$

The section of zero shear and maximum bending moment is distant to the right of Support 1,

$$\frac{630 + 570}{67 + 60} = 9.45 \text{ ft.}$$

The maximum bending moment is,

$$M_{12} = 1\,200 \times 9.45 - 127\,\frac{(9.45)^2}{2} = 5\,670 \text{ ft-lb.}$$

which checks the author within 1 per cent.

The inflection point is distant to the left of Support 2,

$$22.5 - 2 \times 9.45 = 3.60 \text{ ft.}$$

The shear at Support 1 is 1 200 lb., and at the left of Support 2, it is,

$$1\,200 - 22.5 \times 127 = -1\,660 \text{ lb.}$$

For Span 23 the loading for maximum bending moment is the same as before. The reaction at Support 2 is,

$$R_2 = 0.783 \times 67 \times 22.5 + 0.5871 \times 60 \times 22.5 = 1\,960 \text{ lb.}$$

and,

$$M_{23} = 1\,200 \times 27 + 1\,960 \times 4.5 - 127 \times 22.5 \times 15.75 - 67 \times 4.5 \times 2.25 = -4\,470 \text{ ft-lb.}$$

which checks the author closely.

The bending moment being negative over the entire middle span, there will be no inflection point between Supports 2 and 3. The shear at the right of Support 2 is,

$$1\,200 + 1\,960 - 2\,860 = 300 \text{ lb.}$$

The maximum bending moment at Support 2 occurs under the full uniform dead load, and uniform live loads over Spans 12 and 23. The reaction at Support 1 for this loading is,

$$R_1' = 630 + 0.4089 \times 60 \times 22.5 - 0.0050 \times 80 \times 22.5 = 1\,170 \text{ lb.}$$

and,

$$M_2 = 1\,170 \times 22.5 - 127 \times 22.5 \times 11.25 = -5\,820 \text{ ft-lb.}$$

which again checks the author closely.

HAROLD E. WESSMAN,* ASSOC. M. AM. SOC. C. E. (by letter).—This and other recent papers† relating largely to moments in continuous spans are focusing the attention of structural engineers more and more on "statically indeterminate" structures. Scientific research has been stimulated and means are being sought to simplify methods of analysis, so that the designer in continuous structures may determine his unknown forces without going through long, involved, tedious, and costly computations. There has been a tendency in some circles to allow for the unavoidable presence of continuity by large factors of safety or arbitrarily selected coefficients, which have been established by well-meaning authorities for use in specific cases only. The writer believes that within the next few years there will be radical developments in this field of analysis, which will not only check the tendency to shroud the so-called "indeterminate" structure in a cloak of mystery, but will present it in such a light that design practice will know it better and use it more intelligently. Some engineers apparently believe that "statically indeterminate" structures are "absolutely indeterminate" structures and cannot be analyzed by any means.

Mr. Oesterblom, however, makes a rather sweeping indictment of universities, municipal authorities, and consulting engineers on what he states is their current practice in the teaching of design or the actual design of continuous structures. No doubt there are cases warranting his indictment, but general conclusions are not justified. The writer has been connected with all

* Instr., Dept. of Civ. Eng., Univ. of Illinois, Urbana, Ill.

† "Moments in Restrained and Continuous Beams by the Method of Conjugate Points", by L. H. Nishkian and D. B. Steinman, Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 1; and "Distribution of Reinforcing Steel in Concrete Beams and Slabs," by Boyd S. Myers, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 174.

three groups mentioned by the author and knows that representatives of each* are facing the facts of design for continuous structures as they exist and are not adhering blindly to those conventional rules found particularly in reinforced concrete design codes and which apply only in a limited number of cases.

The author takes the familiar three-moment equation in a form similar to that presented by Clapeyron and from it derives expressions for the moments at the critical points in a three-span system due to loading one span at a time with a unit uniform load per foot. The two outside spans are alike and of length unity and the center span is of variable length, x. The critical points are at the supports and at or near the center of each span. For the system outlined, the three-moment equation is not particularly burdensome and lends itself readily to the computation of a table such as the author makes (Table 3); but when the systems are decidedly unsymmetrical, when they have three or more spans, and involve variable moments of inertia, this method becomes very complex and tedious. Moreover, when the beams or girders are framed into restraining columns or walls at the supports, it cannot ordinarily be used at all. The writer is familiar with several methods for computing moments and shears in continuous systems. The one which he prefers, is extremely flexible, may be readily applied regardless of the number of spans, varying moment of inertia, or restraint at supports, and gives accurate results with remarkable rapidity. This method has been used in checking the author's Table 3 and in obtaining results which follow.

The author loads one span at a time and computes "moment factors" for the point of maximum moment in the loaded span, for the mid-points of the unloaded spans, and for the supports. In the middle span, the point of maximum positive moment is the center of the span; but in each outside span when loaded, it is approximately at 0.41 from the support instead of at the center. For the effect in the same span due to loads on the other spans, the author computes the moment ordinate, not at the same point where his maximum positive moment occurred, but at the center of the span. For the combined moment due to loading all the spans, he consequently adds moment ordinates which do not occur at the same point. An inspection of Fig. 2 will make this clearer. This procedure is somewhat inconsistent, but the author justifies it by stating that, "on all the spans the lines representing the two unloaded effects are compensating, and the resultant of the two is almost horizontal." That is only true for the outside spans when $x < 0.60$. (See Table 3.) When $x > 0.6$, the secondary $-M$ in the first span, due to the second span load, becomes very much greater than the secondary $+M$ in the first span due to the third span load.

The total combined moment is not exact (as the author states), but it is close enough for practical purposes, being 1% in error when the ratio of center span to end span is 0.5 and about 4% in error when all the spans are equal in length. If all ordinates had been determined at the mid-points, the error would vary within nearly the same range.

* "Structural Design of Bridges in Grant Park," by C. R. Hoyt, Assoc. M. Am. Soc. C. E., *Journal*, Western Soc. of Engrs., October, 1925; and, "The South Park Boulevard Viaduct," by T. L. Condron, M. Am. Soc. C. E., *loc. cit.*, July, 1923.

Moreover, the author's coefficients are based on the assumption of knife-edge supports. Even in slabs and beams not framed into columns or deep girders, the actual conditions give area support rather than line support. In addition, they develop some restraint, the effect of which is to reduce the $+ M$ in the center of the span and in some cases the $- M$ at the support.

Those responsible for the codes of the Joint Committee on Specifications for Concrete and Reinforced Concrete, both old and new, and the American Concrete Institute Code may have had this effect in mind when they specified the clear span as the effective length to be used in determining moments. Definite information on this point apparently is difficult to obtain.

In view of the foregoing, the writer believes that the author could have saved himself some work by computing the span moments at the mid-points only and at the supports. The results are accurate enough for those practical purposes for which the author's moment factors may be used, namely, the design of three-span slabs, and beams symmetrical, or approximately so, about the center span and with little or no restraint at the supports.

The author illustrates the use of his table of moment factors (Table 3) by application to a typical design problem, a three-span system with a 9-ft. corridor span and two outside spans, 22 ft. 6 in. each. After finding total maximum positive and negative moments for dead load over all spans and moving uniform live load, he compares them with the moments obtained by using the conventional coefficients, $\frac{1}{10}$ and $\frac{1}{12}$, which were never intended to apply to anything but equal spans. Naturally, there is a large discrepancy in the two results. (See Table 4.) The author points to this as a very common case in which moments are most erroneously calculated. The writer feels that the case is the exception rather than the rule, for he doubts very much whether the average designer would try to apply the conventional coefficients for equal spans to systems similar to that of the author, in which the center span is so much shorter than the end spans. The picture of the physical action of the short center span would be apparent enough to most designers to warn them of high negative moment at the supports and the possibility of negative moment over the entire center span.

The author calls attention to the value of the moment factors in showing the effect on any critical point due to loading in any one span and how certain span loads must be omitted to obtain maximum effects. The writer would like to call attention to the value of qualitative influence lines for determining the placing of live loads to cause greatest effect at the points to be considered. For those to whom the concept of the influence line as the shape of the deformed structure when the particular effect is acting at the point under investigation is familiar, the sketching of the shape of the influence line is only a moment's task. The positive and negative areas under the influence line then indicate the position of live loads to give maximum positive and negative effects.

Fig. 3 shows influence lines for moments at various governing points in a three-span system. Loading conditions for maximum positive and negative

effects are also indicated. For the three-span system, positions of loading are apparent to some designers without drawing influence lines, but where there are more than three spans, and especially where there is multiple-bent or multi-story framing, qualitative sketching of influence lines is of great value. In most cases, only the sketch is needed; but, occasionally, where maximum moments or shears due to a small number of heavy moving concentrated loads is wanted, it may be advisable to determine the actual influence ordinates, in other words, to find the quantitative influence line. It is a matter of incidental interest to note that the author's moment factors are measures to some scale of the area beneath the influence lines, the scale depending on the ratio of span lengths.

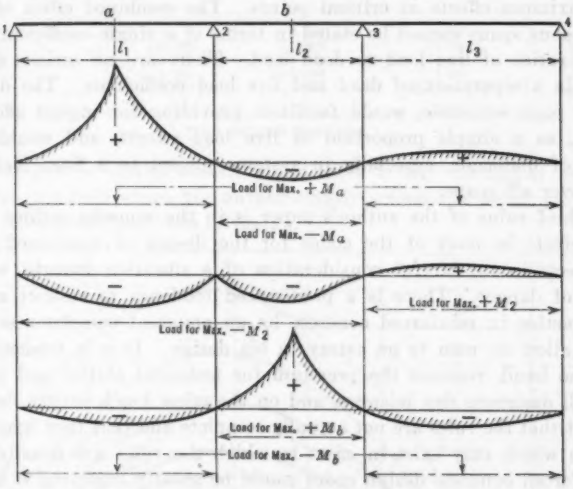

FIG. 3.—INFLUENCE LINES FOR MOMENTS AT CRITICAL POINTS.

The author is to be commended for calling attention to the possible existence of negative moments over the entire center span, but he sets his point of danger too low. He states,

"Indeed, the center spans are very severely punished by the end span loads, and the span ratio has to reach 0.60 before the danger of negative moments is avoided."

The author overlooks the effect of varying the ratio of $\frac{\text{live load}}{\text{dead load}}$. This does not have to be large or unusual to cause negative moment over the entire center span, even when the center span is greater in length than the outside spans. Moreover, as the span ratio becomes greater than 1.0, negative moment may occur along the entire length of the outside span, necessitating tension steel all the way across the top as well as in the bottom of slabs, beams, and girders. This is a fact which is often overlooked in design, particularly in equal span systems, because they are usually designed in

accordance with codes, in which the moment coefficients specified completely ignore the great possibility of the existence of negative moment at the center of the spans. Conditions very often arise, that require tension reinforcing in the top across the entire length of the system.

The author is also to be commended on his plea for the separation of dead load from live load in computing moments. In steel design, they are usually separated, but in reinforced concrete design, it seems to be quite general practice to combine the two. The writer believes this is due largely to the prevailing codes of design for reinforced concrete which specify moment coefficients to be used for combined dead and live load.

Dead load is present over all spans; live load is placed only where it will cause maximum effects at critical points. The combined effect of the two in continuous spans cannot be stated in terms of a single coefficient that will cover all ratios of live load to dead load. There are no serious difficulties involved in a separation of dead and live load coefficients. The distinction would be more scientific, would facilitate providing for impact effects when necessary, as a simple proportion of live load effects, and would promote economy of materials, especially in systems subject to a fixed loading that extends over all spans.

The chief value of the author's paper is in the remarks calling attention to the defects in most of the codes for the design of reinforced concrete. Such defects invite careful consideration of a situation fraught with some elements of danger. There is a pronounced tendency to restrict and guide design practice in reinforced concrete by an apparent completeness of rules that will allow no man to go astray in his design. It is a tendency which, on the one hand, removes the premium for technical ability and judgment, making all designers day laborers, and on the other hand, invites danger due to the fact that the rules are not actually complete and that they ignore actual conditions which may exist in cases to which the rules are usually applied. The reinforced concrete design codes would be greatly improved if they were patterned more closely after existing specifications for steel design which do not attempt to "corral" structural analysis.

ROBERT M. WILDER,* JUN. AM. SOC. C. E. (by letter).—The writer thoroughly agrees with the author as to the danger of neglecting such important factors as variability in span lengths, loads, and sections. The author has very ingenuously evolved a table (Table 3) to facilitate the calculation of moments in continuous beams with due regard to these factors.

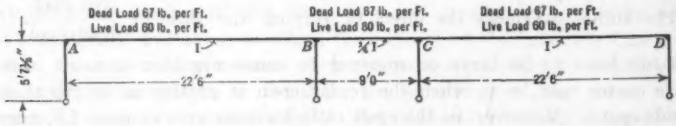

FIG. 4.

One factor which influences the moments in beams just as certainly, has been entirely neglected; that is, the restraint offered at the support to angular

* Asst. Supt., Seaboard & Southern Const. Co., Jacksonville, Fla.

deflection of the beam at that point. This restraint may be due to the supporting columns in the case of beams, or to the supporting beams in the case of slabs.

TABLE 7.—MAXIMUM MOMENTS IN FIG. 4, DUE TO VARIOUS DEGREES OF COLUMN RESTRAINT, IN FOOT-POUNDS.

Maximum moment at Point.	COLUMN RESTRAINT OR MOMENT OF INERTIA OF COLUMNS DIVIDED BY MOMENT OF INERTIA OF END BEAMS.			
	0*	$\frac{1}{8}$	$\frac{1}{2}$	∞
A (toward *B*)	0	2 080	−3 870	−5 360
Center *A B*	±6 800	±5 200	±3 880	±2 680
B (toward *A*)	−3 540	−4 200	−4 800	−5 360
B (" *C*)	−3 540	−2 680	−1 830	− 990
Center *B C*	−2 010	−1 200	−460, or +220	± 500

* No column restraint.

This restraint is seldom absent where there is any continuity, especially in buildings, the field which the author rightly stressed as being particularly subject to "handbook" methods of design.

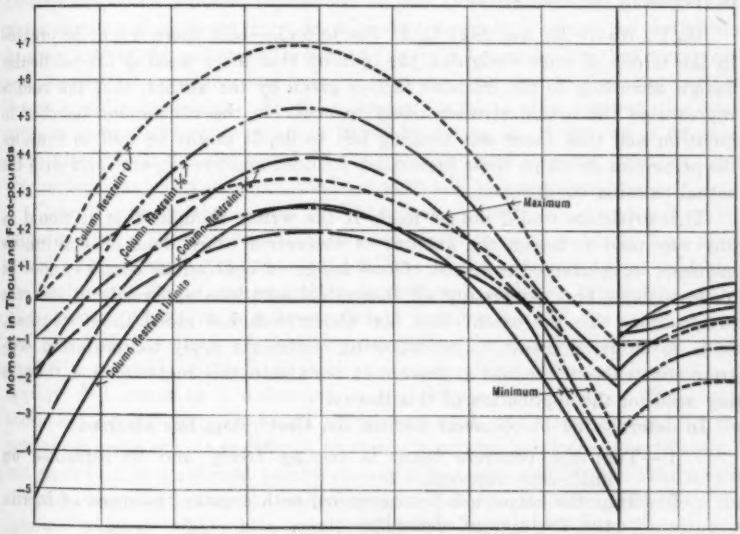

FIG. 5.—EFFECT OF COLUMN RESTRAINT ON THREE-SPAN BEAMS.

To determine the actual effects of column restraint, the writer used the same illustration presented by the author, added various conditions of column restraint, and calculated the maximum moments. This case is shown in Fig. 4. It might be noted that within the limits of practical computation the results would have been the same with columns above as well as below, their

moments of inertia being one-half those used in the case of columns below only. The results of the calculations are given in Table 7.

The results are shown graphically in Fig. 5. The upper curve in each case is for loadings producing maximum moments; the lower, minimum moments. Only one-half of the three spans is shown, as the other half would be symmetrical.

The cases of restraint used are quite common in any building and, in most instances, the values would be between the nominal value, ½, and infinity. It can thus be seen that neglecting the effect of column restraint is quite as dangerous as neglecting the other factors.

In the case of concrete construction still another factor presents itself, which was not noted in this paper, namely, the effect of moments of inertia varying from center to support in the same beam.*

The arbitrary moment factors used in so many specifications and building codes are admittedly intended only for certain general conditions of spans, loads, and sections. Where the actual conditions depart from these general conditions to such an extent that the code cannot be modified by ordinary judgment, the designer should make a careful analysis of the structure, taking into consideration not only the factors of continuity, span, load, and section, but also such important factors as restraint at supports and varying moments of inertia in the same span.

W. F. Way,† M. Am. Soc. C. E. (by letter).—Lest there might be created in the minds of some designers, the opinion that after making his particular design according to the moment factors given by the author, that the results represented the actual stresses likely to occur in the continuous member in question and that there was nothing left to do, it might be well to consider the principles on which these factors are founded and to compare them with the actual existing conditions.

This criticism would not be made if the writer thought that it would in any way tend to lessen the amount of theoretical work done on continuous members in reinforced concrete. Good design in continuous beams cannot be made without first exhausting all theoretical solutions applicable to the case in question. To the extent that Mr. Oesterblom has aided these solutions, he is to be given credit. The following comments apply to reinforced concrete construction because at present it is only in this material that there is any need for the application of this theory.

In determining his moment factors Mr. Oesterblom has assumed:

1.—That the concrete beam is resting freely and unrestrained on knife-edge supports.
2.—That the beams are homogeneous, with constant moment of inertia and modulus of elasticity.
3.—That the stresses in the beams are unaffected by shrinkage.
4.—That the temperature stresses are negligible.

Consider these assumptions in order to see how nearly they parallel actual concrete construction.

* The effect of this factor was shown by Mr. R. E. Spaulding in an able article in *Engineering News*, January 13, 1910.

† Constr. Engr. for Henry & McFee, Seattle, Wash.

Instead of the beam resting freely on a knife-edge support, more often it is resting on a building column and frequently on haunches. In addition, there is often a column above the beam continuous with the support. In this case the author's moment factors are certainly altered, the amount depending on story height, spans, and moments of inertia of columns and beams. In a few instances these factors may be small enough to be neglected, but not in many; more often they will alter the factors considerably. Building codes and most textbooks alike neglect this case, the only one suggesting a method for the amount of negative moment in a continuous beam over a wide support, that has come to the writer's attention, is given in "Beton Kalender."* In important and repeat work this method should be only one of several used in arriving at a fair average for the proper figure for design.

Referring to the second assumption, it is true that a reinforced continuous concrete beam is not composed of a homogeneous material, nor has it a constant moment of inertia or modulus of elasticity. In most instances, the difference between this assumption and actual conditions is probably so small that it may be neglected. However, the facts should be realized as it is not improbable that they may materially affect the moment factors in special cases.

It is well known that concrete shrinks considerably during the early period of hardening. This shrinkage induces considerable compression in the reinforcing steel—the amount depending on the steel percentage, cement used, water content of concrete, etc. In a precast concrete project† the writer set gauge points in the main reinforcement for forty beams before they were cast, and observed the compression induced into the steel due to shrinkage of the concrete while hardening. In these beams, tested in this manner, the compression amounted to an average of 12 000 lb. per sq. in. at the end of 60 days. Even after placing these beams in the structure and pouring the slab, thus placing full dead load on them, the bars were still in compression.

There is even another aspect to this property of reinforced concrete which probably affects the stresses in continuous beams more than in the case mentioned. For example, assume a tall building of the apartment type, in which the continuous beams are supported by two wall and two interior columns. The usual construction is a large column forming part of the exterior wall and very lightly reinforced, while to save space the interior column is made as small as possible with a high steel percentage. This difference in steel percentage will result in a difference in the shrinkage coefficient. Since this coefficient depends on the brand of cement used, the water content in the poured concrete, etc., it is difficult to assign a general value for this difference, but according to published results it might be taken as 0.0003. This means that for every 10-ft. story the wall column will shorten 0.036 in. more than the interior columns. This is a small difference but in a 7-story building it amounts to a total of ¼ in. Even this is not realized in buildings, but it must be acknowledged that some force is required to reduce this difference and that this same force is altering the stresses in the continuous beams tying the columns together, which added to the stresses induced into the continuous

* 1923 Edition, p. 305.

† *Engineering News-Record*, March 13, 1924.

beams, due to difference in column shrinkage, would be of sufficient magnitude to alter the theoretical moment factors considerably.

As for temperature stresses in reinforced concrete building construction, the effect is similar to the case of shrinkage stresses. Take the apartment house example again and assume the exterior walls to be of concrete, stuccoed. During the winter season the difference between the temperature of the interior and exterior columns may easily be as much as 60° Fahr., which would mean that for every 10-ft. story there would be a difference of 0.043 in. in the expansion between the interior and exterior columns. During the summer seasons this condition might easily be reversed. The changing elevations of the supports of the continuous beams will most certainly alter the moment factor, and the temperature stresses added to the shrinkage stresses will most likely be of measurable magnitude.

In the closing paragraphs of the paper severe criticism is made of the report of the Joint Committee on Specifications for Concrete and Reinforced Concrete, principally because no definite regulation was made for "continuous beams with unequal spans". A similar criticism might well be made of the author because he has offered no solution whatever for continuous beams with fixed ends. In general construction it is seldom that continuous beams with free ends occur. They are usually at least partly fixed if not entirely, and it is quite as important to have a solution for one case as for the other.

Since it is impossible to make an accurate mathematical design for a reinforced concrete beam, empirical factors must be used for building codes. Committees writing these codes have realized this and, as a member of the Building Code Committee of Seattle, Wash., the writer felt no chagrin at Mr. Oesterblom's severe criticism.

Reinforced concrete buildings have been built and are still being constructed that have and will give satisfaction. It is not the writer's intention in the least to discredit properly designed and constructed reinforced concrete structures. It is the intention of this discussion to show that the assumptions on which Mr. Oesterblom based his calculations for his moment factors are far from being realized in actual construction in reinforced concrete. It is well that these limitations should be clearly understood by the designer, and, while it may be impossible to solve their numerical influence exactly, still this influence can at least be sensed by the designer and some provision made in the finished structure to carry these stresses.

H. M. HADLEY,* ASSOC. M. AM. SOC. C. E. (by letter).—The author's discussion of and comments on the practical present-day methods of designing continuous beams very happily describes and appraises them. They are arbitrary; even capricious. The only thing to be said in their favor is that they are simple, and that things are accomplished by them. The designer looks at his spans and his loads; considers for a moment; decides that $w\,l$ over something is about right; and forthwith proceeds with his computations. An experienced man will form judgments that may quite closely approximate the theoretical stress distribution; the judgments of the inexperienced man

* Dist. Engr., Portland Cement Assoc., Seattle, Wash.

will not be so close. In either event some definite result will be obtained and some decision reached that will find expression in designated sizes of beams, specified quantity of reinforcement, or similar directions. Such designs, when built and submitted to the actual test of gravity, will in most cases appear to be satisfactory. Nothing alarming happens; a few cracks may develop; nothing more. The construction stands up and carries applied loads without pronounced signs of distress, and, in the busy rush of affairs, with these results the designers are, perforce, content.

Probably no one is wholly pleased with such methods of design, but in the absence of reasonably simple and economical means of obtaining a correct solution of the problem, the arbitrary and expeditious ways of designing continuous beams will doubtless continue to find favor.

Mr. Oesterblom's selection of the continuous beam of three spans as the one of outstanding importance is well taken. It is of more frequent occurrence than any other, and in multi-storied, typical construction that is repeated over and over again in the same building, this specific problem, if any, is deserving of a correct solution, because the economies that may be effected thereby are multiplied manyfold. Similarly, such buildings offer opportunities for repeated mistakes.

In giving separate consideration to dead and live loads and in treating the spans individually, determining the separate moment effects, and combining them for maximum conditions, Mr. Oesterblom's treatment is most excellent and logical. The effect of loads on adjacent spans is made clear and plain by this method, and one can see the influence of the several parts in the combined result.

The statement that moment factors are not properly a subject for regulation by anything akin to a code has an engaging interest. King Canute and the rising tide come to mind. Will the day come when $\frac{w\,l^2}{12}$ will no longer be established and ordained in American building laws?

As to the moment factors in Table 3, they apply exactly to uniform loads and symmetrical span arrangements; but as loads depart from uniformity and spans from symmetry, so do these moment factors depart from true and proper values. Why "moments due to equi-distant concentrated loads are so nearly equal to uniform loads that the same moment factors would apply", is not wholly apparent. The adaptation of these moment factors to the case of different moments of inertia in the different spans is not a matter of simple facility. Neither is it clear why an attempt should be made to develop moment factors except for the supports. With the moments at the supports known, the stress distribution elsewhere becomes a simple problem, and it is only for uniform loads that these mid-span factors apply at all.

These difficulties seem to be inherent in the approach to the problem by the Theorem of Three Moments. Mr. Oesterblom himself recognizes the trouble in his statement that "clearly it is impracticable to make a table of moment factors for all possible and reasonable span combinations." He states that 2 025 combinations with 15 moment factors each would be required to

cover spans varying from 8 ft. to 30 ft. by 6-in. increments. It is many times as impracticable if, to the moment factors for all possible and reasonable span combinations, are added the moment factors for all possible and reasonable load combinations.

From another angle of approach, however, all possible and reasonable span combinations together with all possible and reasonable load combinations become subject to an extremely easy and simple treatment. A method of "unbalanced moments", developed by the writer, which is a special application of the slope deflection method, makes it possible to derive coefficients for the support moments, which are as true and "universal" as Equation (1).

Such coefficients, for the author's case of a continuous beam of three spans, with free ends and unyielding supports, are given in Fig. 6. They are in algebraic form and are expressed in terms of the "stiffness factors" of the three spans. For a constant value of the modulus of elasticity, these "stiffness factors" are simply the values obtained by dividing the moment of inertia of each span member by the span length, that is, $K = \frac{E\,I}{l}$. Fortunately, it is the relative and not the absolute value of these "stiffness factors" that is of importance and affects the stress distribution in the system. The derivation of these coefficients will not be presented herein, but the method of their use will be briefly stated and they will be applied to two problems.

The successive steps in their application are as follows:

(1) Determine the relative "stiffness factors" of the several spans.

(2) Substitute these values in Fig. 6 and obtain the numerical coefficients that are applicable to the particular problem under consideration.

(3) Consider each span of the continuous beam as a separate, individual, single span with fixed ends. Compute the end moments which would result from the loads upon the span under this assumption.

(4) Next, imagine these separate and individual fixed-end spans with their end moments to be joined and connected, to form the three-span continuous beam with free ends. Following this joining of the separate, individual, fixed-end spans, a complete re-adjustment of stress from that assumed under Step (3) occurs throughout the system. At Support (1), the free end of the continuous beam, there is nothing to resist or balance the moment which would develop there if Span 12 were the separate, fixed-end span that has previously been assumed. Consequently, this moment, unbalanced, must change and fall to zero, but in so doing it changes the stress distribution and the elastic curve of the beam in all spans. For a moment at any support to change its value implies a movement or rotation at that point, which movement and elastic adjustment carries out to the extremities of the system.

At Support (2), Spans 12 and 23 meet and are joined. Each of these spans had end moments under the assumption in Step (3). These end moments are opposite in direction—clockwise and counter-clockwise—and although they may be equal and may exactly balance one another, are generally unequal, either one side or the other being larger. It is the excess moment, the amount by which one side is greater than the other, that is unbalanced, and that, in

changing, lessening, and developing a resistance, produces a re-adjustment of stress throughout the entire system. As for the equal, opposite, and balanced moments—the full end moment of one span, and its equal and opposite

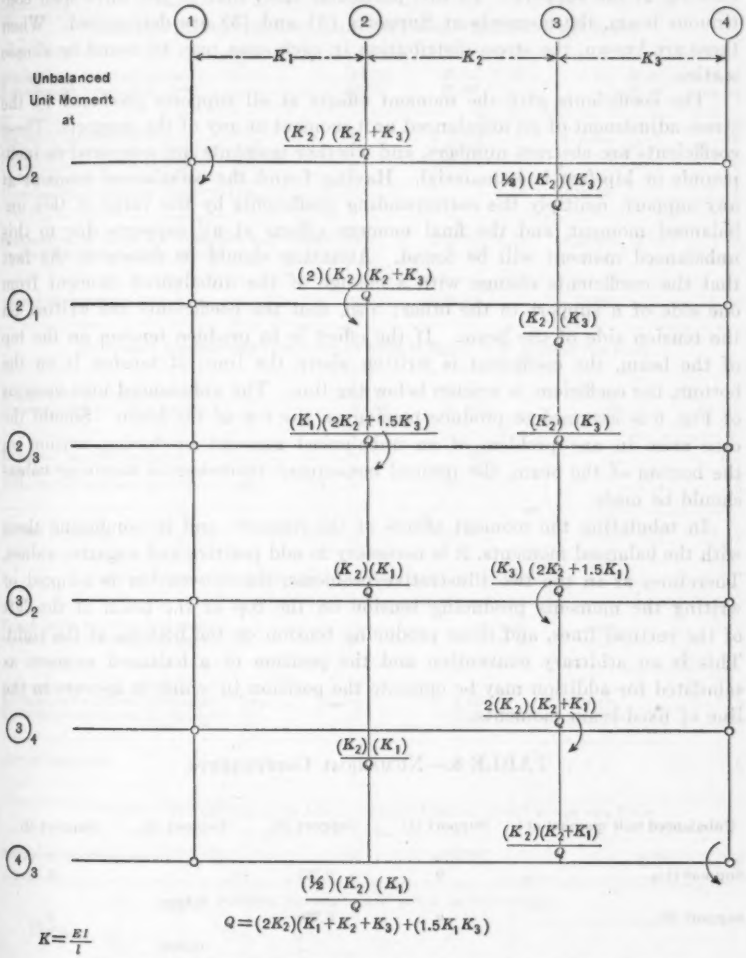

FIG. 6.—VALUES OF MOMENTS AT SUPPORTS DUE TO STRESS ADJUSTMENTS OF UNBALANCED UNIT MOMENTS.

part of the end moment of the other span—these are balanced and create no change in stress anywhere in the system, regardless of their value or magnitude. Follow a similar procedure at Supports (3) and (4).

(5) The final step is to calculate the balanced moments at each support, and the moment effects produced at each support by the several unbalanced moments. The algebraic sum of these quantities gives the actual moments existing at the supports. In this particular case, that of the three-span continuous beam, the moments at Supports (2) and (3) are determined. When these are known, the stress distribution in each span may be found by simple statics.

The coefficients give the moment effects at all supports produced by the stress adjustment of an unbalanced unit moment at any of the supports. These coefficients are abstract numbers, and whether moments are measured in inch-pounds or kip-feet is immaterial. Having found the unbalanced moment at any support, multiply the corresponding coefficients by the value of this unbalanced moment, and the final moment effects at all supports due to this unbalanced moment will be found. Attention should be drawn to the fact that the coefficients change with a change of the unbalanced moment from one side of a support to the other; also, that the coefficients are written on the tension side of the beam. If the effect is to produce tension on the top of the beam, the coefficient is written above the line; if tension is on the bottom, the coefficient is written below the line. The unbalanced unit moment of Fig. 6 is assumed to produce tension on the top of the beam. Should the case arise in any problem of an unbalanced moment producing tension on the bottom of the beam, the natural consequent inversion of resulting values should be made.

In tabulating the moment effects at the supports and in combining them with the balanced moments, it is necessary to add positive and negative values. Therefore, as in the two illustrative problems, the convention is adopted of writing the moments producing tension on the top of the beam at the left of the vertical lines, and those producing tension on the bottom, at the right. This is an arbitrary convention and the position of a balanced moment as tabulated for addition may be opposite the position in which it appears in the line of fixed-beam moments.

* All bending moments are given in kip-inches.

Then,

$$K_1 = \frac{I}{22.5} = 1.0 \text{ (relatively)}$$

$$K_2 = \frac{I}{9} = 2.5$$

$$K_3 = \frac{I}{22.5} = 1.0$$

Substituting these values in the algebraic coefficients given in Fig. 6, the results are as shown in Table 8. The numerical solution of Example 1 is given in Table 9.

The maximum "positive" moment in Span 12 will occur when the moment at Support (2) is a mimimum. By inspection of the values found, this will occur with dead load on all spans and live load on Spans 12 and 34. With this loading the moment at Support (2) is 62 410 in-lb.

For the case of a beam of span length, l, subjected to a uniform load, w lb. per ft., with a moment, M, applied at one end, the distance of the inflection point from the end at which the moment is applied is given by Equation (36):

$$X \text{ (feet)} = \frac{2\,M}{w\,l} \qquad (36)^*$$

Between the free end and the inflection point, the stress distribution is that of a simple beam of load, w, and span, $l - x$. Therefore, the maximum positive moment in Span 12 is as follows:

Inflection point:

$$x = \frac{2 \times 62\,410}{127 \times 270} = 3.64 \text{ ft.}$$

New span:

$$22.5 - 3.64 = 18.86$$

$$M = 127 \times 355.7 \times 1.5 = 67\,600 \text{ in-lb.}$$

At Support (2) the maximum moment occurs with dead load on all spans and live load on Spans 12 and 23; combining, this is 69 570 in-lb.

At mid-span, in Span 23, the "negative" moment will be greatest with dead load on all spans and live load on Spans 12 and 34. With such loads the moments at Supports (2) and (3) are 62 410 in.-lb. Then, the moment at mid-span is,

$$62\,410 - 67 \times 81 \times 1.5 = 54\,270 \text{ in-lb.}$$

Support (3) and Span 34 are determined by symmetry. These values all agree closely with those found by the author.

Example 2.—A certain large apartment house in Seattle, Wash., has fourteen floors with spans of 22 ft. 6 in., 7 ft. 0 in., and 18 ft. 0 in.; dead load of 70 lb. per ft.; live load of 55 lb. per ft.; and relative $I_s = 5$, 1, and 5. The "stiffness factors":

$$K_1 = \frac{5}{22.5} = 0.222 = 1.6 \text{ (relatively)}$$

$$K_2 = \frac{1}{7} = 0.143 = 1.0$$

$$K_3 = \frac{5}{18} = 0.278 = 2.0$$

The numerical coefficients are as given in Table 10. The numerical solution of Example 2 is given in Table 11.

As in Example 1, the moments may be determined from Table 11 to be as follows:

* M and l must be given in same linear units.

TABLE 10.—Numerical Coefficients.

Unbalanced moment at:	Support (1).	Support (2).	Support (3).	Support (4).
Support $(1)_2$	0	0.214	0.071	0
Support $(2)_1$	0	0.429	0.143	0
Support $(2)_3$	0	0.571	0.143	0
Support $(3)_2$	0	0.114	0.628	0
Support $(3)_4$	0	0.114	0.372	0
Support $(4)_3$	0	0.057	0.186	0

Moment at Support (2), maximum..... 40 900 in-lb.
" " " (2), for maximum mid-span moment in Spans 12 and 23..... 36 100 in-lb.
Moment at Support (3), maximum..... 19 700 in-lb.
" " " (3), for maximum mid-span moment in Spans 23 and 34..... 11 600 in-lb.

The maximum mid-span moment in Span 12 is:

Inflection point:

$$x = \frac{2 \times 36\,100}{125 \times 270} = 2.14 \text{ ft.}$$

New span:

$$22.5 - 2.14 = 20.36$$

$$M = (70 + 55) \times 20.36^2 \times 1.5 = 77\,700 \text{ in-lb.}$$

and the maximum mid-span moment in Span 34 is:

Inflection point:

$$x = \frac{2 \times 11\,600}{125 \times 216} = 0.86 \text{ ft.}$$

New span:

$$18.0 - 0.86 = 17.14$$

$$M = 125 \times 17.14^2 \times 1.5 = 55\,100 \text{ in-lb.}$$

In the case of the mid-span moment in Span 23, there are moments at both ends, 36 100 and 11 600 in-lb. The excess of the larger moment at Support (2) over the smaller moment at Support (3) is 24 500 in-lb. Ordinarily, for the determination of the maximum or minimum values of the mid-span moment, this excess moment is treated precisely like the end moments in Spans 12 and 34 for finding an inflection point and new span length, etc., and, after this, a final correction is made for the smaller end moment, the value of which is applied as a constant to the results obtained. Here, however, the excess moment is so great that there is no inflection point, and no maximum or minimum value of the mid-span moment. If it is assumed that the mid-span moment is the average of the end moments, the assumption will closely approximate the truth, and any error involved will be on the safe side.

* All bending moments are given in kip-inches.

These examples have dealt with uniform loads. Any other system of loads—concentrated or variable—for which fixed-beam end moments can be calculated, can be treated with equal ease, since the method deals with unbalanced moments and not directly with the beam loads. Variable span lengths and different moments of inertia of the several spans can be handled with practically the same facility as equal spans and constant moments of inertia. The effect of settlement of supports likewise can be included in the calculations with these same coefficients in an extremely simple and ready manner.

For other than three spans, and for the cases of free ends, fixed ends, one end free, and one fixed, and of variable amounts of restraint at the ends, similar tables of coefficients can be prepared and thereby the continuous beam (continuous also in the interminable length of its required calculations) becomes simple indeed. With a simple and easy method available for calculating results, the designer can vary the moments of inertia of his members, and thereby obtain a control over the distribution of stresses in his continuous beam that heretofore has been attempted only by varying the span lengths.

While he can do this, it is to be recognized, of course, that "The Building Code", or something equally authoritative, will have its final say in the matter, and, again, the distinction between "can" and "may" is to be acknowledged and admitted—by Man, if not by Nature.

T. F. Hickerson,* M. Am. Soc. C. E. (by letter).—The writer wishes to commend Mr. Oesterblom for his interesting and valuable paper, even if it does fall far short of meeting all the conditions of practice. His Equation (1) fails to be "universal", in that it ignores restraints occurring at the beam terminals and at the connections with intermediate columns.

By means of the slope-deflection method, the writer has developed formulas and compiled a set of tables covering continuous beams of three symmetrical, two unsymmetrical, and four symmetrical, spans. Various cases of relative column stiffness have been taken into account. Three conditions of beam terminals have been assumed: (1) Ends hinged; (2) ends one-half fixed; and (3) ends fixed. All column terminals have been assumed as hinged, but the tables are readily adaptable to the case of fixed ends since the point of inflection (occurring at a known point along the column) corresponds to a hinge. Hence, the relative stiffness factor for a column with fixed ends is greater by a known amount than that for one with hinged ends.

Referring to Fig. 7, showing three symmetrical spans constructed monolithically with the columns, beam moments have been computed for Points 1, 2, and 2′ at the supports; Points *a*, *b*, and *c*, at the quarter, middle, and three-quarter points, respectively, of the first span; and Points *d*, *e*, and *f*, at the quarter, middle, and three-quarter points, respectively, of the second span. The total moments absorbed by the interior columns have also been computed and tabulated for all reasonable values of the middle-to-end span ratios. The reactions, R_1, R_2, R_3, and R_4, as well as the shears at Sections 1, 2, and 2′ have been computed.

* Prof. of Civ. Eng., Univ. of North Carolina, Chapel Hill, N. C.

Similarly, the case of two unequal spans has been treated, x being the ratio of shorter to longer span. Thus, if the longer span, l_1, is taken as unity, the shorter will be $x = \frac{l_2}{l_1}$.

Continuous beams of four and five equal spans have been solved for moments and shears at numerous points. The effect of a load is practically negligible beyond two adjacent spans, hence beams continuous beyond five spans may be solved with sufficient accuracy by considering three, four, or five consecutive spans as a unit. This statement is particularly true for the usual case when the beam terminals are restrained and the columns are constructed monolithically with the beams.

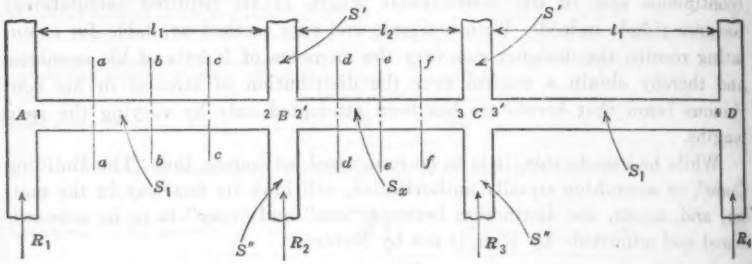

FIG. 7.

Table 12, which is typical, gives factors for the maximum bending moment at Point 2 of the second support (Fig. 7) in continuous three-span construction. Three conditions of beam terminals are considered; that is, hinged, half fixed, and fixed. Five values of the relative column stiffness, $\frac{S}{S_1}$, are considered, namely, 0, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, and 1.

The upper left-hand corner of Table 12, corresponding to hinged-beam terminals and no column restraint, embraces the special case treated by Mr. Oesterblom in Table 3.

The following notation has been used:

x = ratio of middle to end spans = $\frac{l_2}{l_1}$.

$S_1 = \frac{I_1}{l_1}$ = stiffness of each end beam.

$S_x = \frac{I_1}{l_2}$ = stiffness of middle beam.

S' = stiffness of upper intermediate columns.

S'' = stiffness of lower intermediate columns.

$S = \frac{S' + S''}{2}$ = average column stiffness.

ϕ = moment factor for a maximum moment, M_2, at Point 2.

TABLE 12.—Moment Factors, ϕ, for Maximum Bending Moment (M_2) at Point 2 (Fig. 7) of First Interior Support in Continuous Three-Span Construction.

Formula, $M = \phi\ w\ l^2$.

(Symmetrical span arrangement; x = ratio of middle to side spans; all moment factors are computed on basis of outside spans.)

In order to illustrate the application of Table 12, let it be assumed: (1) That the two end spans are each 16 ft. and the middle span is 8 ft.; (2) that the beam terminals are one-half fixed (that is, the terminal moments are one-half the values for absolutely fixed conditions); (3) that the ratio of average column stiffness to that of the end beam is $\frac{1}{2}$; and (4) that the dead load is 1 000 lb. per lin. ft., and the live load is 2 000 lb. per lin. ft. of beam. Then, $x = \frac{8}{16} = 0.5$, and from Table 12, the values of ϕ are as follows: -0.078 for first span loaded; -0.007 for second span loaded; $+0.007$ for third span loaded; giving a total of $\phi = -0.078$.

Dead moment (full loading) $= -0.078 \times 1\,000 \times 256 = -19\,968$ ft-lb.
Live moment (first and second spans loaded) $=$
$-(0.078 + 0.007) \times 2\,000 \times 256 = \ldots\ldots\ldots\ldots -43\,520$ ft-lb.

Total maximum moment $= \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots -63\,488$ ft-lb.

Considering now the moment factors which Mr. Oesterblom gives for the outside spans, the writer believes it is better to deal with the mid-sections, for the sake of simplicity. It is true that for the case of hinged or fixed beam terminals, the moment is not quite a maximum at the mid-section (the maximum being on the left of the center for hinged ends, and on the right for fixed ends); yet when the beam terminals are one-half fixed, the maximum occurs practically at the center. In any case, it is well to have coefficients for all the reactions so that complete shear and moment diagrams may be easily drawn if desired.

What Mr. Oesterblom has to say about different moments of inertia applies equally well to the cases where restraints occur at the beam terminals and column connections. These conclusions, however, are independent of the long mathematical expressions (Equations (34) and (35)). Thus, if the moment of inertia of the middle span is only one-half that of the end spans, then its stiffness is reduced one-half, just as if its length were doubled. Hence, the proper value of x (the ratio of middle span to end span) would be doubled. The load on the middle span, however, is not doubled but remains the same, but the moment factor corresponding to the middle span loaded should be divided by 4, since the bending moment varies as the square of the span.

The illustrative example given herewith was based on the assumption of equal cross-sections throughout. If the moment of inertia of the middle span is only one-half that of the end spans, then this problem requiring the true total maximum moment (M_2) would be solved as before, except that values of the moment factor in Table 12 are found opposite $x = \frac{0.5}{\frac{1}{2}} = 1.00$. Then, the values of ϕ are: -0.069 for first span loaded; $\frac{-0.034}{4} = -0.0085$ for second span loaded; and $+0.007$ for third span loaded; giving a total of $\phi = -0.0705$.

Dead moment = $-0.0705 \times 1\,000 \times 256 =$.... $-18\,048$ ft-lb.
Live moment (first and second spans loaded) =
$-0.0775 \times 2\,000 \times 256 =$..... $-39\,680$ ft-lb.

Total maximum moment =..... $-57\,728$ ft-lb.

JOHN I. PARCEL,* M. AM. SOC. C. E. (by letter).—The writer has read this paper with much interest, and while (as the author is doubtless well aware) it does not, by any means, completely solve the problem of stress analysis in building girders continuous over three spans, nevertheless, as a step toward advancing scientific design in this field, it merits the thanks of all conscientious designing engineers.

The paper serves to emphasize again the fact that the road leading to the accurate and scientific design of structures is a long one and is beset with many difficulties. Designers need, for example, a great many more experimental data to determine how far formulas, developed for homogeneous materials, will apply to composite construction, such as reinforced concrete. They also need vastly more knowledge of the actual effects of shrinkage and time yield in such construction. Nevertheless, the fact that there are so many important factors about which designers know very little, can hardly serve as a reason for disapproving any step, however incomplete, toward rationalizing the basic methods of design, and this, the writer understands to be Mr. Oesterblom's purpose.

Since many important cases are not covered in the paper, as, for example, those in which marked asymmetry exists; in which supports are yielding; or important support moments are introduced by the action of columns or walls, it would appear that an extension of the investigation would be very desirable. On account of the tedious character of the calculations of such special cases, this would seem an excellent field for the application of the mechanical method of stress analysis by means of model structures, such, for example, as has been developed and perfected by George E. Beggs, M. Am. Soc. C. E., at Princeton University, Princeton, N. J.† It is the writer's opinion that there is a large opportunity for useful investigation, not only in the field covered by the paper, but in many allied fields as well.

R. A. CAUGHEY,‡ M. AM. SOC. C. E. (by letter).—In the presentation of this paper, Mr. Oesterblom has well emphasized the need of more care in the computation of moments in beams and girders continuous over several supports. He has also done well in presenting Table 3 and in giving a treatment for continuous beams of variable moments of inertia. In spite of all this the writer fears that this or other similar papers stop somewhat short of the goal which structural engineers would like to reach.

When continuous slabs or joists are supported by girders, the torsional rigidity of which is comparatively small, the theorem of three moments is applicable; but when beams or girders of any kind frame into columns, it seems that some other means of computing the moments should be adopted.

* Cons. Engr. (Sverdrup & Parcel), St. Louis, Mo.
† *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1208, *et seq.*
‡ Associate Prof. of Structural Eng., Iowa State Coll., Ames, Iowa.

This would hold in the case of the construction mentioned by Mr. Oesterblom if the girders were placed in the transverse direction of the building and joists of one type or other were placed parallel to the length. Under such arrangement one would find, by using the slope deflection theory, a large moment in the columns and, in case the columns were very heavy, a considerable decrease of positive moment in the beams or girders between them.

Some of the structural steel companies are considering very carefully the possibilities of the welded structure, and it is probably true that in a few years the bending moments in steel beams and girders may be changed materially as they should be in concrete construction at present. In both types of construction the columns will be called upon to take moment; but even then there will be a saving of materials. These facts might suggest the use of the slope deflection theory,* but any one who has ever attempted to apply that theory will agree that the necessity of anticipating the size of sections and the labor involved in the solution of large numbers of simultaneous equations will rule it out of consideration in most cases. The writer believes, however, that with certain approximations this method can be adopted, and that it will give results sufficiently close for practical use—much closer than some of the arbitrary coefficients in common use and far closer than will be obtained by the theorem of three moments. The writer has prepared a series of curves in order to apply the method rapidly enough to make it practicable.

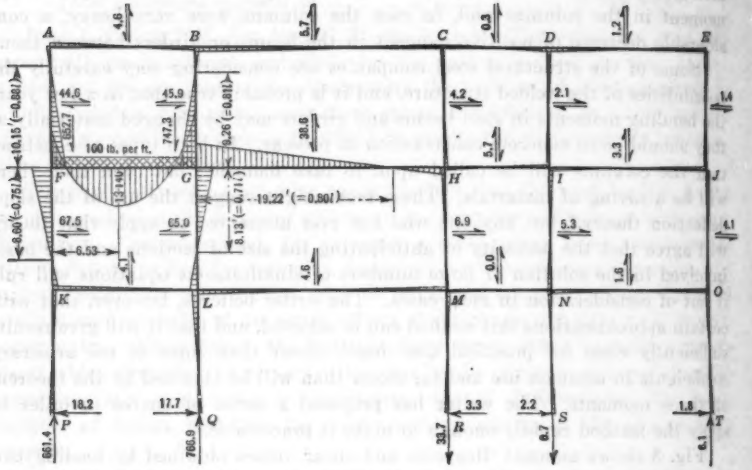
Fig. 8 shows moment diagrams and shear values obtained by loading two different panels of an unsymmetrical building frame with a uniform load.† In both cases, the effect of the load in any given panel is negligible beyond those immediately adjacent to the loaded panel. The highest value of moment outside the limits mentioned is that in Column $L\,Q$ (Fig. 8(*b*)), but very little computation is necessary to show that for any reasonable load on the girder, $G\,H$, the moment in $L\,Q$ will produce very small unit stresses in the column and that they will be maximum at the end of the column where it is stayed against buckling. This will be true generally for other members similarly located.

This would suggest dividing the structure into several parts similar to that shown in Fig. 9(*a*) and considering each part with its load separately. In the inspection of quite a large number of moment diagrams it was observed that the inflection points on columns are generally located about eight-tenths of the height above or below the floor-beams or girders. The inflection points on the horizontal members may be located from Fig. 9(*b*) which was made up from several conditions of loading on symmetrical and unsymmetrical frames. As will be noticed the location of the inflection point seems to be a function of the ratio of the lengths of loaded and adjacent spans.

The application of the slope deflection theory to such a structure becomes a very simple problem as there are only two equations to be made up and solved simultaneously. In order to simplify the derivation of equations to be

* *Bulletin No. 108*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

† These curves by E. E. Ebling, Assoc. M. Am. Soc. C. E., are obtained by the slope deflection method and are taken from a thesis prepared under supervision of the writer and submitted for the degree of Master of Science at the Iowa State Coll.



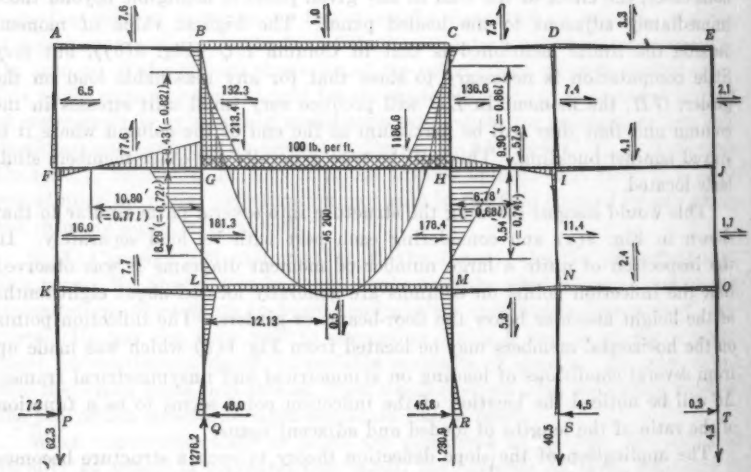


FIG. 8.—MOMENT DIAGRAMS AND SHEAR IN AN UNSYMMETRICAL BUILDING FRAME.

used, ΣK_1 will be taken as the sum of the K-values of all the members meeting the loaded beam on the left; K_2 will be the K-value for the loaded beam, and ΣK_3 the sum of the K-values of all members meeting the right end of the loaded beam. The structure can then be considered as a three-span continuous beam, $X\ A\ B\ Y$ (Fig. 9(a)), hinged at the ends, X and Y.

Applying the slope deflection equations:

$$M_{AX} = E \Sigma K_1 (3\theta_A) \quad \ldots\ldots (37)$$

$$M_{AB} = 2E K_2 (2\theta_A + \theta_B) - C_{AB} \quad \ldots\ldots (38)$$

$$M_{BA} = 2E K_2 (\theta_A + 2\theta_B) + C_{BA} \quad \ldots\ldots (39)$$

$$M_{BY} = E \Sigma K_3 (3\theta_B) \quad \ldots\ldots (40)$$

In order to have equilibrium at A and B:

$$M_{AX} + M_{AB} = 0 \quad \ldots\ldots (41)$$

and,

$$M_{BY} + M_{BA} = 0 \quad \ldots\ldots (42)$$

Substituting the values given by Equations (37), (38), (39), and (40), in Equations (41) and (42):

$$E \Sigma K_1 (3\theta_A) + 2E K_2 (2\theta_A + \theta_B) - C_{AB} = 0 \quad \ldots\ldots (43)$$

and,

$$E \Sigma K_3 (3\theta_B) + 2E K_2 (\theta_A + 2\theta_B) + C_{AB} = 0 \quad \ldots\ldots (44)$$

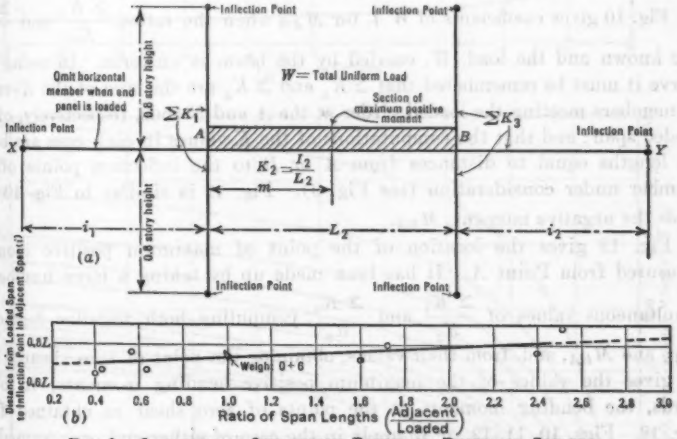

FIG. 9.—LOCATION OF INFLECTION POINTS IN BEAMS OR GIRDERS.

Assuming a symmetrical loading for $A\ B$ (Fig. 9(a)), in which case, $C_{AB} = C_{BA}$; and solving Equations (43) and (44) simultaneously, values of θ_A and θ_B are obtained which, when substituted in Equations (38) and (39), give values of M_{AB}* and M_{BA} as follows:

$$M_{AB} = -3 \Sigma K_1 C \left(\frac{2K_2 + \Sigma K_3}{4K_2 (\Sigma K_1 + K_2) + \Sigma K_3 (3 \Sigma K_1 + 4K_2)} \right) \quad \ldots\ldots (45)$$

*It will be noted that M_{AB} and M_{BA} have opposite signs. For the method of determining signs and applying the slope deflection method generally, *see Bulletin No. 108*, Eng. Experiment Station, Univ. of Illinois.

and,

$$M_{BA} = 3 \Sigma K_3 C \left(\frac{2 K_2 + \Sigma K_1}{4 K_2 (\Sigma K_1 + K_2) + \Sigma K_3 (3 \Sigma K_1 + 4 K_2)} \right) \ldots (46)$$

It is obvious that both M_{AB} and M_{BA} produce tension in the top fibers of the horizontal member, $A B$, ordinarily referred to as "negative".

Positive moment near the center line of $A B$ may be calculated with little difficulty, by first computing, by means of "moment transfer", the shear at one or both ends of $A B$ and then finding the point of zero shear or maximum moment and transferring the moment from one of the supports.

As has been suggested by Mr. Ebling, the moments carried by members of adjacent panels may be obtained by apportioning the moments, M_{AB} and M_{BA}, in such a way that the moment carried by each of the members meeting the end of the loaded girder is proportional to its K-value. These latter moments act to oppose the moments, M_{AB} and M_{BA}, thus holding the joint in equilibrium.

Explanation of Curves for Computing Moments.—In actual practice it may be necessary, in order to secure the proper sections for the beams and columns of a building, to design preliminary sections and revise them at least once and probably oftener. This would involve a large amount of computation and consume quite a little time. In order to overcome these difficulties, the writer has prepared curves which are practically self-explanatory.

Fig. 10 gives coefficients of $W L$ for M_{AB} when the ratios, $\frac{\Sigma K_1}{K_2}$ and $\frac{\Sigma K_3}{K_2}$, are known and the load, W, carried by the beam is uniform. In using this curve it must be remembered that ΣK_1 and ΣK_3 are the sum of the K-values of members meeting the loaded girder at the A and B ends, respectively, of the loaded span; and that the computations of the K-values in each case are based on lengths equal to distances from A or B to the inflection points of the member under consideration (see Fig. 9). Fig. 11 is similar to Fig. 10 and gives the negative moment, M_{BA}.

Fig. 12 gives the location of the point of maximum positive moment measured from Point A. It has been made up by taking a large number of simultaneous values of $\frac{\Sigma K_1}{K_2}$ and $\frac{\Sigma K_3}{K_2}$, computing both negative moments, M_{AB} and M_{BA}, and, from their values, obtaining the point of zero shear. Fig. 13 gives the values of the maximum positive bending moments; in other words, the bending moments at the points of zero shear as obtained from Fig. 12. Figs. 10, 11, 12, or 13 apply in the case of either end or intermediate spans.

Illustrative Problem.—Compute the bending moments and shears in a building frame, a part of which is shown by Fig. 14, for a uniform load of 2 000 lb. per lin. ft. of girder.

Moment Diagrams.—First, load Span $A B$ and disregard all the structure to the right of Point C. The ratio of adjacent to loaded span length is $\frac{9}{22.5} = 0.4$; then, from Fig. 9 (b), the point of inflection of Span $B C$ is found to be $0.72 \times 9 = 6.48$ ft. to the right of Point B. The points of inflec-

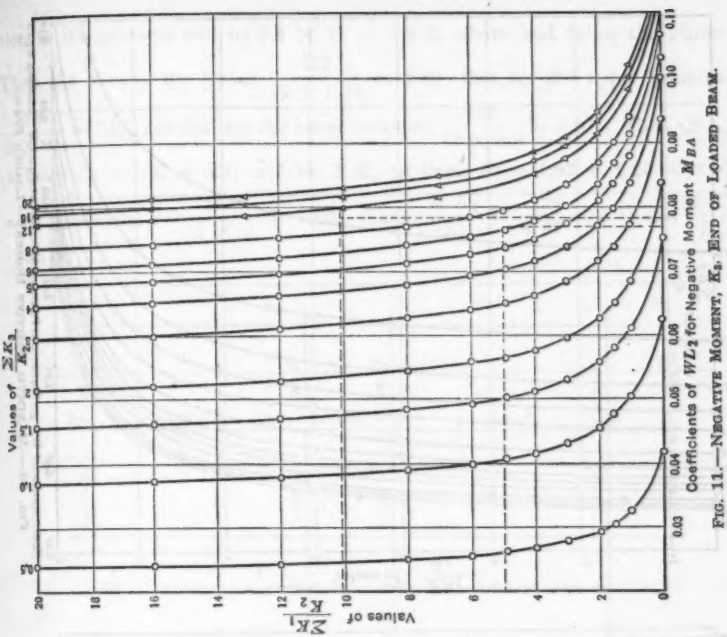

FIG. 11.—NEGATIVE MOMENT, K_2, END OF LOADED BEAM.

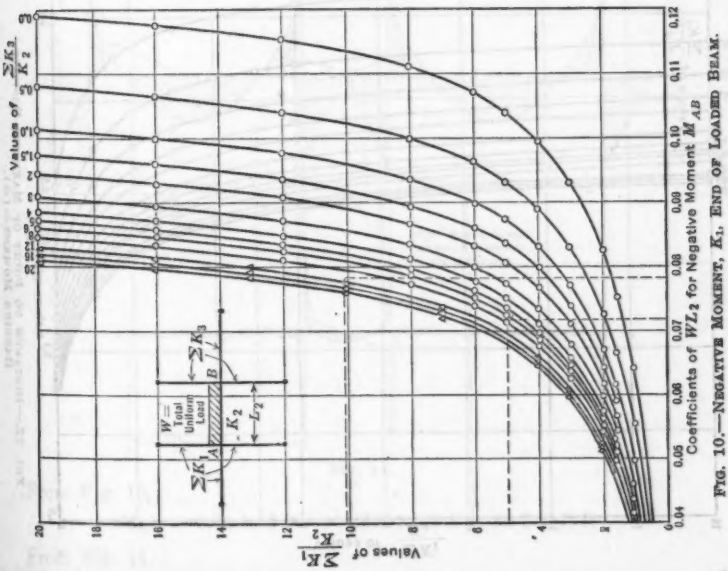

FIG. 10.—NEGATIVE MOMENT, K_1, END OF LOADED BEAM.

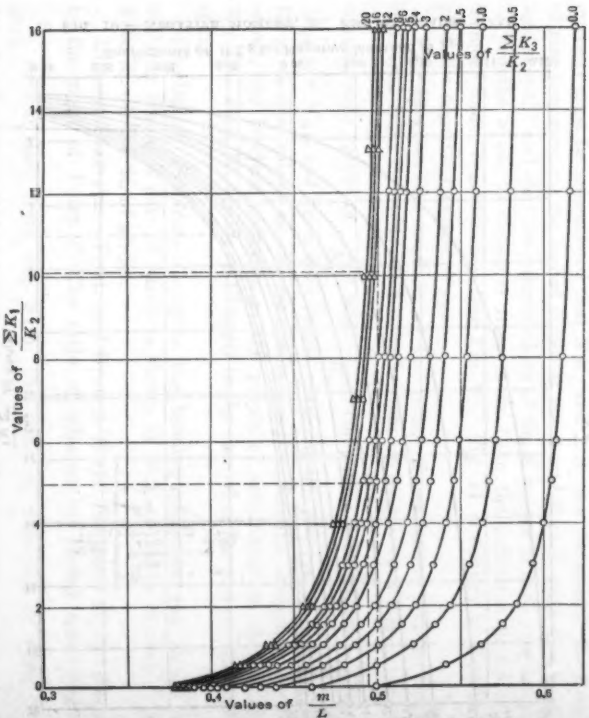

FIG. 12.—DISTANCE TO POINT OF MAXIMUM POSITIVE BENDING MOMENT—(m).

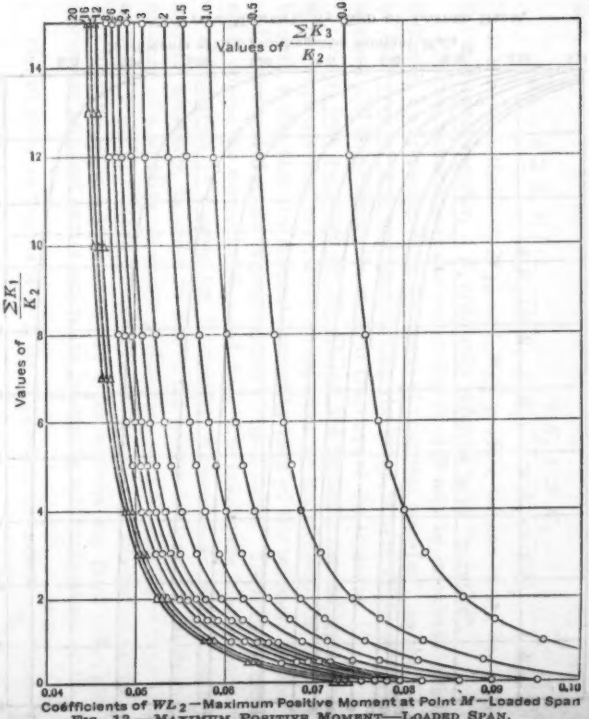

FIG. 13.—MAXIMUM POSITIVE MOMENT—LOADED SPAN.

tion in the columns will be $0.8 \times 11 = 8.8$ ft. above and below the girder. Then, the K-value for BC is $\frac{173}{12 \times 6.48} = 2.23$; that for the upper columns, $\frac{208}{12 \times 8.8} = 1.97$; and that for the lower columns, $\frac{630}{12 \times 8.8} = 5.97$. Then, ΣK_1 (at Point A) $= 1.97 + 5.97 = 7.94$; ΣK_3 (at Point B) $= 1.97 + 2.23 + 5.97 = 10.17$; and $K_2 = \frac{173}{12 \times 9} = 1.60$. Then, $\frac{\Sigma K_1}{K_2} = \frac{7.94}{6.67} = 1.19$ and $\frac{\Sigma K_3}{K_2} = \frac{10.17}{6.67} = 1.52$.

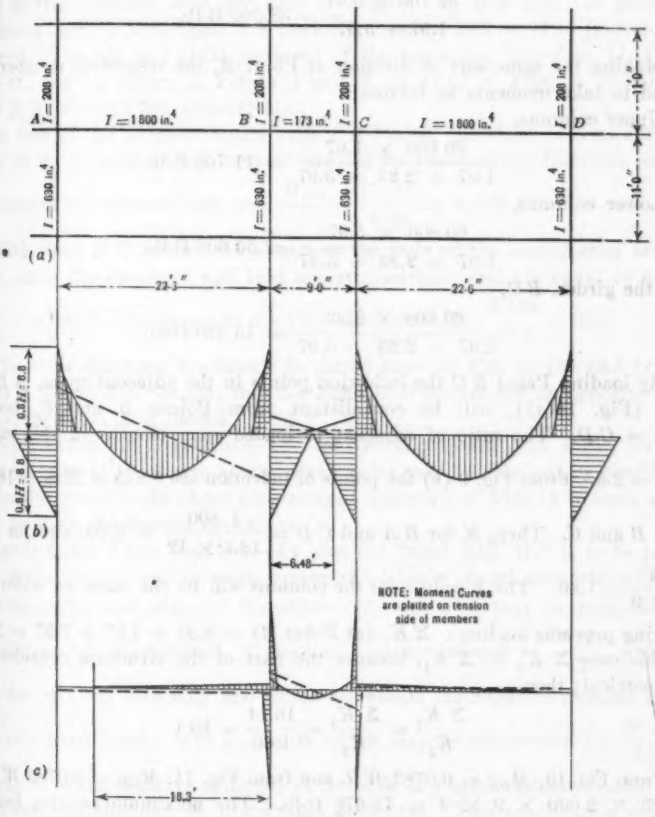

FIG. 14.

From Fig. 10,

$$M_{AB} = 0.05 \times 2\,000 \times 22.5 \times 22.5 = 50\,700 \text{ ft-lb.}$$

From Fig. 11,

$$M_{BA} = 0.06 \times 2\,000 \times 22.5 \times 22.5 = 60\,800 \text{ ft-lb.}$$

From Fig. 13,
Maximum positive moment $= 0.071 \times 2\,000 \times 22.5 \times 22.5 = 71\,800$ ft-lb.

From Fig. 12 the maximum bending moment occurs $0.49 \times 22.5 = 11.02$ ft. from Point A. (See Fig. 14(b).) Dividing the moment opposing AB between the upper and lower columns in proportion to the K-values of the columns, the moment in the upper columns is,

$$\frac{50\,700 \times 1.97}{1.97 + 5.97} = 12\,570 \text{ ft-lb.}$$

and that in the lower columns is,

$$\frac{50\,700 \times 5.97}{1.97 + 5.97} = 38\,000 \text{ ft-lb.}$$

Making the same sort of division at Point B, the respective members are found to take moments as follows:

Upper columns,

$$\frac{60\,800 \times 1.97}{1.97 + 2.23 + 5.97} = 11\,700 \text{ ft-lb.}$$

Lower columns,

$$\frac{60\,800 \times 5.97}{1.97 + 2.23 + 5.97} = 35\,600 \text{ ft-lb.}$$

and the girder, $B\,C$,

$$\frac{60\,800 \times 2.23}{1.97 + 2.23 + 5.97} = 13\,320 \text{ ft-lb.}$$

By loading Panel $B\,C$ the inflection points in the adjacent spans, $A\,B$ and $C\,D$ (Fig. 14(a)), will be equi-distant from Points B and C, because $A\,B = C\,D$. The ratio of adjacent to loaded span lengths in this case is $\frac{22.5}{9} = 2.5$. From Fig. 9 (b) the points of inflection are $0.815 \times 22.5 = 18.3$ ft. from B and C. Then, K for $B\,A$ and $C\,D = \frac{1\,800}{18.3 \times 12} = 8.20$, and for $B\,C$, $\frac{173}{12 \times 9} = 1.60$. The K-values for the columns will be the same as when considering previous loading: ΣK_1 (at Point B) $= 8.20 + 1.97 + 5.97 = 16.14$. In this case $\Sigma K_3 = \Sigma K_1$, because the part of the structure considered is symmetrical; then,

$$\frac{\Sigma K_1}{K_2} = \frac{\Sigma K_3}{K_2} = \frac{16.14}{1.60} = 10.1$$

From Fig. 10, $M_{BC} = 0.0783\ W\,L$ and from Fig. 11, $M_{CB} = 0.0783\ W\,L = 0.0783 \times 2\,000 \times 9 \times 9 = 12\,670$ ft-lb. The maximum positive bending moment at mid-span (Fig. 13) in this case is, $0.047 \times 2\,000 \times 9 \times 9 = 7\,610$ ft-lb.

Apportioning the resisting moments, M_{BC} and M_{CB}, between adjacent members at Points B and C,

$$M_{BA} = M_{CD} = \frac{12\,670 \times 8.2}{8.2 + 1.97 + 5.97} = 6\,430 \text{ in-lb.}$$

$$M \text{ (upper columns)} = \frac{12\,670 \times 1.97}{8.2 + 1.97 + 5.97} = 1\,547 \text{ in-lb.};$$

and,

$$M \text{ (lower columns)} = \frac{12\,670 \times 5.97}{8.2 + 1.97 + 5.97} = 4\,680 \text{ in-lb.}$$

Shear Diagrams.—The computation of shear for these cases is very simple. In the loaded spans the point of zero shear is the point of maximum bending moment; and, since the uniform load is known, the inclination of the line representing the variation in shear is known and the shears at the ends can be obtained by multiplying the length of right and left segments of the loaded beam by the uniform load per unit of length. In this case the point of maximum bending with Span $A\,B$ loaded is $0.495 \times 22.5 = 11.15$ ft. from the left end. The left and right segments of the beam are, therefore, 11.15 and 11.35 ft., and the shears at Points A and B are $11.15 \times 2\,000 = 22\,300$ and $11.35 \times 2\,000 = 22\,700$, respectively.

In case of the adjacent spans with $A\,B$ loaded, the shear is constant and equal to the maximum end moment divided by the distance from the end to the point of inflection; in this case, $\frac{M_{BC}}{i} = \frac{13\,200}{6.48} = 2\,060$.

With Span $B\,C$ loaded, the shears at the ends of the loaded span are the same, since the structure and load are symmetrical, and are equal to $4.5 \times 2\,000 = 9\,000$ lb., the shears in the adjacent spans being $\frac{6\,430}{18.3} = 355$.

The shear diagrams are drawn in dotted lines on Fig. 14 (*b*) and (*c*) for Spans $A\,B$ and $B\,C$ loaded; that for Span $C\,D$ loaded will be opposite hand to that for Span $A\,B$ loaded.

Combination of Diagrams.—The maximum moment and shear for any given member of the frame at any given point may be obtained by combining the results given in the shear and moment diagrams of Fig. 14 in such a way as to produce the desired maximum.

Loads Other Than Uniform.—In case the "total load, W," is to be placed on a given span as one or more concentrated loads placed symmetrically, the moments, M_{AB} and M_{BA}, of Equations (45) and (46) may be computed by substituting for the constant, C, another constant instead of $\frac{W\,L}{12}$, which is used for uniform load only and which represents the negative moment at the ends of a fixed beam. The constants which may be substituted for $\frac{W\,L}{12}$ are the values of the negative moments at the ends of a symmetrically loaded fixed beam carrying the load, W, distributed as desired. This substitution suggests computing first the ratio of the value of C with the new loading condition to $\frac{W\,L}{12}$ and multiplying the values of the negative moments at the ends of the loaded girder found from Figs. 10 and 11 by the ratio thus obtained. With

these moments computed, all necessary moments and shears may be calculated in a manner similar to that used in the example given for uniform loads.

As to the accuracy of the results obtained by this method and by the curves submitted, the writer has checked the results obtained by Mr. Ebling and has found that in four loading conditions in a very unsymmetrical building, the moments in the girder of the loaded panel (at ends and near mid-span) obtained by the curves have checked Mr. Ebling's slope deflection results with a maximum error of 7.6 per cent. The moments in question taken from the curves have occurred, of course, on the working line of the building frame, which is, in this case, on the center line of the columns. The moment at the face of the column would be actually somewhat less than that at the center line, and since higher unit stresses are usually allowed in a monolithic building frame in sections of members adjacent to supports, it would seem that the 7.6% variation mentioned, would cause no trouble.

The check has not been as good on members in which the moment has been obtained by proportion between the values of K, because the maximum error in one case—and in only one case—reached 14 per cent. All checks, however, have been close enough in the writer's opinion to warrant the use of these curves or similar ones in place of arbitrary coefficients or even the three-moment equation, when there is a possibility of the columns and beams (or girders) forming a rigid frame. This opinion is based on the fact that the allowable increase in unit stresses at the ends of members, together with a decrease in moment at the face of the members into which they frame, as compared to the moment at the center line of the latter, would absorb, in practically all cases, a difference as great as 14%; in some cases much more.

JOHN B. SNETHLAGE,* ASSOC. M. AM. SOC. C. E. (by letter).—The author has certainly given a clear idea of how he thinks continuous beams over three spans ought to be designed, and the results are most efficiently laid down in tables which cover a sufficient number of span varieties to warrant usefulness. Little is to be added to his general treatment of the problem. It is well known that normally the conditions at the supports are not as he assumes them to be and that restraining moments at the ends counteract the theoretical ones.

The author makes a severe attack on conventional moment factors, of building codes, joint committee regulations, etc., and attempts to illustrate their shortcomings with an example which seems to make their use prohibitive.

When his method gives the correct negative moment as —4 490 ft-lb. in the center span, and the conventional moment-factor method, according to him, calls for + 940 ft-lb. (see Table 4), the writer can hardly believe that there can be compensating features to prevent failure. In the writer's opinion the author does not apply these moment factors as they were intended.

As shown in Table 4, the correct maximum moments for the conditions given, are: + 5 740 ft-lb. for outer spans; —4 490 ft-lb. for center span; and —5 770 ft-lb. for center supports.

* Civ. and Hydr. Engr., Hawthorne, N. J.

By applying the conventional moment factors, a positive moment is found in the outer spans equal to $\frac{1}{10} \times 127 \times 21.75^2 = 6\,000$ ft-lb., and at the center supports, not some kind of an average as stated by the author, but a negative moment is used of the same absolute value as the positive moment, or $-6\,000$ ft-lb. (See Fig. 15.)

This negative moment prevails over the entire center span only to be reduced by the positive moment of the center span, or $\frac{1}{12} \times 147 \times 8.3^2 = 850$ ft-lb. Therefore, this span must be reinforced for a negative moment, in the middle, of $6\,000 - 850 = 5\,150$ ft-lb.

Comparison of these figures with Table 4 shows that the moment factor method requires 4% more steel at the center supports and 4.5% more steel at the outer spans, against which hardly any objection can be raised. On the center span, however, this waste is 15% which seems excessive; but in reality it is of little importance, as that negative moment increases very rapidly toward the center supports.

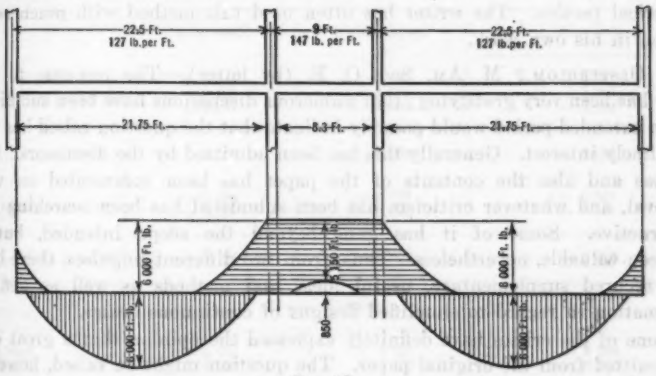

FIG. 15.

Moreover, in detailing it will not be found possible to follow the fluctuation accurately by decreasing and again increasing the amount of steel over so short a distance as 9 ft., and most likely the steel from the negative moment at one center support will be continued over the entire center span to the other support.

This demonstrates clearly what the writer believes to be the proper application and true interpretation of the use of the conventional moment factors of building codes, joint committee regulations, etc., and although by no means ideal, they certainly do not deserve such unreasonable criticism.

T. D. MYLREA,* M. AM. SOC. C. E. (by letter).—The author is certainly justified in his criticism of the practice of using arbitrary moment coefficients in many cases to which they do not apply, and is to be commended for his

* Prof. of Building Constr., Carnegie Inst. of Tech., Pittsburgh, Pa.

efforts toward simplifying the methods of finding the true moment coefficients in a three-span continuous beam. The labor involved and the time consumed in computing the true coefficients by the usual methods are undoubtedly responsible for the present reliance on arbitrary coefficients. As the author points out, this is particularly true in the usual analytic solution when a beam of more than three spans is encountered. In that case, the graphical solution of Messrs. Nishkian and Steinman* may prove more expeditious.

The analytic solution, however, may be approached from a standpoint distinctly different from that taken by the author, and one which permits of the solution of multi-span beams with comparative ease. The kernel of this method is suggested in Mr. Hadley's discussion. It consists of distributing throughout the beam the unbalanced, or excess, fixed-end moments. The method Mr. Hadley proposes is not entirely new, however, for the solution by distributing unbalanced moments has been taught by Hardy Cross, M. Am. Soc. C. E., for several years.

Furthermore, Professor Cross' method† is applicable to beams of any number of spans, as well as to continuous bents, and the labor involved is small. Moreover, by this method there is no need to schedule equations and certain numerical factors. The writer has often used this method with much satisfaction in his own work.

I. Oesterblom,‡ M. Am. Soc. C. E. (by letter).—The response to this paper has been very gratifying; that numerous discussions have been submitted for an extended period would possibly indicate that the question raised has real and timely interest. Generally this has been admitted by the discussors. The purpose and also the contents of the paper has been commented on with approval, and whatever criticism has been submitted has been searching and constructive. Some of it has gone beyond the scope intended, but it has been valuable, nevertheless. Thus, from two different impulses, there have been secured supplementary, useful ideas and methods as well as definite information in regard to simplified designs of continuous beams.

Some of the critics have definitely expressed the opinion that a great deal was omitted from the original paper. The question might be raised, however, if a very complete paper on the subject would not have been an unfortunate contribution. It would have reduced the opportunity of supplementary contributions from interested engineers, but even worse than that, it would have entered into the more general field of stresses and strains in elastic frames, already so thoroughly and competently treated by a legion of highly qualified authorities.

It was the purpose of the paper—unfortunately it seems to have been insufficiently emphasized—to reduce to easily workable form some of the very complicated combinations of formulas for continuous beams, so that reasonably correct moment factors might be quickly ascertained for the most common cases of simple continuity.

* "Moments in Restrained and Continuous Beams by the Method of Conjugate Points", by L. H. Nishkian and D. B. Steinman, Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 1.

† Available in mimeographed copies for the students of the Univ. of Illinois.

‡ Structural Engr., St. Louis, Mo.

Perhaps the examples given were presented in a manner which seemed to contradict the purpose of speed in execution. By neglecting variability of load the elements of each moment factor may be summed up into one. This, in most cases, would be warranted either by fact or a very close approximation. The examples should be left as shown, however, because they give very completely and accurately all that is essential for simple cases of continuity within the limits outlined. They are typical of cases with most extensive variations.

For the routine work in a designing office, the computation form shown in Table 13 would possibly serve best. (See Example 1.)

TABLE 13.—FORM FOR COMPUTATION OF MOMENTS.

	Bending moments.		
Dead load	$67\ \phi \times 22.5^2 = 34\ 000\ \phi$		
Live load	$60\ \phi \times 22.5^2 = 30\ 500\ \phi$		
	MOMENT FACTORS (ϕ).		
	Outer span.	Middle span.	Supports.
Dead load	+ 0.084 − 0.003 + 0.007	− 0.039 + 0.015 − 0.039	− 0.091 − 0.005 + 0.013
Total	+ 0.088	− 0.063	− 0.083
Live load	+ 0.084 + 0.007	− 0.039 − 0.039	− 0.091 − 0.005
Maximum	+ 0.091	− 0.078	− 0.096
	TOTAL MOMENTS.		
Dead load	+ 2 980	− 2 130	− 2 800
Live load	+ 2 760	− 2 360	− 2 930
Total	+ 5 740	− 4 490	− 5 730

A small error occurs, for the support moment only, and this is due to taking the live load at 60 lb. instead of 80 lb. for the center span. The error is less than 1 per cent.

Rapid pencil notations obviously are sufficient, with the multiplications done by slide-rule. The simplest problems thus can be solved in less than 5 min. and the more complicated in less than 10 min.

It has become necessary to emphasize the simplicity and the time element, because so many "simplified methods" have been suggested in the discussion. These are all excellent, and will be referred to in the proper place, but they generally fail to take the final step of producing directly applicable moment factors. While there must be problems which require a great deal of care and

a corresponding amount of time, because they are complicated by supplementary restraints and variabilities, the majority of cases should be, and are, elementary enough to be solved by exceedingly rapid methods. Anything less than this would merely induce, as it has in the past, many rough approximations with corresponding inaccuracies. This is an economic problem; if the cost of designing should run too high, it will be turned into a game of chance.

This is not discounting the many excellent contributions which are of a supplementary nature. They are truly supplementary, because they show how the problems should be solved when they fall beyond the scope of the paper.

Indeed it is difficult to imagine a more graceful, ingenious, and efficient method than that of Professor Cross, or the equally ingenious one by Professor Beggs, both of which have a general application and each its special, although somewhat overlapping, field of usefulness. Professor Cross' method contains a very slight approximation, but it is entirely too small to consider in view of the exceedingly valuable time-saving procedure.

Professor Cross' method is especially recommended for all cases of continuity, that are not soluble, or should not be solved by means of ready-made moment factors. Professor Beggs' method requires a set of instruments and the manipulation of celluloid models. With the complete equipment at hand its usefulness would be unlimited.

It is particularly gratifying, therefore, that these two methods were introduced by Professors Mylrea and Parcel, but while this acknowledgment is made with gratitude for the reference and admiration for the methods, it is only fair to state that they offer neither negation nor obsolescence for the writer's contribution.

The paper is elementary in its nature; but none the less it was not intended as a text for junior students. It assumed that the reader would know that there were additional restraints; it also assumed that he would know when the use of the simplified formulas and tables would not be permissible. If the writer took this knowledge for granted erroneously, it has been made very clear by the discussion that there are limits beyond which the formulas and factors should not be used.

As soon as one has to deal with more than three spans, or additional restraints from supporting or supported elements, all possibilities for considerable simplification vanish.

Fortunately, however, the vast majority of continuous beams are of three spans and are freely or almost freely supported. The tables and formulas in the paper are, therefore, an offering to those engineers—and their assistants—who thoroughly know their elasticity problems, but who are none the less looking for a rapid and accurate solution of those that confront them most frequently.

In a sense it may be considered an accident that, from the many methods possible, the three-moment theorem was selected as a basis for the paper. It is more than that, however. It is a tribute to a most graceful and accurate solution of an old problem, which has lost nothing by having attained a classical distinction.

From another point of view it stands out with compelling clarity that the one thousand and one (more or less) mathematical masterpieces analyzing stress and strain in elastic frames have had the practical effect of beclouding the elementary issues and setting up—instead of desired simplicity and accuracy—a chimera of faith, hope, and fantasy, which, unfortunately, has been set in a golden frame by committees of authorities and experts. This evil is international, but, curiously enough, it is subject to worship, nationally.

From this viewpoint the method introduced by Professor Cross is particularly significant. From the mass of formulas that are always necessary he has extracted all the essential factors and eliminated others which have insignificant effects on the result and merely tend to confuse the designer in his mathematical operations.

The question has been raised as to what extent brick walls would serve as a restraint for the floor construction. Seemingly, there can be no mathematical answer. To one who has spent a great deal of time in the field, the restraint appears to be generally small. Sometimes, the walls may be heavy, the brick especially good, and the mortar excellent—any one or all of these—and restraint then may be considered. It certainly should be considered whenever it may introduce an element of weakness, but this is seldom the case with the supported three-span elements. More often the restraint is very small, the reduction of moments will likewise be small, and the proposed formulas and factors will be sufficient. In general, the smaller and simpler structures analyzed in this paper are by far in the majority.

The temperature stresses in three-span construction are largely insignificant, but allowance for them can be made by the usual method, as soon as fundamental proportions have been once established. Mr. Way has made reference to the possible dangers, but his examples do not seem to be convincing. Generally, structures are more protected than he has assumed. The writer agrees that shrinkage stresses in concrete frames are of definite significance, but, unfortunately, little is known of the extent and magnitude of these colloidal changes, as measured by prevailing moisture conditions in their relation to the impermeability of the mass. Fortunately, these changes are of small significance in temperate climates; but in the tropics they are very destructive.*

The writer has made a general study of this subject, but there is a great deal of specific investigation yet to be done along these lines, before colloidal stresses may be definitely predetermined. As the shrinkage stresses, in their nature, are colloidal, Mr. Way is due special thanks for pointing out their significance. Greater danger, however, is to be found in longitudinal changes of beams and girders than in columns, as noted; this is on account of their relative positions and also because setting stresses in columns are confined to one story at a time, and are not cumulative.

From the viewpoint of bringing out the necessity of further investigations along these lines, the discussion has been especially fruitful. Some discussors have wrongly assumed that the paper was intended as a guide solely for

* *Journal*, Inst. of Engrs. (India), April, 1925, p. 52.

concrete work. As a matter of necessity, the concrete designers were long ago compelled to pay attention to continuity in a frame, but steel designers also soon had to "follow suit." To assume a free connection for a girder in computing stresses due to load—and that the same connection was elastic for wind effect—was indeed absurd.

Professor Morris' contribution is, therefore, especially welcome. He has expressed the desirability for a clear statement of fundamentals and for reserving for special discussion the peculiarities of individual materials. Some discussion has been unnecessarily critical for want of clarity on this point; on the other hand, there have been most excellent supplements with many useful methods, formulas, tables, etc., added to the original paper. The discussions of Messrs. Hyde, Wilder, Hickerson, and Caughey are very valuable from this point of view.

Messrs. Wessman, Way, and Snethlage seem to agree that the paper has been unduly critical in regard to conventional practice. Mr. Wessman's experience evidently is limited to more recent years, during which better design methods have been making remarkable progress. His connections, likewise, have been fortunate.

The writer's experience, of being forced to battle against antiquated methods, has been duplicated by many. He has heard statements from progressive and prominent men of experience, that younger engineers have turned cynics because they have often been forced by older men in authority —the commercially minded or the "stick in the mud" variety—to do what they knew to be incorrect.

Mr. Way seems to have been fortunately placed. His cheerful statement is, therefore, gratifying, but it does not cover the full field. That so many, who are consistently at fault, have failed to offer any contributions is significant as contrasted with so much constructive discussion.

The discussion by Mr. Snethlage has special interest, because he admits that there is a "true interpretation of the use of the conventional moment factors" for variable spans, whereas no such use was ever intended by the members of the Joint Committee on Specifications for Concrete and Reinforced Concrete or bodies of equal authority. There could be no better demonstration that confused ideas prevail and that greater clarity is needed. His short method, however, is among the best; but, unfortunately, it is very far from being generally used. It suffers also from an element of uncertainty in that the designer never knows how far from danger he really is, or how much material is being used wastefully.

Professor Mylrea makes reference to the excellent graphical methods of Messrs. Nishkian and Steinman. There seems to be one error in the presentation, which must be guarded against in use—the necessity for transforming load values when spans are changed, to compensate for variability of section.

There is an especially clear statement of the economic significance of the writer's formulas and tables from Mr. Hadley. He dwells again on the importance of repeated typical designs, and in a much clearer manner than the writer did in the paper. Possibly several hundred similar beams and

joists may be built. Error and waste are, therefore, both multiplied; but, likewise, the economies are worth while when the calculation is done carefully and correctly.

There must be some inducement, however, to designing even the numerous small structures correctly, and no inducements could be more attractive than simplicity of method, accuracy of results, and economy of materials. Therein lies the justification for this paper. It is to be hoped, however, that the tables may soon be supplemented and ultimately supplanted by experimental moment factors obtained by Professor Beggs' method.

Mr. Hadley refers to the writer's statement about equi-distant concentrated loads and demands a more complete explanation. Reference is obviously first and foremost to the many so-called joist designs, where complete uniformity may be assumed. It should be noted, however, that even quarter-point and half-point loading will increase the moments only a very small fraction. Hence, the tables may be used—judiciously, of course—even for concentrated loads within fair limits.

Thanks to Professor Hickerson it has been possible to verify and correct the numerical factors in Table 3.

The Joint Committee on Specifications for Concrete and Reinforced Concrete has found a defender in Mr. Way. The excellent work by the Committee cannot be questioned. It was merely its attitude of inconsistency in regard to proposed moment factors which was deplored. Either the subject should have been treated more fully, or it should have been treated in general terms only. To select the simplest problems and to treat these in great detail, while at the same time omitting completely all the more difficult ones, can only confuse those who specially need the guidance of the report. Because of frequent errors of design due to misinterpretation of the moment factors specified by the Joint Committee, this criticism seems pertinent.

Erroneous application of conventional moment factors to a series of spans of different lengths, is common—almost universal. It is Mr. Way's belief that the impossibility of creating "an accurate design" has made it necessary for Code Committees to adopt empirical factors. The effect of these empirical factors seems to have been the reverse of what was intended, namely, to induce unqualified people to undertake difficult designs by the simple expedient of letting these very limited factors do serious work in the dark hinterland beyond the borders of their own ignorance.

This obviously raises the question as to the true function, as well as the limitations, of a legal "code" or a "committee report" (which, in advance of full knowledge on a subject, anticipates the code). It is not the writer's intention to dwell largely on this, but simply to raise again the point that no committee should endeavor to establish by code or rule simple matters that pertain to gravity, or anything experimentally determinable therefrom. A code should cover only matters of judgment where there is a chance of judicious selection and where the mature judgment of especially selected men will benefit the community as a whole.

Paper No. 1715

THE O'SHAUGHNESSY DAM AND RESERVOIR*

By John H. Gregory,† C. B. Hoover,‡ and C. B. Cornell,§
Members, Am. Soc. C. E.

With Discussion by Messrs. J. Ernest Carman, B. F. Jakobsen, W. H. Dittoe and G. Gale Dixon, and John H. Gregory, C. B. Hoover, and C. B. Cornell.

Synopsis

This paper describes the design and construction of a dam and reservoir built to increase the storage of raw water for the water supply of the City of Columbus, Ohio. The masonry portion of the dam is of the overflow gravity type, the spillway section, 879 ft. in length between end abutments, being spanned by a 12-arch reinforced concrete bridge. The crest of the spillway is 64 ft. above low water in the river and has a discharge capacity of 110 000 cu. ft. per sec. The reservoir, formed by the construction of the dam, is 8 miles in length, has a maximum width of 1 900 ft., and a total available storage capacity of 5 341 000 000 gal. The total cost of the dam and reservoir was $2 220 080.

Introduction

The water supply of the City of Columbus, Ohio, is taken from the Scioto River. In 1908 the city completed a five-year program of important waterworks improvements which included the construction of a water purification and softening works and pumping station adjacent to the Scioto River, about 2 miles from the center of the city, and of a masonry dam and storage reser-

* Presented at the Fall Meeting, Columbus, Ohio, October 12, 1927.
† Cons. Engr.; Prof. of Civil and San. Eng., The Johns Hopkins Univ., Baltimore, Md.
‡ Supt., Water and Sewage Disposal Divisions, Columbus, Ohio.
§ Field Engr., Mahoning Val. San. Dist., Youngstown, Ohio.

voir on the river about 4.5 miles above the purification works. These improvements were fully described in a previous paper presented to the Society.*

In the fall of 1925 the city completed a second five-year program of important water-works improvements, this program including enlargement of the water purification and softening works and the construction of a second masonry dam and storage reservoir on the Scioto River.†

It is the purpose of this paper to describe the construction of the second masonry dam and reservoir, known as the O'Shaughnessy Dam and Reservoir.

Names of Dams

To avoid confusion, in case reference should be made to the paper and the report referred to, it will be well to state how the names, by which the two masonry dams are now known, came to be given. In the report recommending the construction of the second masonry dam, it was referred to, for the purpose of description, as the Dublin Dam, the proposed location being about 2 miles north of the Village of Dublin.

When the second five-year program was begun in 1920 Mr. Jerry O'Shaughnessy was the Superintendent of the Columbus Water-Works. Mr. O'Shaughnessy had been in the employ of the Water-Works Department for nearly fifty years, rising from the humblest position to the highest, and it was one of his greatest ambitions that the second five-year program should be carried to completion while he was still Superintendent of the Department, the work having been organized under a separate bureau of the Water-Works Department. This was not to be. Mr. O'Shaughnessy died on January 28, 1921, more than a year before the second dam was put under contract. The City Officials wished to recognize Mr. O'Shaughnessy's long years of service to the City of Columbus and decided to name the new dam for him. A bronze tablet, setting forth the action of the City Council in naming the new dam for Mr. O'Shaughnessy, has been mounted on the dam and bears the following wording:

O'Shaughnessy Dam

> By Resolution of the Council of the City of Columbus, Adopted, February 7, 1921, This Dam Was Named and Designated the "O'Shaughnessy Dam" in Honor of the Late Jerry O'Shaughnessy, Who so Faithfully and Well Served the City as Superintendent of Its Water Works for Many Years.

In the paper describing the construction of the works built under the first five-year program, beginning in 1904, the first masonry dam was referred to as the Scioto River Storage Dam and it was built while the late Julian Griggs, M. Am. Soc. C. E., was Chief Engineer of the Board of Public Service, the work under this program having been organized as practically a separate

* "The Improved Water and Sewage Works of Columbus, Ohio," by John H. Gregory, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXVII (1910), p. 206.

† This second five-year program was carried out substantially as recommended in a "Report on Enlargement of the Water Supply, Purification and Pumping Works of the City of Columbus, Ohio," by John H. Gregory, dated August 2, 1919.

branch of the Engineering Department of the Board. It was largely through the untiring efforts of Mr. Griggs that the first five-year program of improvements was started, and the first masonry dam was completed while he was still Chief Engineer of the Board. Mr. Griggs died on December 4, 1922. Having honored Mr. O'Shaughnessy for his long service to the City by naming the second dam for him, the City Officials then wished to honor Mr. Griggs for his very valuable services in connection with the construction of the first dam. Hence, the first dam was renamed the Julian Griggs Dam. The following is from the resolution adopted by the City Council on December 18, 1922:

"That the present storage dam in the Scioto River be and is hereby designated as 'The Julian Griggs Dam' in honor of Julian Griggs, who so faithfully and well served the City as Chief Engineer and who was one of the prime movers in the movement to construct said dam, and who had general supervision of its construction."

The two dams and reservoirs will be referred to, therefore, as the O'Shaughnessy Dam and O'Shaughnessy Reservoir and the Julian Griggs Dam and Julian Griggs Reservoir.

Capacity of Works

In the report previously referred to it was recommended that, in addition to increasing the size of the water purification and softening works and pumping station, the water supply works be enlarged to provide for an average water consumption of 55 000 000 gal. daily. This recommendation has been carried out and the O'Shaughnessy Reservoir, together with the Julian Griggs Reservoir, provides sufficient storage to meet this requirement. With an estimated water consumption of 110 gal. per capita daily the source of supply will now provide for a population of 500 000, estimated to be reached somewhere between 1950 and 1955.

In the operation of the purification and softening works and the pumping station, water is used for washing filters, flushing mixing chambers and settling basins, boilers, etc., and a study of the past operation of the Columbus works indicated that an allowance of 5%, or 2 750 000 gal. daily, should be made for water so used. Consequently, the water supply works will provide for an average raw-water draft of 57 750 000 gal. daily, corresponding to an average water consumption of 55 000 000 gal. daily.

In the carrying out of the second five-year program the water purification and softening works were enlarged, and, although it is not the intention in this paper to describe the enlargement of these works, their capacity before and after enlargement will be given, as a matter of reference. As first built, the purification works included ten rapid sand filters, each with a then rated capacity of 3 000 000 gal. daily, or a total of 30 000 000 gal. per day. While the piping and the filter rate controllers will permit running the filters at a somewhat higher output for a short period, in case of emergency, experience gained in the operation of the works for the first ten years demonstrated that it is not safe to run the filters, under Columbus conditions, at a rate greater

than 30 000 000 gal. daily for any considerable time. The maximum capacity of the first filter installation, therefore, must be put at 30 000 000 gal. daily.

The average daily capacity of a water purification works to supply filtered water is dependent on the maximum daily filter capacity, that is, the maximum safe rate at which it is possible to filter water, on the volume of filtered water stored in the filtered water reservoir and available for equalizing the fluctuating rates of water consumption, and on maximum and long continued high rates of water consumption. No general rule can be stated which will apply to all purification works, as the conditions at no two works are alike. From a study of Columbus conditions it was found that, with a maximum filter capacity of 30 000 000 gal. per day, an average daily capacity of only 22 300 000 gal. could be relied on.*

In the second five-year program the purification works were enlarged to a maximum filter capacity of 54 000 000 gal. daily by the addition of eight 3 000 000-gal. daily filters. The existing 10 000 000-gal. filtered water reservoirs were enlarged so as to have a total filtered water capacity of about 16 500 000 gal. Under these new conditions, following the method referred to, the purification works now have an average capacity of 40 000 000 gal. daily. A third and final enlargement of the purification works to an average daily capacity of 55 000 000 gal. will bring them up to the capacity of the water supply works.

In 1926 the City of Columbus had an estimated population of about 285 000. The water consumption for the same year was 27 400 000 gal. daily, including water supplied to a population of about 15 200 outside the city limits.

Water-Shed and Flow of the Scioto River

At the Julian Griggs Dam the Scioto River has a water-shed of 1 052† sq. miles, and at the O'Shaughnessy Dam, 988 sq. miles. On the water-shed the rock is of a limestone formation and is exposed at many places. Where the rock is covered, the drift is of varying thickness. The water is hard and is unsatisfactory for domestic and industrial uses unless softened. The average total hardness of the water for the 18 years, 1909-26 inclusive, was 272 parts per million, 160 parts being carbonate and the remaining 112 parts non-carbonate hardness. The maximum total hardness recorded on any one day was 495 parts per million. The average turbidity was 75 parts per million, but, during freshets and flood flows, turbidities in excess of 2 000 parts per million have been recorded. At such times, however, the total hardness drops to less than 100 parts per million. The maximum recorded turbidity was 2 250 parts per million. The water is softened and filtered before delivery into the distribution system.

* The method by which the average daily capacity was arrived at is a very interesting one and was described in detail, with graphs, by Mr. Gregory, in his report of August 2, 1919, on the enlargement of the water supply, purification, and pumping works of the City of Columbus. So far as the writers are aware, that was the first time this method was used. A description of the method may also be found in Chapter XIV, "Relation Between Filtered Water Storage and Filter Capacity," by John H. Gregory and Robert B. Morse, Members, Am. Soc. C. E., in the Manual of the American Water Works Association (1925), pp. 330–345.

† In *Transactions*, Am. Soc. C. E., Vol. LXVII (1910), p. 218, the area was given as 1 032 sq. miles. The new area of 1 052 sq. miles is from measurements made on the more recently issued topographical maps of the U. S. Geological Survey.

The daily flow of the Scioto River at the Julian Griggs Dam varies between very wide limits, from a minimum of 20 to 30 cu. ft. per sec. (roughly, 13 000 000 to 20 000 000 gal. daily), during the dry months of the summer

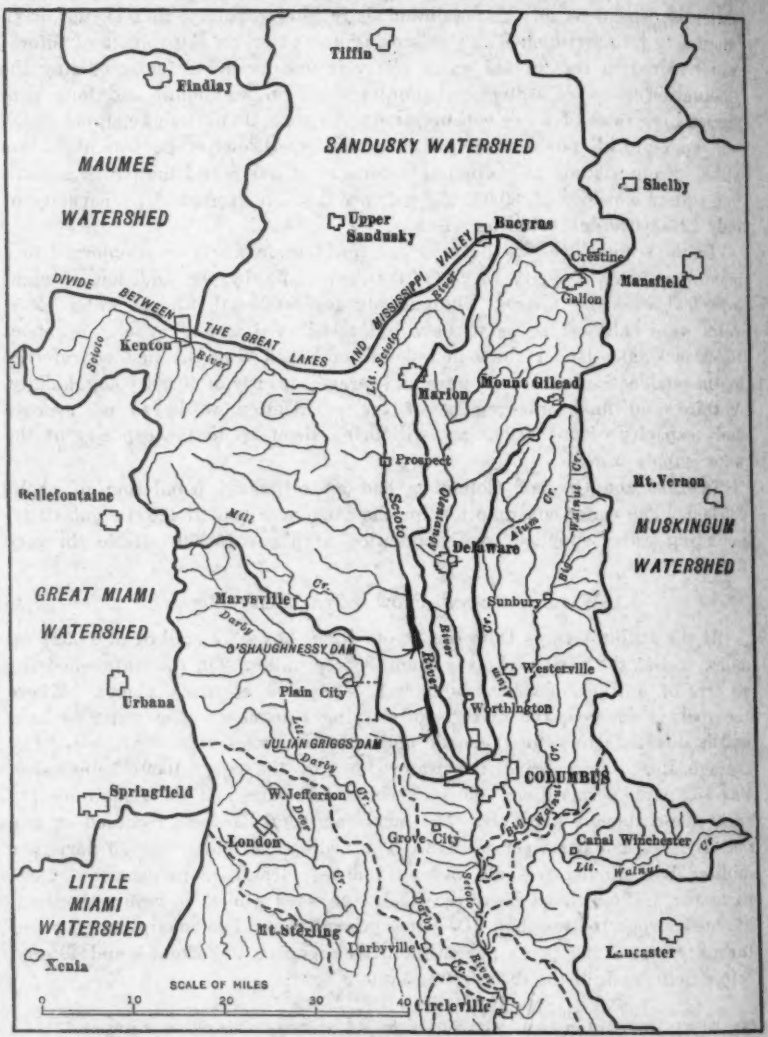

FIG. 1.—MAP SHOWING WATER-SHED OF SCIOTO RIVER, NEAR COLUMBUS, OHIO.

and early fall to upward of 1 000 cu. ft. per sec. during the winter and early spring months. Storage, therefore, is necessary in order to meet a water consumption demand of 55 000 000 gal. daily.

Beginning in February, 1909, records have been kept daily of the water level in the Julian Griggs Reservoir and of the opening of the sluice-gates in the dam when water was drawn from storage. From these records the daily flow was computed. Although there are a few gaps in the record, they are only of minor importance. The Julian Griggs Dam is a curved masonry structure of the overflow type, the length of the spillway being 500 ft., and the crest 30 ft. above low water in the river. From the dam the water flows down the river a distance of 4.5 miles to the intake of the purification works.

The water-shed of the Scioto River near Columbus and the location of the O'Shaughnessy and Julian Griggs Dams are shown on Fig. 1.

Storage Capacity Needed

From a study of the daily flow records of the Scioto River it was found that the maximum available storage needed to sustain a raw-water draft of 57 750 000 gal. daily at the Julian Griggs Dam, the lower of the two dams, would be in the last half of a year having daily flows similar to those which occurred in 1914. This storage may be readily obtained from the mass diagram shown on Fig. 2.

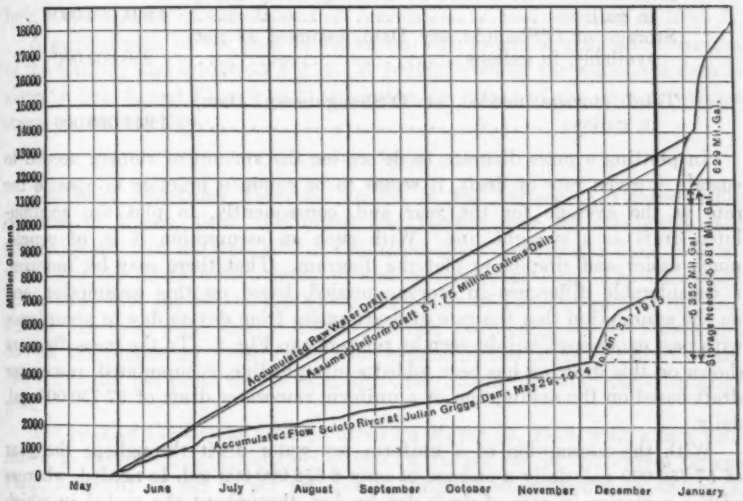

Fig. 2.—Storage Mass Diagram, Scioto River.

The lower curve gives the accumulated flow of the Scioto River at the Julian Griggs Dam from May 29, 1914, to January 31, 1915. The upper curve gives the accumulated raw-water draft for a similar time of the year, with an average raw-water draft for the year of 57 750 000 gal. daily, corresponding to an average water consumption for the year of 55 000 000 gal. daily. In computing the data for the plotting of this curve, it was assumed that the ratio of the raw-water draft, day by day, to the average daily raw-water

draft for the year would be the same as the ratios experienced on corresponding days in the period June, 1913, to January, 1914, it having been found, from a study of the daily water consumption records, that the maximum daily rates of long continued water consumption occurred in the period mentioned.

From these two curves it is seen that a total available storage of 6 981 000 000 gal. is needed above the Julian Griggs Dam to sustain a raw-water draft of 57 750 000 gal. daily. The available storage needed above the O'Shaughnessy Dam was then found, as follows:

Total available storage needed, in gallons.....		6 981 000 000
Available storage at Julian Griggs Dam, without flash-boards, in gallons	1 487 000 000	
Additional storage at Julian Griggs Dam, with 4-ft. flash-boards, in gallons	500 000 000	
Total available storage at Julian Griggs Dam, with 4-ft. flash-boards, in gallons	1 987 000 000	1 987 000 000
Available storage needed at O'Shaughnessy Dam, in gallons		4 994 000 000
Storage at O'Shaughnessy Dam, assumed as not available, in gallons		250 000 000
Total storage needed at O'Shaughnessy Dam, in gallons		5 244 000 000

In plotting a mass diagram to determine the amount of storage needed to sustain a given rate of draft, it seems to be common practice to assume the rate as the average for the year and, consequently, to plot the accumulated draft as a straight line. With such an assumption it is, of course, much easier and simpler to plot the diagram. That there may be, however, a considerable difference in storage needed, based on this assumption and on the assumption that the rate of draft varies from day to day in accordance with past experience, will be seen by reference to Fig. 2. To the mass diagram shown on this drawing has been added a straight-line, accumulated, raw-water draft based on the assumption of a uniform raw-water draft of 57 750 000 gal. daily.

With the assumption of a uniform raw-water draft throughout the year of 57 750 000 gal. daily a storage of only 6 352 000 000 gal. is needed, whereas with a variation in rate of draft day by day, throughout the period in which storage is needed, in accordance with past experience during a similar period of the year, a storage of 6 981 000 000 gal. is seen to be necessary, an increase of 629 000 000 gal.; that is, 9.9% more storage is needed in order to maintain higher rates of daily raw-water draft which are to be expected during the period when storage is necessary than under the assumption of a uniform daily rate of raw-water draft throughout the year.

From discussion with other engineers, as well as from examination of reports and books in which mass diagrams are given, it has appeared to

the writers that many have not appreciated that the assumption of a uniform rate of draft throughout the year may give too small a storage, about 10% in the case just illustrated. Therefore, they have taken this opportunity to bring the matter to the attention of engineers.

Type of Structure

The O'Shaughnessy Dam is a concrete masonry dam, of the gravity overflow type, straight in plan, and 1 750 ft. in length, including the approaches. The masonry portion of the dam is 879 ft. long, measured face to face of copings on the abutments. The two approaches have a total length of 871 ft., but they are not of equal length, the east approach being slightly longer than the west one.

Crossing the dam, above the overflow or spillway section, is a reinforced concrete arch bridge of twelve spans, each span measuring 64 ft. 6 in. in the clear. The net length of the spillway, under the bridge, after deducting the length of the bridge piers and the outlet gate-house, is 765.7 ft.

The crest of the spillway is 64 ft. above low water in the river on the down-stream side of the dam and 84 ft. above the rock foundation. The roadway on the bridge is 21.3 ft. above the crest of the spillway making, therefore, a total height of dam from rock foundation to roadway level of 105.3 ft.

A general plan of the dam is shown on Fig. 3, and a plan and elevation of the spillway and bridge on Fig. 4. A general view of the completed dam is given in Fig. 5, and Figs. 6 to 11, inclusive, are views of the dam at various stages of construction.

Capacity of Spillway

The most disastrous floods on record in the history of Central Ohio occurred in March, 1913. Columbus and Dayton were the two cities that suffered most. On the west side of Columbus great damage was done to property when the levees were overtopped and 93 lives were lost. The Olentangy River flows into the Scioto just above the center of the city and, at the confluence, the total water-shed is 1 612 sq. miles, 1 076 being on the Scioto and 536 on the Olentangy. Fortunately for Columbus the peak-flood flows of the two rivers did not occur at the same time, the Scioto following the Olentangy peak.

The peak of the Scioto flood occurred on March 25, 1913, with a flow estimated to have been approximately 80 000 cu. ft. per sec. at the Julian Griggs Dam, or about 76 cu. ft. per sec. per sq. mile of water-shed. At the peak, the depth of water passing over the 500-ft. spillway of this dam was 12.8 ft.

Assuming the same flood flow per square mile at the site of the O'Shaughnessy Dam, the discharge from the 988 sq. miles of water-shed above this point would have been about 75 000 cu. ft. per sec. After mature consideration of the subject it was finally decided to provide spillway capacity at the new dam for a flood of 110 000 cu. ft. per sec., or about 50% in excess of the 1913 flood, and also to increase the length of the spillway about 50% over that of the Julian Griggs Dam. Under these assumptions to discharge 75 000 cu. ft. per sec. over the spillway of the O'Shaughnessy Dam will

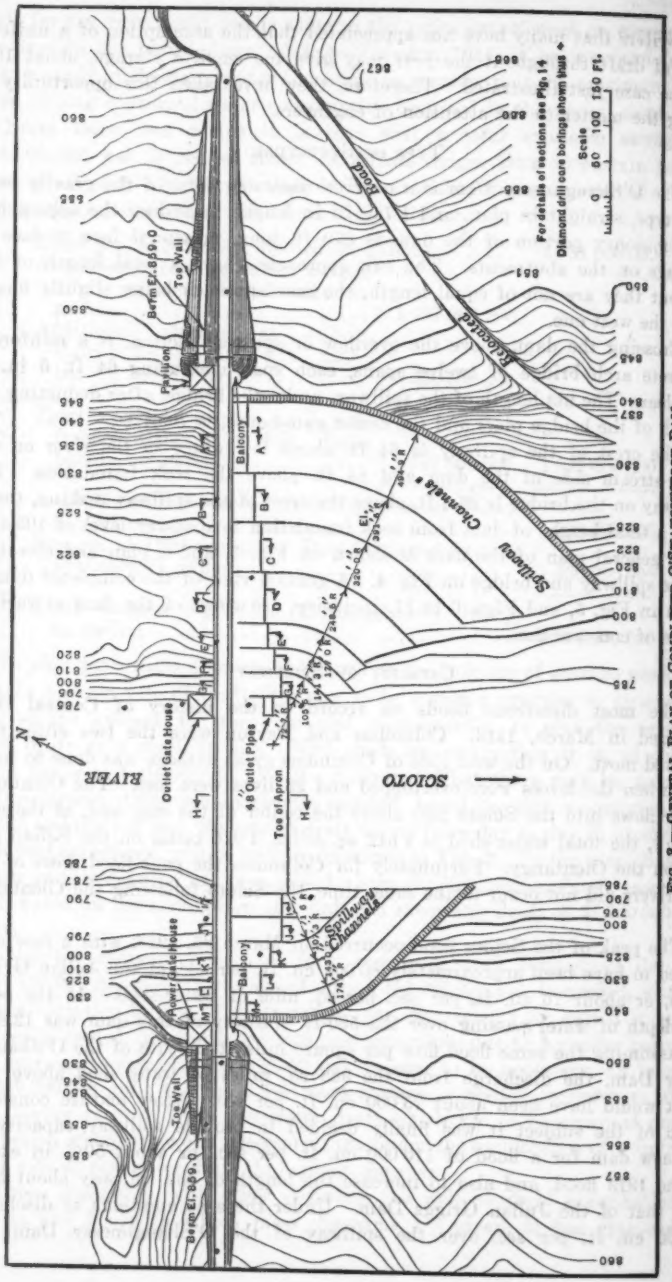

FIG. 8.—GENERAL PLAN OF COMPLETED O'SHAUGHNESSY DAM.

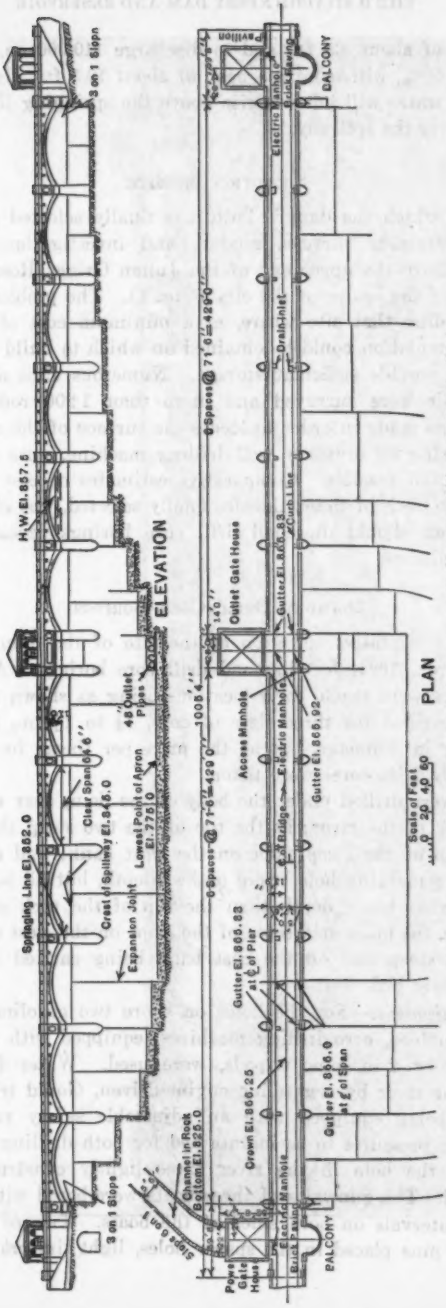

FIG. 4.—PLAN AND ELEVATION OF SPILLWAY AND BRIDGE, O'SHAUGHNESSY DAM.

require a head of about 9.5 ft., and to discharge 110 000 cu. ft. per sec., the 1913 flood plus 50%, will require a head of about 12.5 ft. Under the extreme flood condition water will have to rise above the springing line of the arches of the bridge over the spillway.

Selection of Site

The site on which the dam is built was finally selected after more than a year of preliminary surveys, studies, and investigations. This site is about 4 miles above the upper end of the Julian Griggs Reservoir and about 16 miles north of the center of the city (Fig. 1). The problem resolved itself into one of finding that site where, at a minimum cost of construction, a suitable rock foundation could be obtained on which to build the dam and, at the same time, provide sufficient storage. Numerous sites above the Julian Griggs Reservoir were surveyed and more than 1 200 rod soundings and spud-drill borings made in order to locate the surface of the rock. The spud-drill borings, using an ordinary well-drilling machine, were made where rod soundings were not feasible. Comparative estimates of cost were then compiled and, on the basis of these, the site finally selected, was chosen, subject to revision, however, should diamond drill core borings reveal unsatisfactory sub-surface conditions.

Diamond Drill Core Borings

Following the tentative selection of the site of the dam a contract was awarded in March, 1921, for diamond drill core borings. All told, twenty-two such borings were made, their locations being as shown on Fig. 3. The specifications provided for three sizes of core, 1¼ to 1½ in., 1½ to 2 in., and 2 in. or greater in diameter, but as the price per linear foot was the same for all sizes, only 2-in. cores were taken.

Deep holes were drilled under the body of the dam, near the water's edge, on the east bank of the river; at the top of the two steep slopes on the east bank; at the top of the steep slope on the west bank; and at the center of the river. The remaining holes were of less depth, but all borings were carried to a somewhat lower depth than the top of the rock at the next hole toward the river, the holes at the top of the slope on the west bank, and at the top of the first steep rise on the east bank being carried down below the bottom of the river bed.

Drilling Equipment.—For the holes on shore two gasoline engine-driven, Sullivan friction feed, core-drilling machines, equipped with single core barrels and served by 2-in. pipe tripods, were used. Water for drilling was pumped from the river by a gasoline engine-driven, Gould triplex pump, the discharge pipe being equipped with an adjustable safety valve which permitted very even pressures to be maintained for both drilling and testing.

For drilling the hole in the river three lightly constructed high-sided dories were used. The gunwales of these boats were bored with pairs of holes at about 3-ft. intervals on both sides of the boats. Two of the boats were lashed together, pins placed in the spacer holes, light timbers placed between

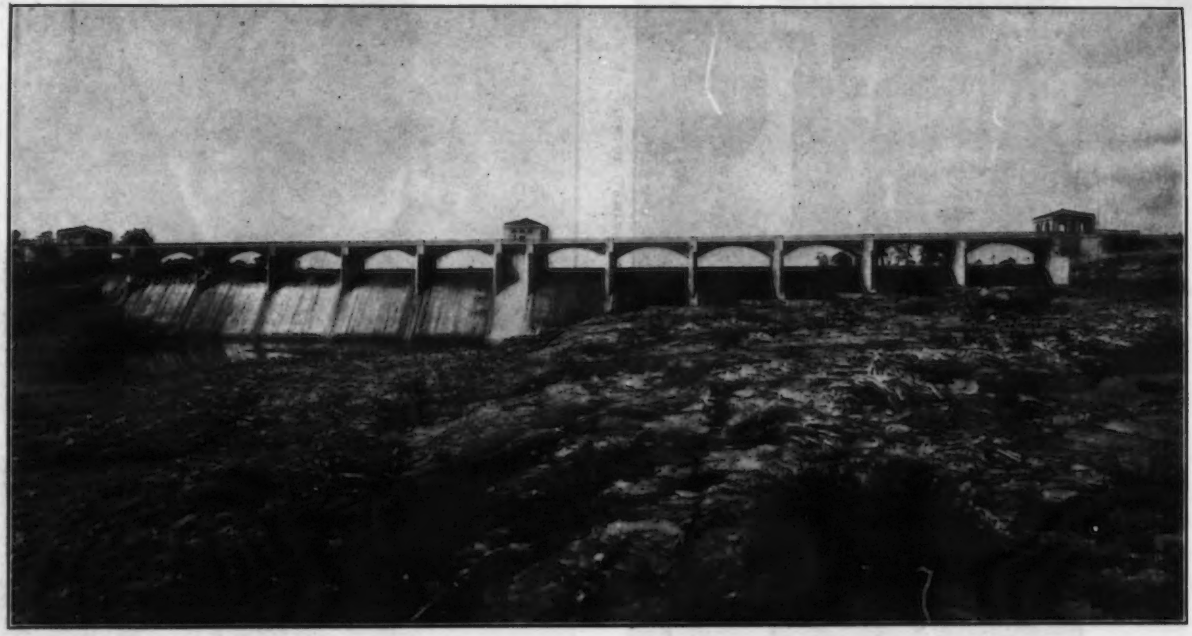

FIG. 5.—VIEW OF COMPLETED O'SHAUGHNESSY DAM.

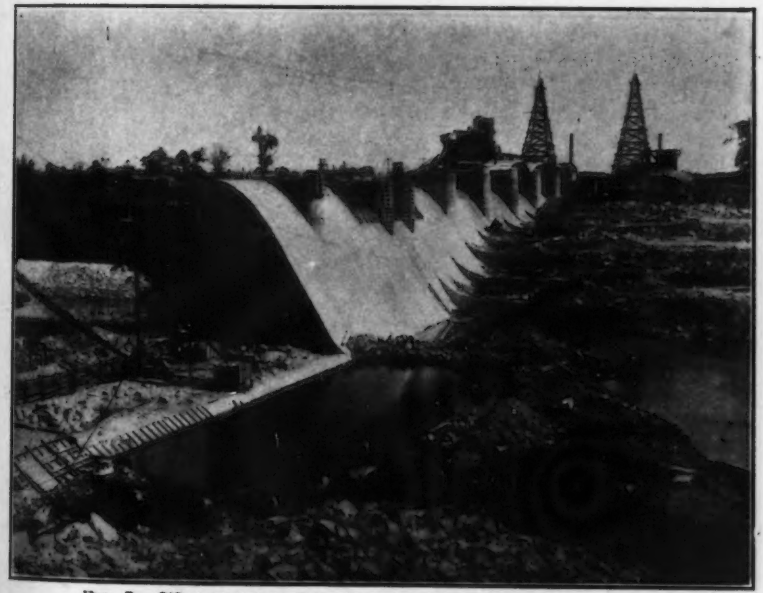

FIG. 7.—O'SHAUGHNESSY DAM, LOOKING EAST, SEPTEMBER 27, 1923.

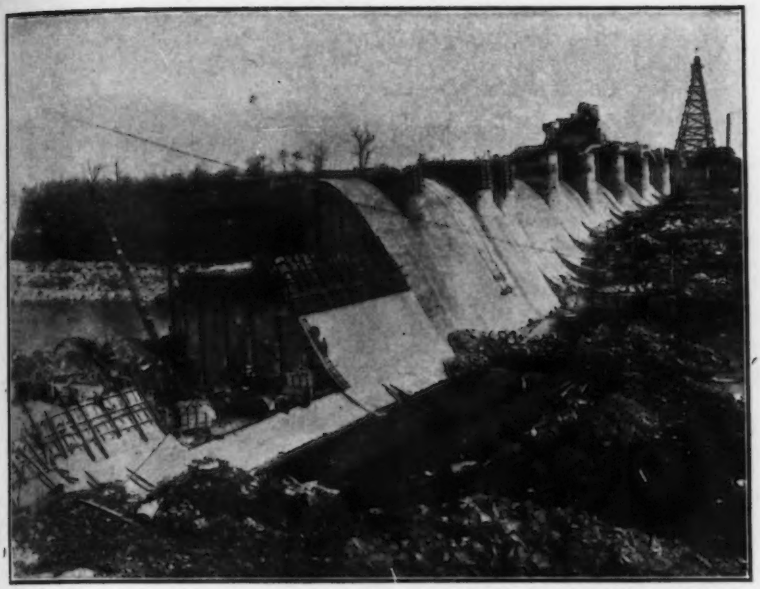

FIG. 8.—O'SHAUGHNESSY DAM, LOOKING EAST, OCTOBER 25, 1923.

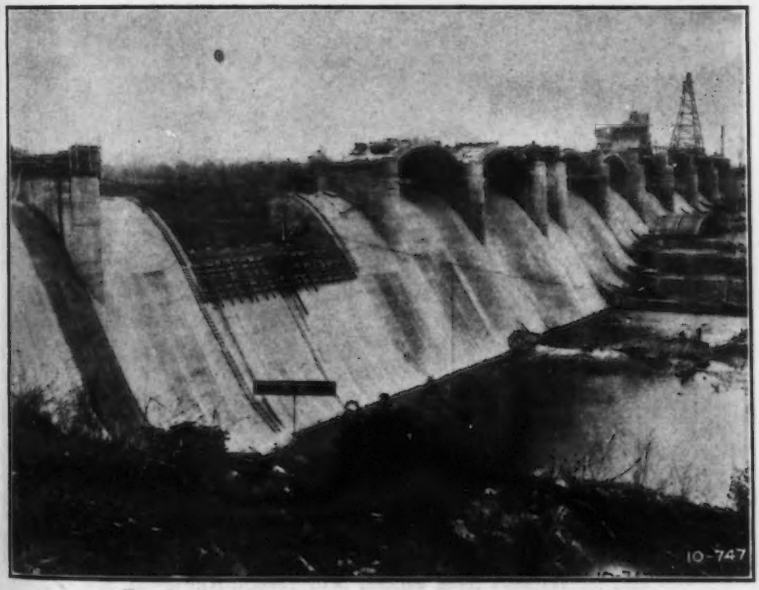

FIG. 9.—O'SHAUGHNESSY DAM, LOOKING EAST, MAY 9, 1924.

FIG. 10.—O'SHAUGHNESSY DAM, LOOKING EAST, JUNE 13, 1924.

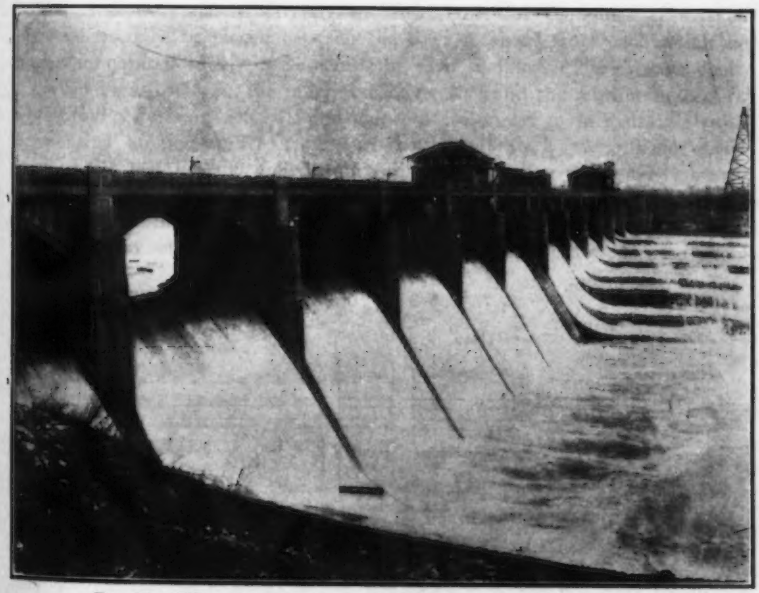

FIG. 11.—O'SHAUGHNESSY DAM, LOOKING EAST, FEBRUARY 13, 1925.

the pins and lashed down, and 2-in. plank laid on the timbers to form a floating platform. The drilling machine was skidded on to this platform from the bank, the whole being towed to position by the third boat and anchored with four heavy ship's anchors.

The equipment furnished also included a small portable shop and tools for making repairs and for resetting the diamonds in the cutting bits, this work all being done on the job. The equipment for testing is described subsequently.

Drilling.—Where the rock was not exposed a 4-in. casing was driven to the top of ledge rock by one of three methods: First, by driving the casing, pulling it up, and knocking out the earth core, and then repeating the operation; second, by jetting out the earth and driving the casing; or, third, where slabs of rock embedded in the earth were encountered, by drilling with a spud bit. All casings were left in place and capped. In exposed rock, short pieces of casing were cemented into the holes in order to save them for grouting during construction.

The drilling of the holes was done in the usual manner, a complete log of each hole being kept, the notes reporting any changes in the color or quantity of the discharged water containing the cuttings, the depth to the bottom of the cutting bit at each pull, a sounded depth, and the length of core obtained at each pull, as well as notes on the physical characteristics of the rock, etc.

The cores were placed directly in boxes built for the purpose, marked blocks of wood being placed between the rock obtained from each pull; the boxes were covered with wire screening as soon as filled. The average depth of the holes was 34.55 ft., the maximum being 65.0 and the minimum, 19.3 ft.

Hydraulic Tests.—Each hole was subjected to one or more hydraulic tests, water being applied under a pressure equivalent to a static head corresponding to Elevation 860, for the purpose of determining the water-tightness of the rock and also for locating any open seams or fissures. More and better information on these essential points was obtained from the hydraulic tests than from any other source, not excluding the information secured from the cores.

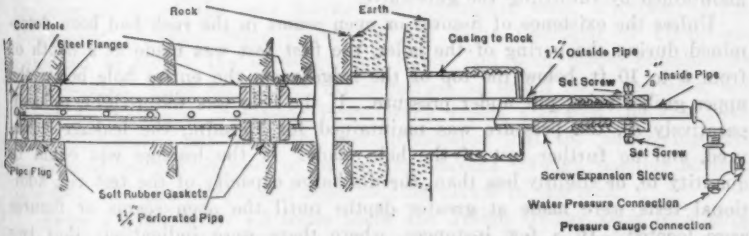

FIG. 12.—HYDRAULIC TEST APPARATUS FOR DIAMOND DRILL CORE BORINGS.

Water, under the pressure noted, was applied to the test hole through a double string of pipe of lengths necessary to reach the point to be tested. The outside pipe, shown in Fig. 12, was 1¼ in. in diameter and was made up

with a set of soft rubber gaskets at the bottom, a short length of pipe above, with several holes drilled through the sides of the pipe, a second set of gaskets, and a second piece of pipe reaching to above the ground. The gaskets were held between iron flanges, the gaskets and flanges having an outside diameter slightly smaller than that of the test hole. The inside pipe, ¾ in. in diameter and about 1 ft. longer than the outside string of pipe, passed through the upper set of flanges and gaskets, through the upper flange and gaskets of the lower set, and was screwed into and through the bottom flange. This inside pipe was closed at the lower end with a removable plug, was perforated with several holes just above the lower set of gaskets, and was fitted with an expanding screw sleeve at the top. The upper half of the sleeve could be securely fastened to the inside pipe with set screws, and the lower half bore directly against the top of the outside pipe. By screwing the sleeve out, the gaskets could be compressed until water-tight connections were made with the sides of the hole and with the outside of the inside pipe. Pressure could be applied from the inside pipe, through the holes in both pipes, to the rock sides of the test hole between the top and bottom gaskets, any desired length of hole being put under pressure by simply placing the desired length of perforated outside pipe between the top and bottom gaskets; or, the entire portion of the hole below the upper gasket could be put under pressure by removing the plug at the bottom of the inside pipe.

Water for testing was supplied under pressure through a short length of hose, the quantity and pressure being controlled by a gate-valve, and the quantity measured by a ¾-in. service meter. The pressure was shown on a small pressure gauge located close to the connection to the top of the ¾-in. inside pipe. Due to the small size of the inside pipe and the high friction loss, it was necessary to determine, in advance of testing the holes, the maximum quantity of water which various lengths of rig would discharge, taking into account the range of pressure required by the elevation of the ground at the several holes. Determinations, sufficient in number to cover the various lengths of test piping and pressures required, were made of the discharge capacity of the pipe by laying the pipe on the ground and measuring the discharge into the air, a constant pressure at the gauge being maintained by throttling the gate-valve.

Unless the existence of fissures or open seams in the rock had been determined during the boring of the holes, the first test was made at a depth of from 5 to 10 ft. below the top of the ledge rock, the entire hole below the upper gasket being put under pressure. If the hole was water-tight, or comparatively so, the pressure was maintained for 15 min., the leakage measured, and no further test of the hole made. If the leakage was equal in quantity to, or slightly less than, the discharge capacity of the test rig, additional tests were made at greater depths until the open seams or fissures were located. In a few instances, where there were indications that two or more small seams had been encountered, the pressure was confined to the space between the gaskets, with the gaskets set so as to be above and below one of the seams, the leakage into this seam measured, and then similar tests were made on the other seams.

Where seams were at a considerable depth, and it was desirable to determine the condition of the rock above the seam, a permanent seal was made by filling the hole with cement mortar to a point above such seam. After a sufficient time had elapsed to permit the mortar to set, the hole above the seal was tested in the usual manner.

Percentage of Core.—The length of core recovered, as measured in position in the core boxes, was 84% of the total depth of all the holes measured from the top of the solid rock to the bottom of the holes.

Cost.—The prices paid for making the diamond drill core borings, for temporary and permanent seals, for conducting hydraulic tests, and for casing left in place were, as follows:

Cores, per linear foot	$4.50
Temporary seals, each	15.00
Permanent seals, each	15.00
Hydraulic tests, each	15.00
Casing, left in place, per pound	0.06

In paying for the core borings the linear-foot measurement was made from the surface of the ground to the bottom of the hole. A temporary seal was paid for each time the testing rig was set in a hole, the pressure turned on, and the flow measured. If the pressure was maintained and the flow measured for a period of 15 min. then payment for a hydraulic test was made, in addition to payment for the temporary seal. The total cost of the diamond drill core-boring investigation was $5 068, exclusive of engineering.

Geology of the Site

The diamond drill core borings and hydraulic tests made at the proposed site indicated that there were no sub-surface conditions seriously detrimental to its selection. The sub-surface investigation showed, however, that grouting of the underlying rock would be required at certain points and that further extension of the grouted areas would be desirable, but as a measure of insurance rather than of necessity.

Before passing final decision on the selection of the site, and following the completion of the core borings and hydraulic tests, Professor J. A. Bownocker, of Ohio State University and State Geologist of Ohio, was requested to review the investigations which had been made, examine the cores secured, make such other investigations as might seem desirable, and report his findings. Professor Bownocker's report approved the site without qualification, but made the recommendation that the underlying rock be grouted for the purpose of preventing leakage through possible solution channels, cleavage planes, and open bedding planes in the rock.

From a point about 4.5 miles below the Julian Griggs Dam to a point well above the limits of back-water from the O'Shaughnessy Dam, the Scioto River flows through a valley cut in the Devonian limestone. The lower reaches of this course cut through the Columbus limestone at normal water level, with the Delaware limestone outcropping in the higher lying portions of the

valley adjacent to the river. Near the Village of Bellepoint, about 6.5 miles above the site, the next lower formation appears in the bed of the river, namely, the Monroe limestone, the part here represented being of the Silurian Age.

Overlying the limestone, at all points in the valley where slopes are flat enough to prevent erosion, is a mantle of Wisconsin glacial drift, consisting very largely of yellow boulder clay with a thin top layer of clay loam, the boulder clay being an ideal material for embankments and the loam suitable for top dressing.

Near Columbus the Columbus limestone has an average thickness of about 105 ft. The Delaware limestone lies above the Columbus limestone, the contact being characterized by the bone-bed, notable among geologists for its high content of fossilized plates, teeth, and other bony structure of Devonian fish life. Below the Columbus limestone is the Monroe limestone, the two being separated, however, by an unconformity. The basal layer of the Columbus formation is commonly a conglomerate which consists of pebbles of Monroe limestone embedded in a matrix of smaller Columbus limestone and quartz sand.

The Columbus formation at the site consists of this basal layer, surmounted by many layers of limestone of varying thickness ranging from 2 or 3 in. to 4 and 5 ft. and varying in chemical composition from a true dolomite to an almost pure calcite, with physical characteristics almost as variable as the chemical composition.

Excavation for that part of the dam west of the outlet gate-house and in the easterly half of the river bed, developed the fact that the bed of the river, at the site, was in the massive lower layers of the Columbus formation and that excavation to the depth shown on the contract drawings would require the removal of much of this massive stone, a procedure which was unnecessary and which was immediately changed by decreasing the depth of excavation, where the rock foundation warranted, to a minimum of about 5 ft. under the dam proper, and with a somewhat less depth under the apron.

Excavation for the cut-off trench in the same location penetrated to a point about 1 ft. below the bottom of the basal conglomerate. The conglomerate was found to be from 6 to 8 in. in thickness and to have both above and below it, and throughout most of its extent, a thin layer of plastic blue clay. This discovery, which was not developed by the borings, led to the decision to carry all the cut-off trench excavation, across the river bed, to a point at least 1 ft. below the bottom of the basal conglomerate.

The dip of the rock in the Columbus District is from 20 to 30 ft. per mile to the east, or a little south of east. At the site it was found to approximate the larger figure and the cut-off trench was made to follow the variation in the level of the rock, being a little higher at the west end of the river section than at the easterly end under the outlet gate-house.

Excavation for the core wall at both ends of the dam encountered a small depth of the basal layers of the Delaware limestone underlaid by the

bone-bed and the top of the Columbus formation. The total thickness of the Columbus formation was about 87 ft., being less than the usual thickness for the Columbus District.

None of the excavated rock was too soft for use as coarse aggregate for concrete and the thicker layers made excellent stone for slope paving. It was necessary, however, to exclude the use of the softer stone for the wearing surface of the macadam roads constructed adjacent to the dam.

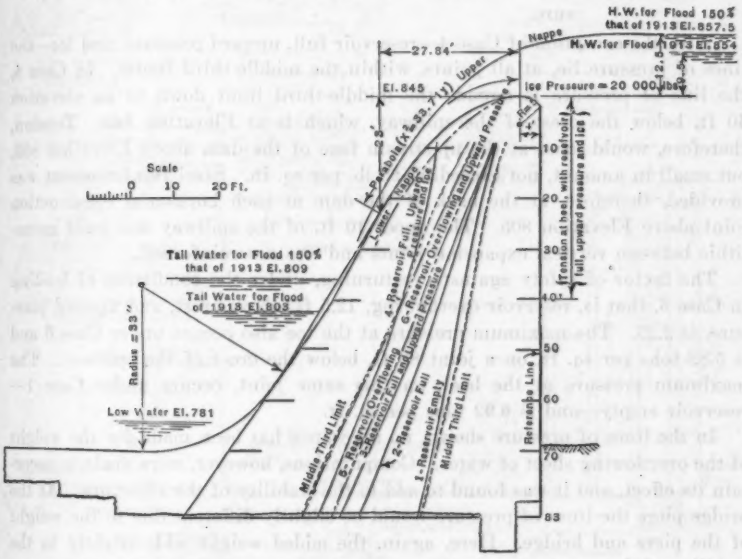

FIG. 13.—SPILLWAY SECTION, SHOWING LINES OF PRESSURE, O'SHAUGHNESSY DAM.

DESIGN OF SPILLWAY SECTION

The maximum section of the spillway, as constructed in the clear between the piers supporting the bridge above, is shown on Fig. 13. This section also shows the lines of pressure under various conditions of loading. In the design of the section the following assumptions were made:

Weight of masonry, in pounds per cubic foot..... 145
Weight of water, in pounds per cubic foot..... 62.5
Ice thrust, acting at crest, in pounds per linear foot.....20 000
Upward pressure: Full head pressure at heel decreasing uniformly to 0 at the toe, acting over two-thirds of the area.
Maximum head over spillway, 12.5 ft., for flood 150% that of 1913.
Surface of tail-water, 36 ft. below crest, for flood 150% that of 1913.
No silt in reservoir.
No wind when reservoir is empty.

The lines of pressure shown are for six different conditions of loading as follows:

Case 1.—Reservoir empty.
Case 2.—Reservoir full.
Case 3.—Reservoir full and upward pressure.
Case 4.—Reservoir full, upward pressure, and ice.
Case 5.—Reservoir overflowing, 12.5 ft. above crest.
Case 6.—Reservoir overflowing, 12.5 ft. above crest, and upward pressure.

With the exception of Case 4—reservoir full, upward pressure, and ice—the lines of pressure lie, at all points, within the middle-third limits. In Case 4, the line of pressure is outside the middle-third limit down to an elevation 40 ft. below the crest of the spillway, which is at Elevation 845. Tension, therefore, would exist at the up-stream face of the dam above Elevation 805, but small in amount, not exceeding 26 lb. per sq. in. Steel reinforcement was provided, therefore, at the back of the dam at each horizontal construction joint above Elevation 805. The upper 10 ft. of the spillway was built monolithic between vertical expansion joints and was not reinforced.

The factor of safety against overturning, under the conditions of loading in Case 6, that is, reservoir overflowing, 12.5 ft. above crest, and upward pressure, is 2.25. The maximum pressure at the toe also occurs under Case 6 and is 5.82 tons per sq. ft. on a joint 83 ft. below the crest of the spillway. The maximum pressure at the heel, on this same joint, occurs under Case 1—reservoir empty—and is 6.92 tons per sq. ft.

In the lines of pressure shown, no allowance has been made for the weight of the overflowing sheet of water. Computations, however, were made to ascertain its effect, and it was found to add to the stability of the structure. At the bridge piers the lines of pressure would be slightly different due to the weight of the piers and bridge. Here, again, the added weight adds slightly to the stability of the structure.

On the spillway section, Fig. 13, are shown the upper and lower nappes for an overflowing sheet of water having a depth of 12.5 ft. corresponding to the 1913 flood plus 50%, and it will be noted that the shape of the crest is such that the face of the masonry projects into the sheet of water well beyond the lower nappe. The maximum and minimum sections of the spillway, as well as the intermediate ones, are shown on Fig. 14.

Reinforced Concrete Arch Bridge Over Spillway

At Powell Road, about 2 000 ft. above the dam, a county highway crossed the river on a 2-span, steel, truss bridge, 240 ft. in length. With the filling of the reservoir this bridge would have been submerged. As it was not feasible to abandon a crossing of the reservoir or river at or near this point, the choice then lay between raising the existing bridge about 51 ft., adding new trusses at each end, and building long expensive approaches, and the construction of a new bridge. Comparative estimates showed that it would be considerably cheaper to build a bridge across the dam and to abandon the crossing at

Powell Road. This solution of the problem was adopted after it had been submitted to and approved by the County Commissioners of Delaware County, in which the dam and reservoir are located. It was also of advantage to the city to have a bridge across the dam, as ready access would thereby be provided from one side of the dam to the other and also to the two gate-houses.

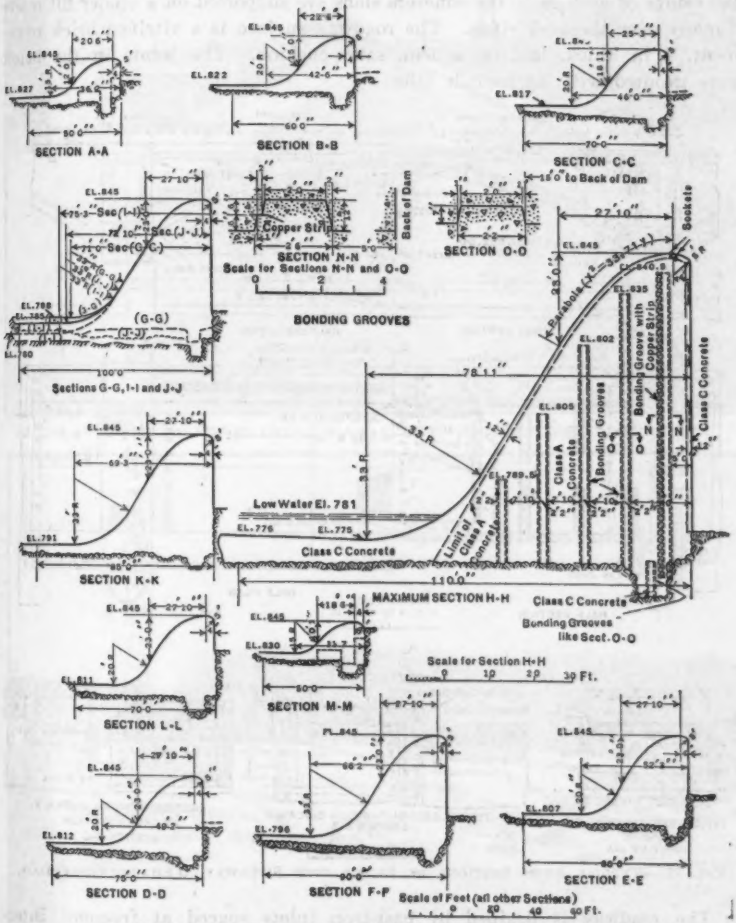

FIG. 14.—SECTIONS OF SPILLWAY, O'SHAUGHNESSY DAM.

The bridge consists of twelve reinforced concrete arches and has a total length of 879 ft., measured face to face of copings on the abutments at each end of the spillway. The arches are segmental, the intrados being struck on a radius of 52 ft. 9⅞ in. Each arch has a clear span of 64 ft. 6 in. and a rise of 11 ft. The thickness at the crown is 18 in., and at the springing line, 3 ft.

At right angles to the axis of the bridge, measured along the intrados, the arches have a length of 19 ft. 4 in.

The roadway over the arches has a clear width of 17 ft. 6 in., and is carried by reinforced concrete slabs supported by spandrel and curtain-walls extending down to the arch rings, except that, for a length of 21 ft. 6 in. at the center of each arch, the concrete slabs are supported on a cinder fill made directly over the arch rings. The roadway surface is a vitrified brick pavement, 4 in. thick, laid on a 1-in. sand cushion. The joints in the brick were grouted with an asphalt filler.

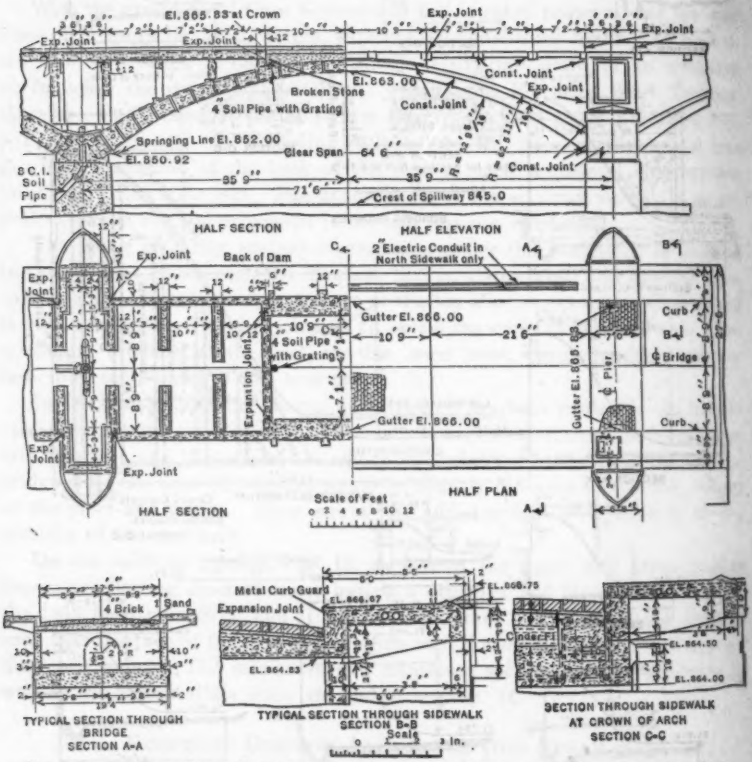

FIG. 15.—TYPICAL ARCH SECTIONS OF BRIDGE OVER SPILLWAY, O'SHAUGHNESSY DAM.

The roadway is drained by cast-iron inlets spaced at frequent intervals along each side of the pavement. The storm water is collected above the arches and is discharged through the arches, or through the piers, depending on the arrangement of the details.

On each side of the roadway is a 4-ft. sidewalk, consisting of a reinforced concrete slab carried on cantilever brackets anchored to the arch ring at the center of the arch and to the spandrel walls over the haunches

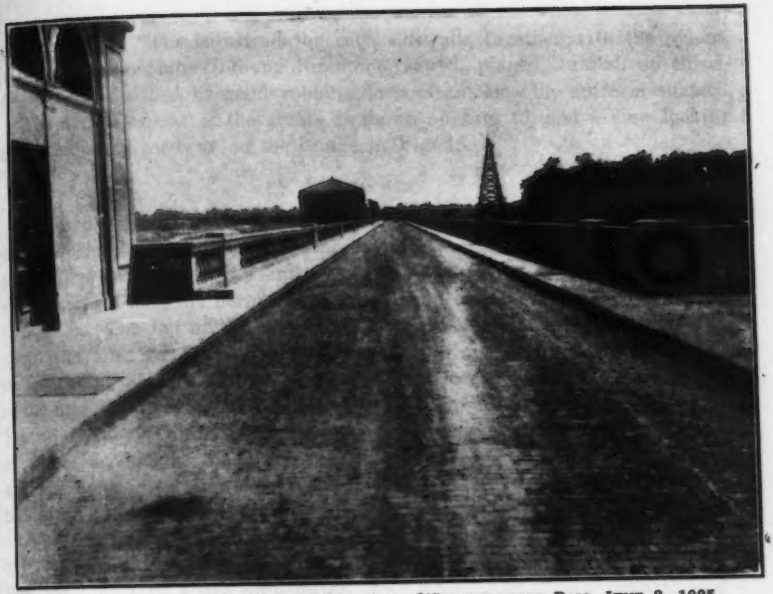

FIG. 16.—VIEW OF BRIDGE OVER SPILLWAY, O'SHAUGHNESSY DAM, JUNE 3, 1925.

FIG. 17.—O'SHAUGHNESSY DAM, EAST SPILLWAY CHANNELS, FEBRUARY 13, 1925.

at other points. The balustrade on each sidewalk, together with the pylons, is constructed of blue Indiana limestone, sawed, planed, turned, or chisel-dressed, and finished by sand rubbing to a clean, smooth, uniform surface.

The details of one of the arches is shown on Fig. 15, and a view looking along the paved roadway on the bridge in Fig. 16.

Approaches

At each end of the spillway section the approach consists of a rolled earth embankment or dike with concrete core wall, Fig. 18. The approaches are 25 ft. 6 in. wide on top and have side slopes of 1 on 2, except that the stone paving below the berm, on the up-stream side of the dike, has a slope of 1 on 3. The top of the dike is at Elevation 866.25, that is, 21 ft. 3 in. above the crest of the spillway and 8 ft. 9 in. above a high-water level, corresponding to the 1913 flood plus 50 per cent. On the reservoir side of the dike the 1 on 2 slope terminates at a berm 10 ft. in width and located 1 ft. 6 in. above high water. The slope paving begins at the outer edge of the berm, and, at the lower end, is either keyed into the rock or abuts against a concrete toe-wall. It is from 12 to 18 in. in thickness and is bedded on 12 in. of free-draining broken stone.

The concrete core wall is 3 ft. wide at the top, has a batter of ½ in. in 1 ft. on each side, and is keyed 12 in. into solid rock. The top is at Elevation 858.5, or 1 ft. above high water.

The roadway on each approach is of bituminous macadam, the width, 17 ft. 6 in., being the same as the clear width, between curbs, of the roadway on the bridge over the spillway. On each side of the roadway the edge of the embankment is protected by a fence built of reinforced concrete posts and rails. Just before the approaches connect with the masonry abutments at each end of the spillway, concrete steps on each side of the roadway provide access to the natural surface of the ground.

Outlet Gate-House

The outlet gate-house (Fig. 19) is 32 ft. square, inside dimensions, and is located at the center of the spillway, projecting out from the up-stream side of the dam. When water is drawn from storage it is taken through the gate-chamber immediately below. In the gate-chamber are two sets of chambers or wells, each set consisting of two separate wells connected by sluice-gates. There is no connection between the two sets of wells, thus providing duplicate means of drawing water from the reservoir. In case of repair to any sluice-gate one set of wells can be shut off.

The up-stream well connects with the reservoir through six 4-ft. by 7 ft. 6-in. rectangular openings, and immediately behind these openings are three sets of stop-plank grooves. In the up-stream groove are placed coarse bar screens, Fig. 20, having clear openings of 3⅝ in. Water drawn from the reservoir, is discharged into the river immediately below the dam and flows into the Julian Griggs Reservoir. A fine screen, therefore, is not needed at present, and the coarse screen serves simply to keep out floating débris and thus protect the sluice-gates. The two inner grooves are for a double set of stop-

planks, Fig. 20, which can be inserted should it become necessary to inspect or repair a sluice-gate. The stop-planks are stored in grooves provided for the purpose in two special wells. The stop-plank lifter is also shown in Fig. 20.

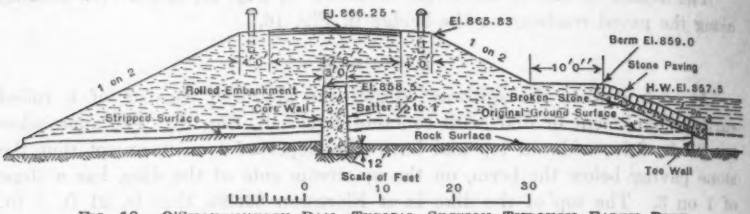

FIG. 18.—O'SHAUGHNESSY DAM, TYPICAL SECTION THROUGH EARTH DIKE.

Each up-stream well is connected with the corresponding down-stream well by three 36 by 60-in. rectangular openings, each opening being fitted with a rectangular sluice-gate of the same size as, and placed at the up-stream end of, the opening. These sluice-gates are set at different elevations so as to permit the drawing of water from storage at three different levels. From each down-stream well water is taken through two 30 by 60-in. sluice-gates into two 48-in., cast-iron pipes passing through the dam and terminating at the up-stream end of the apron. The ends are submerged so that the discharge is into the water cushion above the apron.

Each well is fitted with a ladder extending from the gate-house floor to the bottom of the well, and at various elevations pockets have been left opposite each other in the side walls of the well for the insertion of temporary platforms, so that access can be had to the sluice-gates and to the steady bearings on the sluice-gate stems.

At the bottom of the gate-chamber four 48-in., cast-iron pipes were placed, Fig. 19, below the bottom of the up-stream wells and connecting the down-stream wells with the up-stream face of the gate-chamber. These pipes took the ordinary flow of the river after the dam and gate-chamber had been constructed to an elevation above low water. After the completion of the dam each pipe was closed at the up-stream end by a cast-iron, blank flange, the pipe filled with concrete, and the lower end closed with another blank flange. Grout was then pumped into the pipe so as to fill it solid. In addition, the down-stream end of the pipe was permanently sealed, outside, by a concrete bulkhead grouted in.

The gate-house superstructure is built of cut and dressed blue Indiana limestone, matching that in the balustrade on the bridge, and is lined inside with a light-colored, salt-glazed face brick. The roof is constructed of steel trusses carrying concrete slabs 3 in. in thickness. The covering is of bright red mission tile laid on a bedding of Nalecode nailing concrete, 1½ in. thick. The doors and windows are of hollow metal construction built of heavy hard copper, stiffened, and reinforced. The windows are glazed with ¼-in. polished wire woven glass. The superstructure houses the hand-operated, ball-bearing, sluice-gate stands and also a 2-ton, hand-operated crane for raising and lowering the screens, stop-planks, etc.

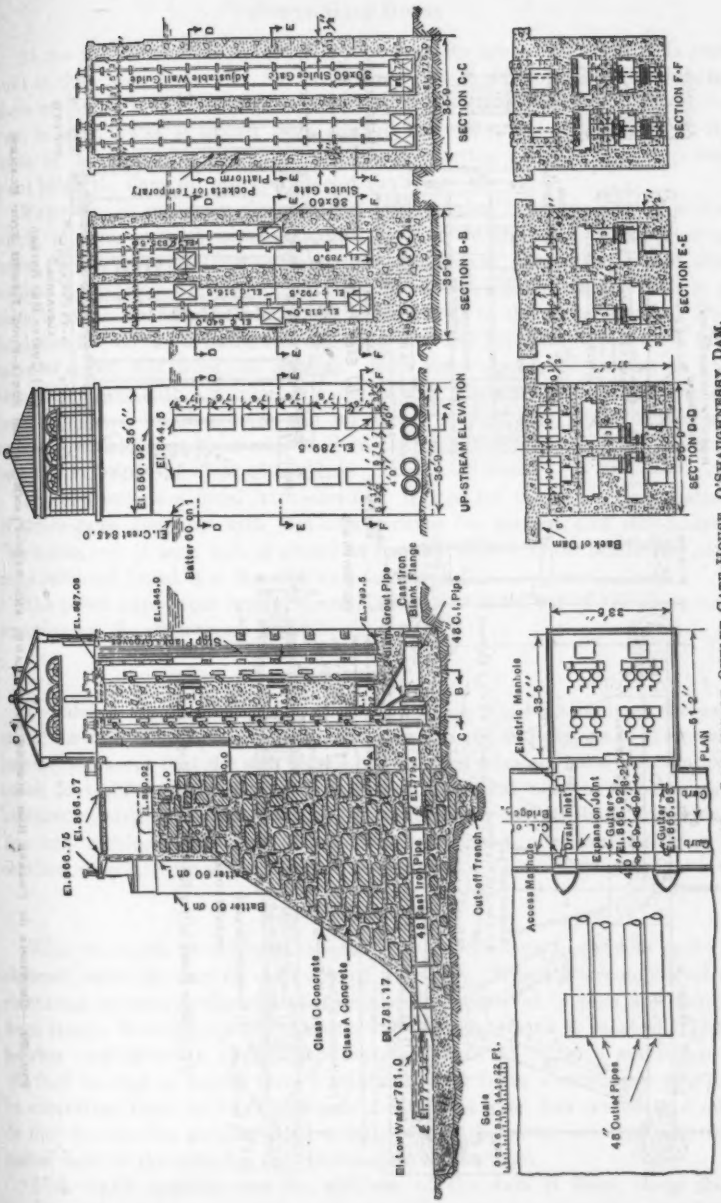

FIG. 19.—SECTIONS OF OUTLET GATE-HOUSE, O'SHAUGHNESSY DAM.

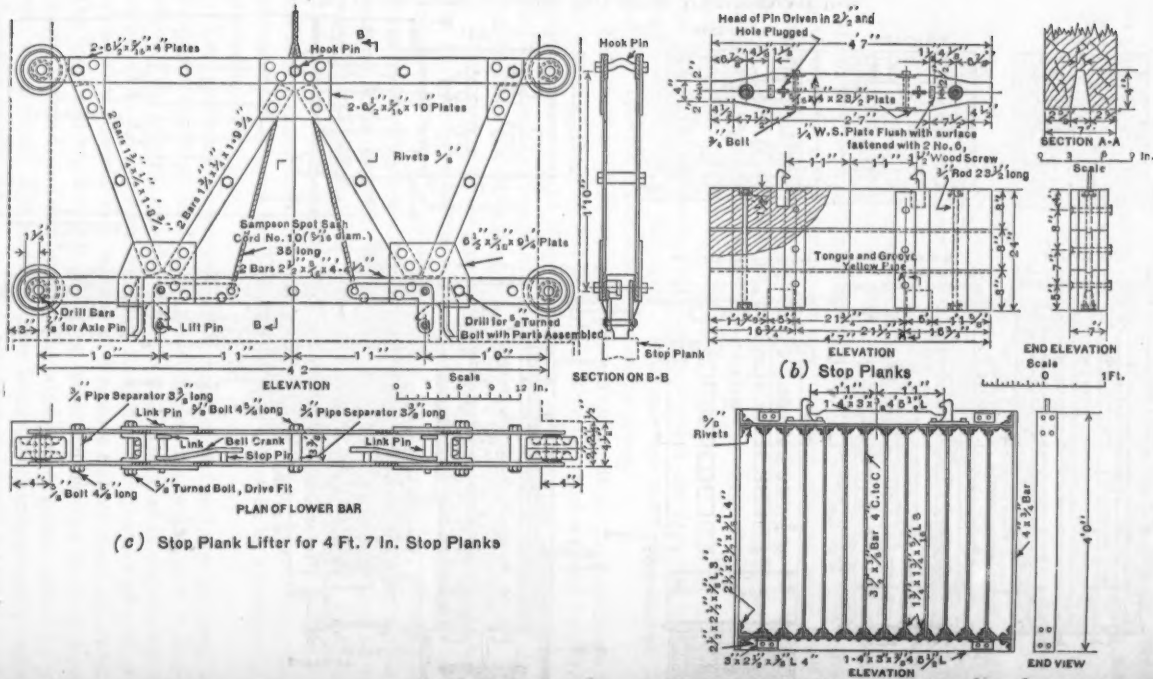

FIG. 20.—SECTIONS OF COARSE BAR SCREEN, STOP-PLANK, AND STOP-PLANK LIFTER FOR 4-FOOT 7-INCH STOP PLANKS.

Power Gate-House

At the west end of the spillway is a power gate-house, Fig. 21. This was built so that, should the city, in the future, wish to develop power at certain times of the year, that is, with reservoir full and water overflowing the spillway, or when water is drawn from storage, say, from the upper 10 or 15-ft. depth in the reservoir, it could do so by constructing a hydro-electric power plant below the dam, on the west side of the river.

Water would be drawn through the gate-chamber into two sets of wells, which, in turn, connect with a conduit, 15 ft. wide and 19 ft. high, passing under the bridge to the down-stream side of the dam. From the end of this conduit a head-race could be constructed along the side hill in the rock to a suitable point where penstocks could be extended to the power house. The head-race has not been built, but the upper end has been excavated for a distance of a few feet from the conduit. This short stretch of excavation has been roofed over with a reinforced concrete slab, above which is a covering of loam and grass sodding. On the up-stream side of the gate-chamber an approach channel has been excavated in the rock, the bottom of the channel being 20 ft. below the crest of the dam.

The two wells are fitted with cast-iron frames for the future installation of sluice-gates and also with cast-iron grooves for screens and stop-planks. The upper end of each well is closed at present with a 12-in. reinforced concrete bulkhead keyed into the side walls of the well.

The power gate-house is slightly smaller in size than, but of the same construction as, the outlet gate-house.

Pavilion

To balance the structure as a whole, a pavilion has been built at the east end of the spillway. It is similar in construction and dimensions to the power gate-house, except that the wall panels between the pilasters have been omitted on all four sides. In the three sides other than that next to the roadway, balustrades, similar to those on the bridge, have been built, both for protection and architectural effect. From the pavilion a commanding view is obtained, especially up stream across the reservoir.

Spillway Channels

With the width of spillway adopted it was necessary to provide spillway channels below the dam on each side of the river. This was accomplished by excavating benches in the rock, the benches being curved in plan and sloping down stream from the toe of the apron until the river bank is reached. These benches vary in width from a minimum of 32 ft. 11 in. to a maximum of 103 ft. 3 in., and in height from a minimum of 5 ft. to a maximum of 20 ft. In excavating these spillway channels a double purpose was served; not only do they provide for guiding flood-water down to the river, but they also furnished most of the rock for the construction of the dam.

With water passing over the spillway of the dam it flows along these benches and, at the same time, spills over from one bench to the next lower

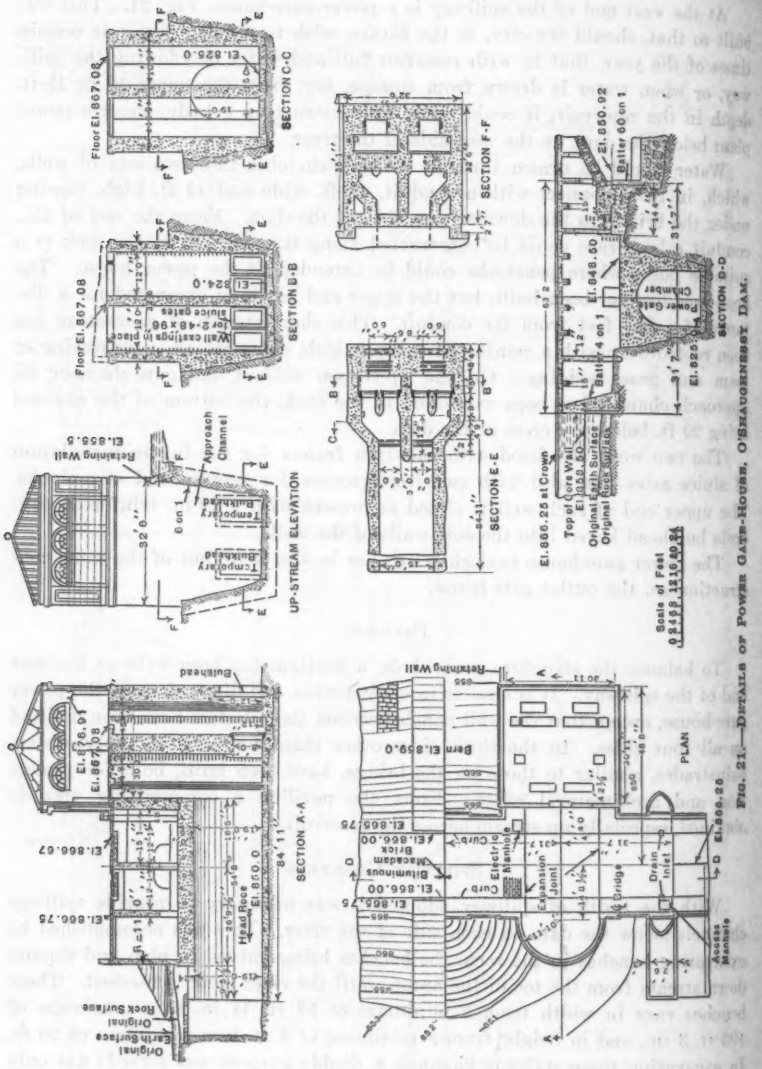

FIG. 21.—DETAILS OF POWER GATE-HOUSE, O'SHAUGHNESSY DAM.

one until it reaches the river. The greater the flow the longer the travel of the water longitudinally of the benches. With any considerable volume of flow over the dam, it is a beautiful sight to see the water rush along the spillway benches and tumble over from one bench to the next. To the present (October, 1927), the greatest depth of water passing over the spillway, on March 21, 1927, was 4.2 ft., corresponding to a flow of about 21 500 cu. ft. per sec. A view of the east spillway channels is given in Fig. 17.

Construction Plant and Methods

For various reasons a more or less elaborate construction plant was required for building the dam. For example, excavated rock, when suitable, and as needed, was to be used as construction material; equipment, other than spouting, had to be installed for transporting concrete as the specifications provided that "spouting of concrete as a means of transportation will not be permitted"; and, again, as the work was located about three miles from the nearest railroad siding, construction equipment, supplies, and building materials, other than those obtained at the site, had to be transported over this distance. It was these, together with other, factors, which determined the type of equipment as well as the methods used in constructing the dam.

Electrically Operated Equipment.—With the exception of the steam shovel, cableway engines, channeling machine, gasoline locomotives, and motor trucks, practically all the plant and equipment used was electrically operated. As there were no power lines in the vicinity of the dam, a 7-mile high-tension line, carrying a 15 000-volt, 3-phase, 60-cycle current, was constructed, connecting the lines of the Columbus, Delaware, and Marion Electric Railroad with a transformer station located near the dam. From the transformer station a 440-volt circuit was run to the crushing plant and 220-volt circuits to the concrete mixing plant, to the air compressor plant, to pumps, and to small motors and lights located here and there on the work and in the camp. About twenty-five motors, of 5 h.p., or more, were in service at various points.

Cableways.—For constructing the masonry part of the dam two traveling cableways were installed, both traveling on the same tracks and having similar equipment and dimensions. The cableways had a span of a little more than 1100 ft. and the towers a height of 103 ft. 6 in. They were equipped with Lidgerwood steam cableway engines and marine type boilers and with electric motor drive for lateral travel of the tail towers. The main cables, lock strand, were 2¼ in. in diameter. On both banks of the river the railroad trackage under the cableways was long enough to permit the up-stream cableway to reach a few feet up stream from the up-stream face of the outlet gate-house and the down-stream cableway to reach the down-stream face of the longest apron. Each cableway had a nominal capacity of 10 tons, but this load was frequently exceeded, as the weight of a full bucket of concrete was something in excess of 12 tons.

Transportation Equipment.—At the beginning of the work the transportation equipment consisted of a fleet of fifteen old White dump trucks; these were supplemented later by a varying number of locally owned trucks, two gasoline locomotives, trackage, and cars. On the east bank, immediately in

FIG. 21.—DETAILS OF POWER GATE-HOUSE, O'SHAUGHNESSY DAM.

front of the cableway towers, two tracks were laid, one running to the concrete plant and the other to the crushing plant. Concrete was hauled, on one track, to either of the cableways in 5-yd. bottom dump buckets set on flat cars; the other track was used for carrying rock from the cableways to the crushing plant.

Trucks were used for hauling all the construction plant and equipment, as well as supplies and building materials, from the railroad spur at Powell, Ohio, 3 miles away; for hauling all the earth excavated, except a small portion used in the coffer-dams; and for hauling a considerable portion of the excavated rock either to the crushing plant direct, or to a point where it could be handled by the cableways. For the maintenance of the trucks a fairly well equipped garage, with repair parts and a few small machine tools, was built.

Excavation.—The bulk of the excavation, both earth and rock, was made with a 1-yd. Osgood steam shovel, mounted on a caterpillar truck. The excavated material was loaded into trucks or into skips handled by the cableways. The cableways delivered the excavated rock to cars on one of the tracks running in front of the cableway towers, or to a grizzly on the east bank where the larger stones were separated, for use in cyclopean masonry, before being discharged into the cars. The cars, in turn, delivered the excavated rock to the crushing plant.

The limestone encountered required extensive drilling and blasting. The drilling of holes for blasting and the drilling of all grout holes less than 15 ft. in depth, was done with jack-hammers driven by compressed air supplied from a stationary motor-driven compressor plant in which were located two, belt-driven, horizontal, Ingersoll-Rand air compressors. A Sullivan channeling machine was used to cut the sides of the cut-off trench, as required by the specifications. The mucking of the rock in the cut-off trench, and in the core-wall trenches, and the trimming of the excavation was all done by hand supplemented by light blasting. Excavation, both hand and machine, was carried on day and night during a large part of the 1922 and 1923 working seasons and during a part of the 1924 season.

Crushing and Screening Plant.—The principal items of equipment installed in the crushing and screening plant were a No. 6 and a No. 25 Kennedy gearless crusher, driven by 40 and 25-h.p. motors, respectively; a rotating cylindrical stone screen, 5 ft. in diameter and 19 ft. long, with a dust screen of larger diameter, 6 ft. long at the inlet end; a four-compartment storage bin and skip hoist; and bucket elevators and belt conveyors, all the equipment being motor-driven. Later, a small rotary screen was installed and used for washing the smallest size stone. The crushers were set at ground level and the screen at the top of the storage bin. The rock to be crushed was dumped into a receiving pit at ground level, hoisted by the skip to the charging platform over the crushers, put through the larger crusher, hoisted to the screen, and screened. The screened material went into bins from which it could be loaded into trucks or to storage piles, the smallest size aggregate being passed through the washer if desired. Tailings from the screen were conveyed to the smaller crusher, were recrushed, and passed through the screen again, together with the crushed stone from the larger crusher. The crushed stone

was screened into four sizes, screenings and dust less than ¼ in., ¼ to ¾ in., ¾ in. to 1½ in., and 1½ to 3 in.

Storage of Crushed Stone and Sand.—The storage plant for crushed stone and sand consisted of a timbered tunnel, with the top at ground level, extending from the concrete mixing plant to a point about 400 ft. distant from the plant; a timber trestle built directly over the first 225 ft. of the tunnel; a Green, portable, belt-conveyor unit; belt conveyors on the trestle and in the tunnel; and a bucket elevator extending from the end of the tunnel conveyor to the top of the concrete mixing plant. Crushed stone, more than ¼ in. in diameter, was delivered from the storage bins under the screen, by conveyor and elevator, to the trestle conveyor which, in turn, discharged it into storage piles over the tunnel and on the ground on each side of the tunnel, the three sizes of stone being kept separate. Sand, hauled by truck from the railroad, was dumped into the receiving end of the portable conveyor unit and was discharged into a storage pile at the outer end of the tunnel beyond the trestle. The sand and crushed stone were discharged through gates in the top of the tunnel and delivered to the concrete mixing plant by belt conveyor and elevator.

Unloading Plant at Railroad Siding.—Bulk material and supplies, principally sand and coal, were unloaded at Powell, on the Hocking Valley Railway, by an unloading plant consisting of a track feeder and bucket elevator and elevated bin from which the material was discharged directly into motor trucks. The equipment was driven by a gasoline engine.

Concrete Mixing Plant.—Practically all the concrete was mixed at a central mixing plant located about 100 ft. up stream from the dam and a short distance east of the east abutment section. The upper part of the plant consisted of four compartments or storage bins for sand and the three sizes of crushed stone; below were two floors above the ground level, the proportioning devices being located on the upper floor and the concrete mixers on the lower. The ground story was a pipe shop.

The equipment consisted principally of two, 1-cu. yd., Smith, tilting mixers; a measuring hopper over each mixer; a collecting hopper, with 2-way chute for feeding the measuring hoppers; four sets of weighing devices, one each for the three sizes of stone and one for the sand; a calibrated water barrel, with 2-way discharge piping; an 8-cu. yd., bottom dump, concrete hopper, in front of the mixers and over the railroad track running under the cableways; and an electrically operated platform elevator for hoisting cement.

Each weighing device consisted of a weigh hopper with a lever-dumping, self-closing bottom; a motor-driven, steel apron conveyor for feeding material to the weigh hopper from an opening in the floor of the storage bin above, from which both were suspended; and a scale-beam with an electric contact so arranged that the lifting of the beam would shut off the conveyor motor. One switch started any one or all of the conveyor motors. The bottoms of the weigh hoppers were connected to a single dumping lever so that, with the scale-beams set, the pressing of the starting switch-button was all that was necessary to weigh out any desired quantities of the three sizes of stone and

of the sand. The pulling of the dumping lever discharged these materials into either of the two measuring hoppers, where the cement was added. The cement was handled direct from and measured as in the original packages.

The specifications required the proportioning of the aggregates by volume. As might be expected, the weight of material for a given volume was not always constant, hence, in order that the materials might be proportioned by weight, which the contractor requested, weighed quantities of the several classes of material were checked, several times during a run, against the volume as measured in the charging hoppers, which were calibrated. If any departure from the required volume was found the scales were correspondingly corrected.

Pumps.—The dewatering of the coffer-dams was done by two, 4-in. discharge, motor-driven, low-lift pumps. When once pumped down the intermittent operation of one pump would handle the leakage. Water for concrete, stone washing, and other plant uses was furnished by two, 3-in. discharge, motor-driven, two-stage centrifugal pumps, one pump being able to supply the demand when the washer was not being operated.

Camp.—The camp included the engineers' office, built for the city by the contractor, as required by the specifications; two contractors' offices; two store buildings; a well equipped emergency hospital, with a graduate nurse in charge day and night; a blacksmith shop; the garage already mentioned; an air-compressor building; a small saw-mill and tool storage building; a large mess hall and commissary; a bath house and latrine; and a varying number of one-story bunk houses, nine being constructed early in the work. All but four of the bunk houses were either torn down or used for other purposes, there being only a few occasions when four were filled. Most of the labor, both skilled and unskilled, drove to the work from the surrounding countryside, or from the dozen or more villages and small towns within a radius of 15 miles, a few making the trip daily from Delaware and Columbus, which were somewhat farther distant.

All the buildings, except the garage and air-compressor buildings, were of frame construction; these two had corrugated iron siding and roofs. The buildings were lighted by electricity and the bunk houses, latrine, and commissary were well ventilated and screened. The engineers' office was the best equipped building in the camp, being provided with a furnace, Delco lighting and power outfit, a drilled well, motor-driven pump, a well-equipped wash and toilet room, and a fireproof concrete vault for the storage of note-books, drawings, and other records.

Sanitation.—Camp wastes were handled in several ways. The large latrine, and smaller ones at several points on the work, and the mess-hall kitchen were provided with galvanized cans which could be removed, through doors at ground level, from the outside of the buildings. All wastes so collected were buried in pits dug at some distance from the work, the contents of the pits being covered with quicklime and a few inches of earth as soon as deposited. Wash water from the latrine and kitchen was run into farm tile drains from which it was allowed, by sub-surface irrigation, to leach into the ground. The engineers' office was provided with a small sewage treatment plant, consisting

of a covered circular concrete septic tank and a sub-surface irrigation system of two units. Each unit had a length of 232 ft. of vitrified pipe, wrapped with burlap at the joints and surrounded with crushed stone. Drinking water, other than that for the engineers' office, was obtained from a 100-ft. well by a motor-driven pump and stored in an elevated wooden tank erected close to the mess hall to which it was piped.

Other Plant and Equipment.—Mention should also be made of the cement storage house, 60 ft. wide by 100 ft. long, with a capacity of about twenty carloads of cement, a stiff-leg derrick with an 80-ft. boom, used for many purposes and at several points on the work, the road-building machinery, a complete compressed-air operated drill dressing outfit, and a grouting machine.

Coffer-Dams

In designing the dam it was obviously desirable to take full advantage of the topography of the top surface of the rock, as developed by the test borings, and to make the spillway as long as possible, in order to keep at a minimum the depth of water which would have to pass over the spillway under the assumed maximum flood flow. It was decided, therefore, to place the ends of the spillway section at about the points where the rock surface reached the elevation of the crest of the spillway. This brought the center of the spillway close to the low-water mark on the east side of the existing river bed, at which point the rock outcropped and there was no question, either from surface indications or borings, as to the suitability of the location for the outlet gate-house.

As previously stated, provision was made in the plans for placing four 48-in. pipes in the up-stream part of the gate-chamber to take care of the ordinary flow of the river during the construction period. The construction of the gate-house was, therefore, the first work started in the river bed. The first coffer-dam, on the east side of the river, was begun in the early part of September, 1922, before the completion of the general construction plant. It was planned by the contractor to extend the coffer-dam to Elevation 790, 9 ft. above low water, but on the recommendation of the engineers the height was reduced to about Elevation 784, roughly 3 ft. above low water in the river, as coffer-dams of this height had proved satisfactory in the construction of the Julian Griggs Dam.

In addition to that section of the dam in which the outlet gate-house is located, sufficient area for the next section to the west, out into the river, was included in the east coffer-dam, the inside dimensions of which were 175 ft., measured at right angles, and between 145 and 150 ft., measured in a direction parallel to the dam. For the construction of the up-stream, down-stream, and river sides of the coffer-dam, cribs, about 10 ft. in width, made of small logs secured on the site of the work, were built, the framing being done on the bank of the river. When complete, the cribs were skidded into the river, floated into position, fastened together, and sunk by filling them with rock. Earth was then deposited around the outside of the coffer-dam, after which 2-in. sheeting was placed, edge to edge, all the way around the outside face of the cribbing. The sheeting was held at the top by waling timbers

attached to the cribbing, and was driven into the earth by mauls. As the water was pumped down in the coffer-dam additional earth and small rock was placed in the cribbing and outside the sheeting, the outside fill being compacted by men, with rubber boots, until the top of the fill was above the water level in the river. In spite of the fact that the entire easterly part of the river bed was bare ledge rock, a remarkably tight contact was secured.

The first construction work in the coffer-dam was started on October 6, 1922, and continued until December 28, when the coffer-dam was topped by a moderate flood. An attempt was made to pump the water out during the early part of the following month, but this had to be abandoned on account of another rise in the river. It was then decided to cease operations until spring. Some trouble was encountered during the winter with ice jams, but only one actually did any damage. A view of the east coffer-dam, taken on November 29, 1922, is given in Fig. 22.

On May 1, 1923, the coffer-dam was pumped out and construction work resumed, but it was again flooded on May 12, and it was not until May 24 that construction work was again started. On June 6, and again on June 15, heavy local showers raised the river sufficiently to flood the work for an hour or two, but operations were resumed the following day.

On June 25, 1923, an opening was made in the east coffer-dam and the river turned into the 48-in. pipes passing through the gate-chamber. On the same day the up-stream portion of the coffer-dam on the west side of the river, previously constructed, was closed. The up-stream side of the west coffer-dam was similar in construction to the east coffer-dam, but was tied into a concrete wall, constructed for the purpose, which projected up stream several feet from the westerly end of the concrete already in place in the east coffer-dam. The river side of the west coffer-dam was also of the same construction, the cribbing resting on the concrete apron, which was already in place, and tying into the westerly end of the down-stream cribbing of the east coffer-dam. The down-stream side of the west coffer-dam consisted of an fill made of earth excavated from the west bank of the river. The up-stream side of the west coffer-dam was also reinforced by dumping excavated material on the river side of the cribbing, raising the effective height to about Elevation 788. The area enclosed by the west coffer-dam was, roughly, 130 ft., up and down stream, by 180 ft. parallel to the axis of the dam.

The west coffer-dam was flooded twice, first, on July 8, 1923, when a part of the down-stream fill was washed out and had to be replaced, and the second time on September 22, when little damage was done. On November 2, 1923, the concrete work was completed to a point above low-water level. From this time, however, the up-stream side of the coffer-dam continued to be used as a means of crossing the river, a timber foot-bridge spanning the opening through which the river flow passed to the 48-in. pipes in the gate-chamber.

Excavation

Before describing the methods used in making the excavation for the dam and appurtenant work it will be well to state briefly the condition existing at the site. The Columbus or Delaware limestone was encountered at all

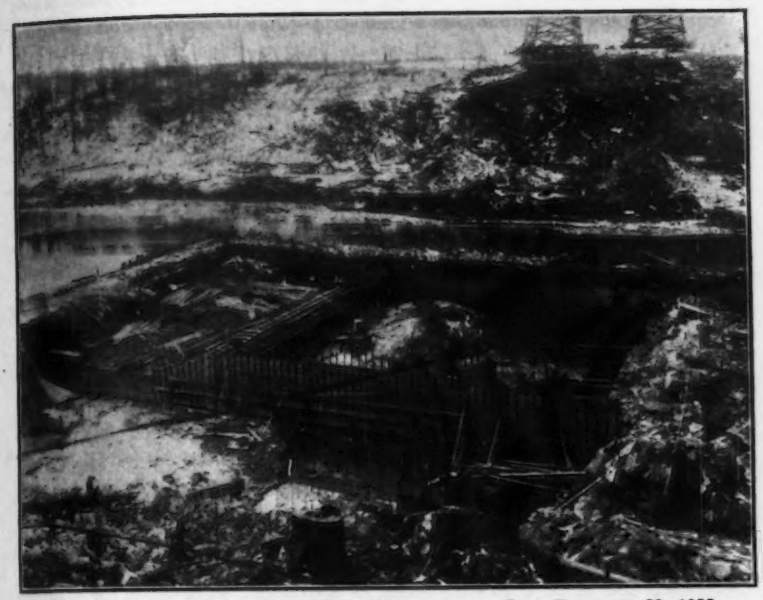

FIG. 22.—VIEW OF EAST COFFER-DAM, O'SHAUGHNESSY DAM, NOVEMBER 29, 1922.

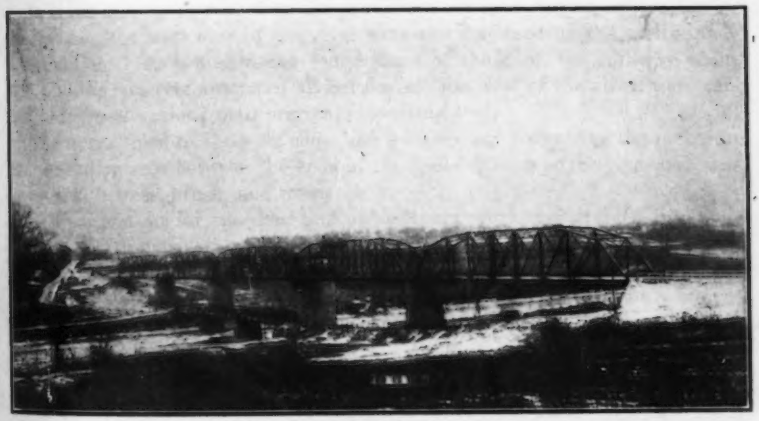

FIG. 23.—RATHBONE BRIDGE—THE OLD AND THE NEW.

points under the dam and core walls, the cover varying, however, both in character and thickness, the latter reaching a maximum of about 15 ft.

The higher lying banks outside of and at each end of the concrete part of the dam were cultivated areas with 2 to 12 ft. of cover consisting of clay loam, yellow boulder clay, and a varying thickness of clay mixed with rock fragments immediately above the ledge rock. The first sharp rise from the river bed on the east bank had only such cover as was held in place by the roots of trees, brush, and weeds. East of this rise was a moderately sloping terrace, the rock being covered with from 2 to 5 ft. of leaf mould, loam, and clay and rock fragments mixed. In this area the top of the rock had been affected by weathering to a greater extent than at any other part of the site except for a few small areas on the west bank. The second sharp rise east of the river was covered with material similar to that overlying the terrace, but of less depth.

The easterly half of the river channel was bare ledge rock, whereas the westerly half was covered to a depth of from 1 to 4 ft. with a bar of dirty sand, gravel, and small fragments of rock. Immediately west of the river was an alluvial terrace from 30 to 50 ft. wide, the cover over the rock running from 4 to 9 ft. in thickness and of material similar to that found in the river, except with a considerable admixture of leaf mould and loam. The lower two-thirds of the steep slope west of the river consisted of rock steps filled, to an evenly sloping top surface, with loam, leaf mould, and clay and rock fragments of all sizes, some measuring as much as 5 or 6 ft. in one dimension. Some of the vertical faces of the steps were 15 ft. high and both the vertical and horizontal faces were more or less weathered, in a few places, to a considerable depth.

It is interesting to note that the conditions revealed during excavation in this area on the west side of the river were not disclosed by the preliminary investigations. As a result, the foundations of the dam, the spillway channels, and the concrete aprons of all but one section west of the river, were carried to lower elevations than originally contemplated.

The upper third of the west slope had scarcely any cover over the rock but, like the entire area between the ends of the spillway, except the river bed, was covered with trees, brush, and weeds.

The excavation for the dam and appurtenant work was divided into four classes: Earth excavation above Elevation 782; rock excavation above Elevation 782; excavation below Elevation 782; and rock excavation in the cut-off trench. The contract prices for the first three classes of excavation were the same, $1.90 per cu. yd., and, for rock excavation in the cut-off trench, $12.00 per cu. yd.

Except for some hand work for the engineers' office and certain small culverts, actual excavation was started on July 22, 1922, on that part of the relocated highway east of the dam where cuts were necessary. This was followed by the stripping of the cover and loose top rock on the terrace east of the river, all the excavated material from these two locations being placed in embankments made necessary by the relocated highway. Excavation for the

east section of the spillway and rough excavation for the east spillway channel came next, followed, successively, by excavation for the sections of dam and spillway channels west of the easterly section, as far as the top of the first steep slope east of the river. Some of the excavated material was used to complete the road embankments, the remainder being placed in storage piles adjacent to the stone crushers up to the time the crushers went into operation. Prior to the completion of the first cableway (there were two), all the hauling of excavated material was done by trucks, and thereafter by both cableway and trucks, the trucks hauling part of the excavated rock direct to the crushing plant and a large part of the remainder to large steel skips which, in turn, were handled by the cableways.

On October 10, 1922, excavation by steam shovel was started in the first coffer-dam, and completed on November 15. On this latter date rough excavation for the remaining sections of the dam and spillway channels east of the outlet gate-house was started. This work was carried on, as weather permitted, during the winter, all the rough excavation for the remaining sections of the dam, east of the river, being completed, as well as a part of the spillway channel excavation, by March 27, 1923, when the shovel was moved to the west side of the river and excavation started for the westerly spillway section.

Excavation on the west bank was carried on, successively, from rock step to rock step, working toward the river, part of the excavated rock being taken to the crushing plant, by cableway and railroad, the remainder being cast over on the next lower section and again rehandled. It was during this period that a second steam shovel was put in operation, on the terrace just west of the river.

On July 14, 1923, steam-shovel excavation was begun in the west coffer-dam, following which came the completion of the excavation on the terrace immediately west of the river. Part of the rock from the coffer-dam was transported to the crushing plant, but the bulk of the mixed earth and rock from the west bank was placed in spoil banks below Elevation 792 on the upstream side of the dam. By the early part of September the steam shovel work for the dam proper was complete, and work was again taken up on the spillway channels. It was necessary to go over the spillway channels at least once and, in some instances, several times to put them in final acceptable condition, this work being partly done during the remainder of 1923 and completed in 1924. The excavation necessary for the new road connecting the west end of the dam with the existing county highways, as well as the excavation of most of the earth used in building the embankment sections of the dam, was made during the latter part of 1924.

A considerable amount of hand excavation was necessary in trimming the area under the dam and apron and the spillway channels. The bulk of the core wall and cut-off trench excavation was hand work supplemented by light blasting of the rock, the sides of the cut-off trench first having been cut with a channeling machine to the full depth. The excavation for the pavilion walls and for the approach channel to and for the head-race below the power gate-house was also done by hand mucking after blasting.

Throughout the work it was necessary to drill and blast the rock before it could be handled by steam shovel, and wherever the excavation had to be brought to neat lines it was necessary to line drill the rock before blasting to prevent overbreaks and to hand trim the faces of the excavation, this being especially the case along the edges of the spillway channels where, even with the precautions noted, some overbreaks occurred. Practically all the rock excavated by hand was carried by the cableways where the work was within the area served by them, and by truck from all points outside this area.

Grouting the Foundation

The information obtained from the core borings made on the site of the dam and from the hydraulic tests made on the cored holes resulted in the decision to grout the foundation in order to close up any open bedding planes, solution channels, cleavage cracks, or fissures that had been located by the borings or tests, or that might exist at points not explored by the borings. The hydraulic tests had further developed the fact that in general the rock was fairly water-tight below a depth of approximately 10 ft. or less below the top of ledge rock, except at a few points which could be given special attention. It was decided, therefore, that in general the grout holes should be drilled to an approximate depth of from 8 to 10 ft. below the top of the rock, after the excavation was completed. The depth, however, was varied by drilling deeper along the edges of the steps in the foundation adjacent to the lower sections of the dam and to a less depth on the other side of the steps, the holes along the side adjacent to a lower section reaching to from 3 to 6 ft. below the top of the rock in that section after the excavation in this section had been completed. It was also decided that there should be a row of holes up stream from the cut-off trench, unless the rock at this location showed no seams or cracks, and a row in the cut-off trench, the holes in these rows to be spaced not more than 12 ft. apart, and also holes on 10 to 12-ft. centers, both ways, down stream from the cut-off trench and under the dam, but not under the apron, and additional holes into every crack and crevice found in the excavated area.

A number of crevices were opened by the excavation, a few at the easterly end of the spillway section and just west of the river bed being filled with earth. Each crevice was cleaned out with water under pressure and grout pipes were placed in the crevice, or holes drilled, so as to intercept the crevice, or both, with the idea of making it possible for the grout to reach every channel through which water might seep under the dam. In several of the spillway sections no attempt was made to follow any regular spacing of holes, the location of the cracks and seams in the rock determining the location and spacing of the holes drilled.

A total of 553 grout holes were drilled under the dam, abutments, and core walls, 526 of this number being drilled with jack-hammers, using a 2-in. bit, the over-run in width at the top of the hole being enough to admit the 2-in. standard weight, wrought-steel pipe used for grouting. These holes ranged from a minimum of 4.1 ft. to a maximum of 11.1 ft. in depth, the average being 9.6 ft. For the holes under the large concrete abutment blocks at either

end of the spillway and under the two westerly sections of the spillway, it was necessary to use a well-drilling machine with a 4-in. spud-bit to reach to a depth lower than the bottom of the adjacent section of the dam. Twenty-seven machine-drilled holes were put down, ranging from 18.0 to 30.5 ft. in depth, the average depth being 26.4 ft.

As soon as the drilling was completed, grout pipes of sufficient length to reach above the first lift of concrete were put in place. In the holes drilled with jack-hammers, 2-in. pipe was used; in the machine-drilled holes, 4-in. pipe was required, the pipe being cemented in, where necessary, to exclude the concrete. Where the elevations of the foundation of adjacent sections of the spillway differed by more than about 8 ft., it was necessary to hold back the grouting of the higher section until part of the concrete had been placed in the lower section, pipe being extended up through any additional lifts of concrete placed in the higher section. In some of the sections at the westerly end of the spillway the pipes were carried through the up-stream face of the dam. In the sections of the spillway in the river bed, it became necessary to limit the length of pipe for which payment would be allowed. The extension of the pipe was permitted, however, in order to expedite the placing of concrete; but the length for which payment was allowed was limited to 4 to 5 ft. under the dam and 11 to 14 ft. in the cut-off trench. For each fitting that was necessary, an allowance of 1 lin. ft. of pipe was made and the figures given subsequently include this allowance.

Excluding the grout-pipe connections to the 48-in. outlet pipes in the gate-chamber, and pipe used for other purposes, a total of 4 363 lin. ft. of pipe was paid for, the minimum length for any one hole being 2 ft. and the maximum, 43 ft. The total length included eight grout-pipe connections to sink holes, springs, and mud seams where no drilled holes were required.

The grouting machine was made on the job from a stock cylindrical steel air reservoir, 28 in. in diameter by 44 in. high, having pressed oval heads, the upper head containing an oval cast-iron clean-out manhole held in place by two pressed steel yokes and bolts. Angle-iron legs were welded to the tank, and a 3-in. outlet pipe, with a 3-in. brass cock and reducer for connecting to 2-in. pressure hose, was screwed into the bottom head. For mixing the grout four ½-in. pipes were screwed through the lower head about 4 in. from the outside shell and on the quarter-points, each pipe having an elbow and short nipple on the inside end and all four pipes being connected to a 1-in. air line running up the outside of the tank. This air line had a 3-way cock, to the outstanding opening of which the air-supply hose was connected, and two tees, one for the pressure-gauge connection, and the other a blow-off, with a valve, which extended through the top head of the tank.

The operation of mixing the grout consisted of filling the tank to the proper point with water, through the manhole, turning in a small quantity of air through the mixing pipes, placing 2 sacks of cement and 2 sacks of sand in the tank, screwing the manhole casting in place, the blow-off being open, and turning on of full air supply to the mixing pipes for at least 1 min.

Connection between the tank and the grout pipes was made with 2-in., rubber-lined linen hose. The grout was applied by closing the blow-off valve

and opening the outlet cock, the air supply being turned in through the top connection if it failed to move the grout when being supplied through the mixing pipes.

Payment for the grout placed was made by the cubic yard which by definition consisted of 8 cu. ft. of cement, 8 cu. ft. of sand, and the necessary water, the actual volume of this quantity of wet grout being somewhat less than 1 cu. yd. A fine brick sand, 45% or more of which would pass a 40-mesh screen, was used. A total of 229 cu. yd. of grout was placed, the quantity in the several sections of the spillway varying widely. The minimum quantity placed in any one section, 71 ft. 6 in. in length, measured along the axis of the dam, was 0.75 cu. yd. The maximum quantity in any one section was 38.63 cu. yd.; and in one hole in this section, 18 cu. yd. were placed, this quantity being the maximum for any one hole. The average quantity per hole, including the sink holes, springs, and mud seams, was 0.41 cu. yd.

The full air pressure carried in the supply lines, of 80 to 100 lb. per sq. in., was applied to the holes, only 50 lb., however, being required by the specifications. If grout rose in any of the holes surrounding the one being grouted, the pipes were capped and the grouting was continued. In one case grout was raised in fifteen holes from one connection. Later, the caps on the pipes were removed; if they were not filled, grout was then pumped into them, the same treatment being applied to all pipes that had taken grout upon the first connection.

The number and length of drilled holes, the amount of pipe and fittings used, and the grout placed considerably exceeded the estimated quantities, but the results obtained have been considered as amply warranting the added cost. A thorough examination of the area down stream from the dam has failed to disclose any leakage other than a slight seepage around the three westerly sections. This leakage is so small as to cause no uneasiness from the possible formation of solution channels through the rock.

Concrete

In the construction of the dam, five classes of concrete were used. For convenience of reference Table 1 gives the mixture used in, the contract price per cubic yard of, the volume placed under, and the location in the work of, each class of concrete. The total volume of concrete placed was 79 565 cu. yd., at an average price of $9.29 per cu. yd.

The specifications permitted the engineer to change the relative volumes of the fine and coarse aggregates in each mixture, but at the same time keeping the total volume of the two classes of aggregate the same. The coarse aggregate was screened into three sizes: No. 1, ¼ to ¾ in.; No. 2, ¾ to 1½ in.; and No. 3, 1½ to 3 in. In most of the work a mixture of the three sizes was used, but in much of the reinforced work the No. 3 coarse aggregate was omitted, and, at times, only the No. 1 coarse aggregate was used, especially in thin reinforced work, in order to ensure satisfactory bedding of the steel reinforcement bars.

The specifications for the fine aggregate provided that the material should contain not less than 80% of silica, graded from fine to coarse, should be

thoroughly screened to reject all particles greater than ¼ in. in diameter, and should not contain more than 3% of material passing a 100-mesh standard sieve; also, that the material should not contain more than 3% of loam, clay, or dirt. The fine aggregate used was a washed bank sand shipped from Dresden, Ohio, distant about 55 miles east of Columbus.

TABLE 1.—CONCRETE USED IN THE O'SHAUGHNESSY DAM.

Class.	Mixture.	Contract price per cubic yard.	Volume placed, in cubic yards.	Location.
A.....	1 : 3 : 6*	$ 6.85	56 189	Cyclopean masonry forming the body of the dam and bridge piers.
B.....	1 : 2½ : 5	13.00	2 032	Core walls of the earth dikes; retaining walls and culverts.
C.....	1 : 2 : 4	14.00	17 362	Exposed faces of dam and bridge piers; cut-off trench; substructures, not including floors of gate-houses and of pavilion; paving and retaining walls in regulating works below dam.
D.....	1 : 2 : 4	21.00	4 002	Bridge arches, spandrel and curtain-walls; floor of bridge, including sidewalks; floor of gate-chambers, pavilion, and balconies; and bulkheads in power tubes.
E.....	1 : 2 : 4	40.00	84	Roof decks for superstructures of gate-houses and pavilion.
Average.....	.....	$ 9.29	.....	....
Total.....	.....	.....	79 569	....

* Not including the embedded stones.

The coarse aggregate was crushed limestone obtained mainly from the rock excavation for the dam and spillway channels and was screened on the job into the three sizes mentioned.

In the 1 : 3 : 6 Class A concrete, designated as cyclopean masonry and forming the main body of the dam and piers of the bridge over the spillway, large stones, from the rock excavation, were embedded to a certain extent, but the percentage of such stones, taken as a whole, was small.

Alpha Portland cement was used throughout the work, the total amount being 93 500 bbl. With a total volume of 79 569 cu. yd. of concrete placed in the dam, the ratio of cement to concrete was 1.18 bbl. of cement per cubic yard of concrete.

The proportioning of the relative volumes of fine and coarse aggregate and of the three sizes of coarse aggregate was adjusted throughout the course of the work with the object of securing concrete of maximum density.

In all the concrete very little departure, in general, was made from the specified proportions of fine and coarse aggregate. When three sizes of coarse aggregate were used, the proportions were, in general, 1 volume of No. 1, 1 volume of No. 2, and 2 volumes of No. 3 aggregate, and when only two sizes were used the proportions were, generally, 1 volume of No. 1 and 2 volumes of No. 2.

Expansion Joints

In the spillway section of the dam, under each arch of the bridge, an expansion joint was located. At each of these expansion joints, in addition to the so-called bonding grooves, Fig. 14, a copper strip, $\frac{1}{8}$ in. thick and 7 in. wide, was inserted across the down-stream side of the up-stream bonding groove. The copper strip was so placed as to be free to move with the contraction, and subsequent expansion, of the adjacent sections of the dam.

The concrete roadway slab, carrying the brick pavement, and the concrete sidewalks had expansion joints at the third points of each arch span, at the center lines of the walls forming the upper extension of the bridge piers, and at suitably placed locations opposite the gate-houses and pavilion. In the sidewalks and curbs, Carey "Elastite" was used in the expansion joints.

Expansion joints were also provided in the Indiana limestone balustrade on the bridge as close to all sidewalk joints as the design would permit, no mortar being placed between the stones at these points, the upper rail being held by 1-in., brass dowel pins, 6 in. long.

Construction of Earth Approaches

At each end of the spillway section the approaches were built of earth embankments, with a core wall in the center of each. In the construction of the embankments the surface of the ground was first stripped and all perishable matter removed, as well as loose stones and boulders. The embankments were made of yellow boulder clay, obtained from borrow-pits, and were free from perishable matter and from stones of more than 3 in. in their greatest dimension. On the up-stream side of the embankments, selected material was used which would compact and be as nearly water-tight as possible. On the down-stream side the requirements as to the materials were less exacting and in certain parts some small stone was placed near the outer face, but not in pockets, and back from the face to allow a sufficient thickness of earth covering. Frozen materials were not permitted to be used, nor were embankments built in freezing weather.

The materials were spread in approximately horizontal layers not exceeding 4 in. in thickness and were compacted by rolling with power-operated grooved rollers weighing not less than 2 000 lb. per lin. ft. of width and not less than 4 ft. wide. If the materials were not sufficiently moist when spread, they were moistened with water so as to permit of proper compacting.

The core walls in the approaches began at the outside of the bridge abutments and extended away from each bridge abutment to a point 20 ft. beyond the point where Elevation 858.5 met the original surface of the ground. They were carried down 12 in. into solid rock.

The bituminous macadam roadways on the approaches connect with the bridge over the spillway and with the relocated roads built to connect with existing county highways. A typical section through one of the earth approaches is shown in Fig. 18.

The Reservoir

The O'Shaughnessy and Julian Griggs Reservoirs are quite similar in general characteristics, in that both are long and narrow, the main differences being that the O'Shaughnessy Reservoir is deeper, somewhat longer, and impounds about three times as much water.

The total length of the O'Shaughnessy Reservoir is 8.0 miles. At Elevation 845, normal water level, the reservoir has an average width of 855 ft.; the maximum width is about 1 900 ft., about 0.4 mile above the dam; the minimum width is about 200 ft., at Bellepoint, where the river widens and forms the upper end of the reservoir.

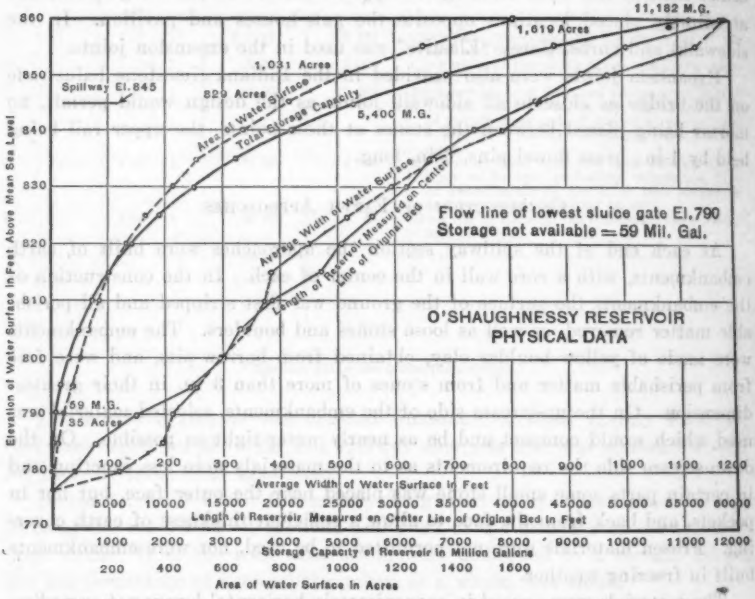

FIG. 24.—O'SHAUGHNESSY RESERVOIR, CAPACITY, AREA FLOODED, LENGTH, AND AVERAGE WIDTH AT VARIOUS ELEVATIONS.

The area of the water surface at Elevation 845 is 829 acres, or 1.57 sq. miles. For sanitary, as well as for general control, a wide marginal strip was acquired by the City on each side of the reservoir. On the west side, this strip has an average width of 227 ft.; on the east side, the average width is 278 ft.; the greater width on the east side being due to the fact that the City acquired all the land between the reservoir and a new highway built to replace one which is now submerged. On the west side the marginal strip has an area of 204 acres, and on the east side, 241 acres, the total area of the marginal strip on both sides of the reservoir being 445 acres, or equal to about 54% of the area of the water surface of the reservoir. The total area of the reservoir and the marginal strip combined, is 1 274 acres, or about 1.99 sq. miles.

On the west side of the reservoir, about 2.5 miles above the dam, at the Girls Industrial School, a correctional institution of the State of Ohio, and for a distance of about 3 200 ft., no marginal strip was acquired, as the land is owned by the State and the City lacked the power to acquire the property except by purchase, and the State did not care to sell. The City, however, did secure the right to flood the State-owned land, along the river, so as to be able to construct the reservoir.

The reservoir has an average depth of 19.8 ft., the maximum being 69 ft., just above the dam. The total volume impounded at Elevation 845 is 5 400 000 000 gal.; of this, 5 341 000 000 gal. are available, taking low water at Elevation 790, or 55 ft. below the crest of the spillway.

The capacity of the reservoir and the area flooded, as well as the length and average width at various elevations, is given on Fig. 24. Table 2 gives comparative data of the O'Shaughnessy and Julian Griggs Reservoirs.

TABLE 2.—COMPARATIVE DATA OF THE O'SHAUGHNESSY AND JULIAN GRIGGS RESERVOIRS.

	O'Shaughnessy Reservoir.	Julian Griggs Reservoir.
Length, in miles	8.0	5.8
Width, in feet:		
Average	855	516
Maximum	1 900	830
Minimum	200	200
Area of water surface, in acres	829	363
Depth below crest, in feet:		
Average	19.8	14.5
Maximum	69	35
Storage, in gallons*:		
Total	5 400 000 000	1 720 000 000
Available	5 341 000 000	1 487 000 000

* By the addition of flash-boards to the Julian Griggs Dam, an additional storage of 500 000 000 gal. can be secured in the Julian Griggs Reservoir.

CLEARING AND GRUBBING

Notwithstanding the fact that the water is purified by filtration, it was considered advisable to grub as well as to clear the reservoir site, as was done in the case of the Julian Griggs Reservoir. Clearing and grubbing, therefore, was carried out over the whole of the area flooded and up to an elevation 2 ft. above normal water surface, the total area so cleared and grubbed being 741 acres.

All trees, saplings, and brush were cut down flush with the surface of the ground, and all stumps and roots larger than 2 in. in diameter were removed to a depth of at least 6 in. below the surface of the ground. In removing stumps both dynamite and stump-pullers were used. Prior to clearing and grubbing, property owners from whom land was acquired, were permitted to cut down and remove such of the timber as they desired.

On the west side of the reservoir the property acquired by the City was not bounded by a highway, and line fences and stone walls were left in place, the City permitting abutting owners, for the present, to water stock at the

reservoir edge. On the east side of the reservoir, where the land acquired is bounded by a new highway, all fences were removed and stone walls leveled. All material removed in the clearing and grubbing operations became the property of the contractor and was either burned or removed to points outside the limits of the property owned by the City. Material was not disposed of by throwing it into the river and allowing it to float down stream. After the clearing and grubbing had been completed, the entire ground surface was burned over, and, prior to filling the reservoir, where grass, weeds, and vegetation had grown up subsequent to the first burning over, the ground was burned over a second time.

The removal of buildings was not included as part of the work of clearing and grubbing, arrangements having been made with some property owners for the removal of their buildings, whereas the other buildings were sold, the prices paid by the purchasers including their removal.

Relocation of Roads

From the dam to the upper end of the reservoir, on the east side, there were county roads running, in general, parallel to the river. For much of the distance these roads were at such an elevation that they would be flooded when the reservoir was filled, and it was incumbent on the City, therefore, to build a new road to replace those flooded. On the west side of the reservoir it was necessary to build a short stretch of new road where an existing road was flooded, above and below Eversole Run, one of the tributaries of the river, and also to build a second short stretch of road from the west end of the dam to an existing north and south highway. At the east end of the dam, the earth section started, practically, at the new road. Where new roads were built arrangements were made with the County Commissioners of Delaware County whereby the City was to acquire the land for and build the new roads and then deed them to the County, the County, in turn, to deed to the City the old roads which would be flooded.

The old roads were mainly gravel roads, in some places nearly impassable in winter. In replacing these roads the City built water-bound macadam highways conforming, in general, to the standards of the Ohio State Highway Department for similar conditions. The macadam surface was 16 ft. in width and had a finished thickness, after rolling, of 6½ in. Crushed limestone, obtained locally, was used. With the exception of the Rathbone Bridge, mentioned later, and the bridge over the dam, the macadam surfacing was carried continuously over the reinforced concrete bridges spanning the small streams tributary to the reservoir. A total length of 7.5 miles of new road was built by the City. In 1926, the new road on the east side of the reservoir was taken over by the State of Ohio and incorporated as a part of the State Highway System, and it has been improved by widening the surfacing and making it a bituminous-surfaced, water-bound macadam.

Reconstruction of Bridges

Mention has already been made of the replacement of the Powell Bridge by the reinforced concrete arch bridge over the dam. At the Girls Industrial

School, about 3.1 miles above the dam, the river was spanned by a bridge known as the Rathbone Bridge. With the filling of the reservoir this bridge would have been entirely submerged. As the bridge was on a main east and west highway, a crossing of the reservoir at this point could not be abandoned.

The superstructure of the existing bridge consisted of three 100-ft. steel trusses. These trusses were in good condition and were suitable for use in a new bridge, if reinforced. Wishing to make use of these trusses in the new bridge if economically possible, the specifications therefore were drawn so as to permit a bidder to submit a proposal for raising the three trusses a total height of about 35 ft. and of moving them on to new piers, and then lengthening the bridge by the addition of eight new 100-ft. trusses of similar construction, or of building an entirely new bridge.

The low bid received, on the basis of using the three old trusses, was $119 240. The low bid for an entirely new bridge, with 16-ft. roadway, was $115 968, and $120 718 with an 18-ft. roadway. The City accepted the bid for an entirely new bridge, with the 18-ft. roadway.

The superstructure of the new Rathbone Bridge consists of five steel trusses, each 207 ft. 6¾ in. in length. The piers and abutments are of concrete. The bridge has a total over-all length of 1 040 ft., face to face of end abutments, and it is the longest bridge in Delaware County. The lower clearance line for the bottom chord and floor members is 13 ft. 6 in. above normal water level in the reservoir. The entire structure was built in accordance with the requirements of the 1918 Specifications for Highway Structures, Class T-15, of the Ohio State Highway Department. A view of the old bridge and the new is shown in Fig. 23.

On the west side of the reservoir at Eversole Run, previously mentioned, a small reinforced concrete bridge was built in connection with the relocation of a part of one of the county roads, and on the east side of the reservoir along the new road several small culvert bridges were built.

Moving Church and Cemetery

Near the upper end of the reservoir was the Scioto Valley Christian Union Church and the Oller Cemetery. The church and cemetery served a rural population and had been there for years. With the flow line adopted for the reservoir, it was found that a part of the cemetery would be submerged and that the church would either have to be moved or a new church built.

Following a series of conferences with the Church Trustees it was decided to move the church. This was accordingly done, the City acquiring and deeding to the Church Trustees the new piece of property on which the church is relocated. The church was a small brick building, 31 ft. wide by 39 ft. long, with 8-in. walls; it was moved horizontally a distance of 350 ft. and, at the same time, raised a distance of 14.2 ft., vertically. To avoid cracking the walls, while being moved, a heavy steel band was placed around the building.

When it comes to moving a cemetery, however small, the question of sentiment has to be taken into account. A happy solution of the problem, however, was found when the Cemetery Trustees agreed to supervise and do all the

work, the City paying all the bills for labor and material. All told, ninety-nine re-interments were made.

Reconstruction at Girls Industrial School

At the Girls Industrial School, a very considerable amount of reconstruction work was necessary. In fact, barring the construction of the dam proper, it was the one most expensive item involved in building the reservoir. The institution, in addition to housing the necessary State officials and employees, houses between 600 and 700 inmates, and for years had been in its present location on the west bank of the river. It had been expanded from time to time and new utilities and conveniences added, some of which were not far from, and only slightly above, the river. The best site for the dam was down stream from the school, but the adoption of that site involved flooding State property, buildings, and utilities. The City had no power to condemn State property, so it was faced with the situation of either securing permission from the State to flood some of the property owned by the State, and replace the buildings and utilities which would be wholly or partly submerged, or of constructing the dam on a very much less desirable site above the school. The City decided to seek permission from the State to flood State property and bear the necessary cost of replacements. To secure this permission it was necessary to secure an Act of the Legislature. Such an Act was passed, putting the matter, in so far as the State was concerned, in the hands of the Department of Public Welfare and authorizing the Director of Public Welfare to make the necessary arrangements with the City. The replacements made by the City included the building of a new power house, laundry, and sewage disposal works, together with the necessary connections thereto, and, after these replacements were made, they were turned over to and became the property of the State.

Power House.—The power house was a short distance from the river and supplied the institution with light, heat, and water. The building was old and in need of repair, and some of the equipment was only in fair condition. The site had been poorly chosen, as the power house had been flooded in the past with high water in the river. The City built for the institution a new brick power house at a much higher and more convenient location.

Such of the existing equipment as could be moved, was transported to the new building and put in running order. The principal items of equipment moved were two 200-h.p. boilers (new brick settings had to be provided), two feed-water heaters, each 6 ft. in diameter by 16 ft. high, two 100-kw. and one 75-kw. engine generator sets, one 5-panel switchboard and appurtenances, one 400 gal. per min., duplex steam pump, two boiler feed pumps, a hot-water pump, a boiler-room scale, and a rapid sand-filter plant of the wooden-tub type; also, such minor equipment and piping as could be used to advantage. While the equipment was being moved, the institution had to be kept running, and at no time was there any interruption in the service of supplying light, heat, and water to the buildings. It was necessary, however, for the City to furnish and install in the new power house some new equipment and material. This consisted mainly of two 200-h.p. boilers and a 400 gal. per min. duplex

steam pump for pumping filtered water, as well as some new piping, etc. In connection with the new power house, the City also built a reinforced concrete coal-pocket opening direct from the boiler room.

After the new power house was in regular service, the old power house was abandoned, the building wrecked, and the chimney dynamited.

Water Supply.—The institution had two sources of water supply, one, from a sulfur-water well for drinking purposes, and the other, filtered river water for general use. With the filling of the reservoir, the sulfur-water well was flooded, so the City provided a new drinking-water supply by drilling a well located inside the new power house. The river water supply was not so simple. With the old power house, located near the river, the raw-water pumps could take water direct from the river without an excessive suction lift, but with the new power house, at a much higher elevation and at a distance of about 550 ft. from the river, it was too expensive to build a suction well about 60 ft. deep and run a low-level suction conduit to the river so that water could be obtained with the reservoir empty, a condition which would be the same as if no reservoir existed.

The solution adopted for supplying raw water was to build an electrically operated raw-water pumping station out in the reservoir and to run duplicate cast-iron force mains from this station to the power house. The substructure of the pumping station was obtained by extending, down stream, one of the concrete piers of the new Rathbone Bridge, the pier being one located in the old river bed, and constructing in it a suction well and two dry pump wells, each pump well being equipped with a horizontal electrically operated centrifugal pump, automatically and manually controlled from the power house, 700 ft. away. Each pump has a capacity of 500 gal. per min. against a normal head of 42 ft. and a maximum head of 90 ft.

The superstructure of the pumping station is a small brick building, with the floor at practically the same elevation as the floor of the bridge. Access to the building is direct from the bridge floor. At the power house the City built a small reinforced concrete coagulating basin, and also a small filtered-water reservoir of similar construction.

Laundry.—The laundry for the institution was built on somewhat higher ground than the power house, but still not sufficiently high to have escaped partial submergence with the reservoir full. The building was of brick and consisted of three wings, connected by narrow galleries, and had a total floor space of 15 820 sq. ft. Below, was a good basement.

Here, again, it was a case of constructing a new building in another and more convenient location. The new building is exactly similar in construction to the old building, except that one wing was omitted, thereby reducing the floor space to 10 540 sq. ft. In lieu of building the third wing, the City did certain additional work at the new power plant, which the State desired, and other than that which the City would have had to do simply to supply the State with a new power plant equal to the old one.

All the laundry equipment was moved from the old building to the new, the larger fixed pieces consisting mainly of four washing machines, three wringers, large dryer, starch machine, water heater, dry tumbler, large steam

mangle, 26 ironing boards, and 21 electric irons and stands. Including those which were portable, a total of 139 pieces of equipment were moved. Further, all the radiators and steam piping, electric and plumbing fixtures, were moved to and installed in the new building. At no time was laundry work entirely shut down, partial operation having been maintained either in the old building or in the new.

After the new laundry was in service the State took down the old building and salvaged much of the material, with which it constructed another building, somewhat smaller, however, than the old laundry.

Sewage Treatment Works.—Prior to the construction of the reservoir the sewage from the Girls Industrial School flowed by gravity to and through a sewage treatment works, consisting of a screen chamber, a flat-bottom, rectangular septic tank, trickling filters, and intermittent sand filters, the effluent being discharged directly into the river. These works were at such an elevation as to be flooded by the reservoir, so new treatment works, at a higher elevation, had to be built to replace the old ones.

The new treatment works consist of a screen chamber, pumping station, septic tanks, sludge-drying beds, a dosing chamber, and intermittent sand filters, constructed in accordance with plans approved by the Ohio Department of Health. The effluent is discharged into the reservoir about 3 ft. below full reservoir level. The works were designed to treat the sewage from a population of 700.

The screen chamber is a small rectangular structure, 3 by 5 ft. in plan, and is fitted with a bar screen, the bars being spaced 1 in. apart in the clear. From the screen chamber the sewage flows to an automatically controlled pumping station of the pneumatic ejector type. The ejectors are in duplicate, of the Shone make, each ejector having a capacity of discharging 150 gal. at each operation, against a total head of 20 ft., and at least once a minute. The air compressors, of which there are two, are horizontal machines, 6 by 5 in., and of the double-acting, single-cylinder, crank and flywheel type, each compressor being driven by a 5-h.p., 220-volt, direct-current, 1 200 rev. per min., electric motor. The air receiver is 42 in. in diameter and 96 in. high. The equipment is housed in a small brick building, the ejectors being in the substructure.

From the pumping station the screened sewage is pumped to a battery of three hopper-bottom septic tanks. Each tank is 12 ft. square in plan and 13.5 ft. deep from the flow line to the bottom of the hopper. Sewage is admitted at one side of the tank, at the top, and is taken out at the opposite side. Scumboards are provided in front of both the inlet and outlet weirs. Running to the bottom of each tank is an 8-in., cast-iron, sludge discharge pipe so that sludge can be withdrawn without unwatering the tanks.

Septic tanks were chosen for simplicity in operation. The treatment works are in the country, at a sufficient distance from the nearest buildings of the school, as well as being screened from these buildings by a heavy thicket of large trees, so that the question of possible odors could be neglected. The tanks were planned to be operated in rotation, that is, in so far as the digestion of sludge is concerned. When the sludge storage space at the bottom of

one of the tanks is filled, the tank is cut out of commission and allowed to stand idle for a few months, until the sludge is digested. The digested sludge is then withdrawn and the tank put back in service. A second tank is then removed from service and allowed to stand idle, and, finally, the third tank, and so on in rotation. In other words, two tanks are sufficient for sedimentation and sludge accumulation, the third tank serving as a sludge digestion tank.

From the septic tanks sludge is first drawn into a sludge manhole and then discharged from it to the sludge-drying beds. These are three in number, two are 30 ft. square and the third, 10 ft. wide by 30 ft. long. The total sludge-drying area is 2 100 sq. ft. The beds are constructed of 9 in. of sand, supported by screened gravel, and are underdrained with 6-in. tile pipes. The sludge is confined to the beds by pre-cast concrete boards and posts which form the sides and partitions of the beds.

From the septic tanks the settled effluent flows to and through a dosing chamber and thence to the intermittent sand filters. The dosing chamber is 12 ft. wide by 18 ft. long and 3.5 ft. deep, is covered, and is fitted with four automatic timed siphons for dosing the filters, each siphon being piped so as to discharge on to one of two filters.

The sand filters, of which there are eight, are each 69 ft. square, the total sand area being 38 088 sq. ft. The banks surrounding the filter area and subdividing it into the eight beds are of earth construction, seeded and sodded. The filter sand is 30 in. in depth, the effective size being between 0.3 and 0.45 mm. and the uniformity coefficient not exceeding 2, and is supported on a bed of clean gravel in which 6-in. tile under-drains are laid.

After the new treatment works were in operation, the old works were abandoned and material from them was used by the State in miscellaneous construction on the grounds of the institution.

Acquisition of Land

There were three distinct steps in acquiring the land for the O'Shaughnessy Reservoir. They were, first, the determination of the amount of land to be taken from every riparian property affected by the reservoir project; second, the securing of a fair appraisement of the land and improvements to be taken in fee, of flood rights, and of the damage to owners resulting therefrom; and, third, the purchase of the various tracts by negotiation or condemnation, the appraisement being used as a guide for negotiation.

The elevation of the crest of the spillway, plus the maximum depth of water which it was assumed might pass over the same, plus a reasonable additional unflooded strip of land for protection and control fixed, in a general way, the elevation of the taking lines on riparian properties. The city purchased the records of the Franklin County Conservancy District, which consisted of all the data collected in connection with the study of flood relief for the Scioto River Valley, following the great flood in March, 1913, and the topographic maps of that section of the Valley embracing the proposed reservoir site were used in a tentative determination of taking lines on the various properties affected.

Abstracts of the titles of all riparian properties were secured and surveys made of the properties and of the tentative taking lines. The final taking lines were then established, taking into account the relocation of roads on the east side of the reservoir and also the requests of various land owners when the interests of the City were not prejudiced thereby. Complete property maps were then made, which showed for each property the total acreage, the acreage to be taken, and the location of the improvements on the property. These maps were turned over to the City Attorney to whom the purchase of the property had been delegated.

The first step taken by the City Attorney was the selection of a competent Board of Appraisers. The City of Columbus is in Franklin County and the O'Shaughnessy Dam and Reservoir in Delaware County. Five appraisers were selected, four from Delaware County and one from Franklin County. The importance of having a competent appraisement made is reflected in the fact that in the purchase of the 56 tracts acquired by the City, 55 were acquired by negotiation at close to the appraised value, the other being taken to Court where a jury fixed the price within 1% of the appraisement.

The appointment of the appraisers and the fixing of their compensation was authorized by an ordinance of the City Council passed January 9, 1922. The first tract of land was purchased on May 15, 1922, and the last tract on September 23, 1925. The maximum price paid for land was $175, and the minimum, $60 per acre. The land purchases were made by Messrs. Charles A. Leach, City Attorney, John L. Davies, First Assistant, and E. W. McCormick, Second Assistant. A summary of the cost of the reservoir lands, subdivided under various headings, is given in Table 3.

TABLE 3.—Cost of Reservoir Lands.

Items.	Unit.	Number of units.	Total amount paid.	Average price paid per unit.	Average price paid per acre, based on 1 155.9 acres.
Land	Acres	1 155.9	$155 026.75	$ 134.12	$134.12
Flood rights	"	51.7	1 797.00	34.72	1.55
Dwellings	Each	17	59 500.00	3 500.00	51.50
Barns	"	17	16 005.00	941.47	13.85

Cost of Work

The total cost of the O'Shaughnessy Dam and Reservoir, exclusive of engineering, was $2 220 080, and a distribution of this cost, subdivided under a number of headings, is given in Table 4. No attempt has been made to dis-

tribute the cost of engineering over the several parts of the work, as it is believed that the costs as presented are of greater value than if they included a percentage for engineering, which, at best, would have to be only approximate.

TABLE 4.—COST OF O'SHAUGHNESSY DAM AND RESERVOIR.

Land, 1 156 acres			$ 290 130
Dam:			
East approach, 483 lin. ft.		$ 29 790	
West approach, 403 lin. ft.		13 580	
Spillway, 879 lin. ft.		635 980	
East bridge abutment, 63.2 lin. ft.		18 440	
West bridge abutment, 63.2 lin. ft.		15 670	
Bridge over spillway, 879 lin. ft.		131 580	
Pavilion:			
Substructure	$ 4 920		
Superstructure	7 940	12 860	
Outlet Gate-House:			
Substructure	$ 64 130		
Superstructure	12 800		
Pipe, gates, and equipment	24 020	100 950	
Power Gate-House:			
Substructure	$ 21 500		
Superstructure	11 470	32 970	
Approach channel to power gate-house		2 700	
Head-race below power gate-house		9 690	
Spillway channels		107 080	
Grouting		15 880	
Engineers' office		9 470	
Unclassified		10 480	1 146 970
Reservoir:			
Clearing and grubbing, 741 acres		$136 320	
Relocation of roads, 7.5 miles		233 050	
Reconstruction of Bridges:			
Rathbone Bridge, 1 046 lin. ft.	$100 110		
Eversole Run Bridge, 40 lin. ft.	5 180	105 290	
Moving church and cemetery		11 130	
Reconstruction at Girls Industrial School:			
Power house	$ 83 850		
Water supply	28 810		
Laundry	40 110		
Sewage treatment works	50 180		
Conduits, sewers, and miscellaneous	89 930	292 880	
Unclassified		4 310	782 980
Total cost, exclusive of engineering			$2 220 080

On the basis of a total available storage capacity of 5 341 000 000 gal., the dam and reservoir, including the land, cost $416 per 1 000 000 gal. available capacity. In Table 5, the cost is subdivided under the headings of land, dam, and reservoir; similar costs are also given, based on the total capacity of the reservoir. The difference in cost per 1 000 000 gal., between that based on available capacity and on total capacity, is just about 1 per cent.

Due to the fact that other engineering work was being designed and constructed under the supervision of the engineering organization that had charge of the design and construction of the dam and reservoir, and at the same time, it would be exceedingly difficult to distribute accurately the cost of engineering to the dam and reservoir and to this other work, notwithstanding that each assistant was required to keep a record of his time. The

difficulty is in distributing accurately the cost of supplies and expenses, and also that part of the pay-roll covering general charge and supervision of the work.

TABLE 5.—COST PER 1 000 000 GALLONS OF O'SHAUGHNESSY DAM AND RESERVOIR.

Items.	Total cost.	COST PER 1 000 000 GALLONS.	
		Total capacity, 5 400 000 000 gal.	Available capacity, 5 341 000 000 gal.
Land	$ 290 130	$ 54	$ 54
Dam	1 146 970	212	215
Reservoir	782 980	145	147
Total, exclusive of engineering	$2 220 080	$411	$416

It is possible, however, to give the total cost of engineering on the dam and reservoir and the other work referred to, which consisted mainly of the enlargement of the water-purification works and the laying of additional cast-iron pipe lines; and it may be said that all this other work would be classed under the general head of water-works construction. The total cost of engineering was $324 810, and, based on a total cost of construction of $3 217 440, the percentage for engineering amounted to 10.10. A distribution of the cost of engineering under the headings of borings and sub-surface investigations, pay-roll, supplies, and expenses is given in Table 6.

TABLE 6.—COST OF ENGINEERING.

Items.	Cost.	Percentage, based on total cost of construction of $3 217 440.
Construction:		
O'Shaughnessy Dam and Reservoir	$2 220 080	69.00
Enlargement of water-purification works	397 140	12.34
Cast-iron force mains	560 920	17.44
Cast-iron distribution mains	34 050	1.06
Miscellaneous	5 250	0.16
Total cost of construction	$3 217 440	100.00
Engineering:		
Borings and sub-surface investigations	$ 10 800	0.34
Pay-roll	271 280	8.43
Supplies	11 110	0.35
Expenses	31 620	0.98
Total cost of engineering	$ 324 810	10.10
Summary:		
Construction	$3 217 440	100.00
Engineering	324 810	10.10
Total cost	$3 542 250	110.10

Beginning and Completion of Work

As stated at the beginning of this paper, the construction of an additional dam and reservoir to provide enlarged storage of raw water was recommended by one of the writers in a report dated August 2, 1919. At a general election held on November 4, 1919, the issuance of bonds in the sum of $3 000 000 for this improvement, together with the extension and enlargement of other parts of the water-supply system, was approved by popular vote.

On March 15, 1920, the City Council passed an ordinance which provided for the issue and sale of these bonds, and on April 12, 1920, an ordinance was passed which provided for the establishment of the Bureau of Water-Works Extension in the Division of Water for the carrying out of these improvements.

The selection of the site for the new dam was made after twenty-six prospective sites between the Village of Dublin and the Powell Road Bridge had been studied. The contract for "The O'Shaughnessy Dam and Appurtenant Works" was awarded on June 6, 1922, to the Thompson-Starrett Company, of New York, N. Y., at an estimated cost of $1 165 511. About two weeks after the signing of the contract, the clearing and grubbing of the site and the erection of the contractor's plant were started. The first concrete was poured on November 1, 1922, and the dam and bridge were completed and ready for use on June 1, 1925.

Construction of the reservoir was carried on coincident with the construction of the dam, and all the work was practically completed by October 1, 1925.

Summary of Principal Data Relating to the O'Shaughnessy Dam and Reservoir

For convenience of reference the principal data relating to the dam and reservoir may be summarized, as follows:

Date of construction	1922-25
Total length of dam, in feet	1 750
Length of masonry part of dam, in feet	879
Length of earth approaches, including concrete abutments, in feet	871
Height of spillway above low water in river, in feet	64
Height of dam from rock foundation to crest of spillway, in feet	84
Height of dam from rock foundation to roadway level, in feet	105.25
Height of roadway above spillway, in feet	21.25
Maximum width of dam at base, in feet	110
Width of paved roadway, in feet	17.5
Width of sidewalks, in feet	4
Net length of spillway, in feet	765.7
Maximum flood capacity of spillway, in cubic feet per second	110 000
Depth of water over spillway with maximum flood, in feet	12.5
Total available storage capacity, reservoir full, in gallons	5 341 000 000

Average depth of water, reservoir full, in feet	19.8
Maximum depth of water, at dam, reservoir full, in feet	69
Length of reservoir, in miles	8
Average width of water surface, reservoir full, in feet	855
Area of water surface, reservoir full, in acres	829
Area of land cleared and grubbed, in acres	741
Area of land purchased, in acres	1 156
Total cost of dam and reservoir, exclusive of engineering	$2 220 080

Contractors

The dam and reservoir were constructed mainly by contract work, the principal contracts and names of the contractors being as follows:

O'Shaughnessy Dam	Thompson-Starrett Company
Diamond drill core borings	Giles Drilling Company
Reconstruction at Girls Industrial School:	
Replacement of buildings	Middle States Construction Company
Moving and replacing equipment and miscellaneous structures	Pitt Construction Company
Replacement of boilers	Heine Boiler Company
Replacement of pumping equipment	Factory Engineering and Sales Company
Centrifugal pumps	Elcon Engineering Company
Relocation of Roads:	
O'Shaughnessy Dam to Rathbone	Uncapher and Gillespie
Rathbone to Bellepoint	J. S. McCann
Reconstruction of Bridges:	
Rathbone Bridge	E. M. Scully
Eversole Run Bridge	Uncapher, Wooley, and Gillespie
Clearing and Grubbing:	
Northern and southeast portions	W. D. Winchell and Company
Southwest portion	J. Livingston and Company

In the construction of the dam, the Thompson-Starrett Company was represented by N. M. Loney, M. Am. Soc. C. E., and in the moving and replacing of equipment and miscellaneous structures at the Girls Industrial School, the Pitt Construction Company was represented by E. D. Harshbarger, Assoc. M. Am. Soc. C. E., President. In the clearing and grubbing, J. Livingston and Company was represented by L. I. Fletcher, Affiliate, Am. Soc. C. E., Resident Manager.

Legislative Procedure

In making the improvements described in this paper it was necessary to comply with State Statutes, with the City Charter, and with City Ordinances, all of which specify terms and conditions governing the expenditure of public

funds. The Legislative Acts required to legalize the carrying out of the work and to both provide and disburse the necessary funds were, as follows:

Statute by State Legislature:		
To authorize agreement with the City to flood State property	1	1
Vote of Citizens at General Election:		
To approve the issue and sale of bonds	1	1
Ordinances by City Council:		
To authorize the issue and sale of bonds	6	
To provide for the engineering organization	9	
To provide for the purchase of supplies and equipment	5	
To authorize contract work	29	
To authorize bed-rock surveys	4	
To authorize the acquirement of property	41	
To authorize miscellaneous projects	22	116
Resolutions by City Council:		
To name the dam	1	
To submit plans to the State Department of Health	2	
To advertise contract work	1	
To appropriate property by condemnation	3	
To modify contracts	5	12
Total Legislative Acts		130

Effect of Additional Storage on Softening of the Water

The O'Shaughnessy Dam was completed June 1, 1925. From May 1 to October 31, 1925, the average daily flow of the Scioto River was 36 000 000 gal. and the average daily water demand of the city, 27 500 000 gal. The flow of the river during 1925 was below normal and would have been a good year for showing the effect of storage in reducing the hardness of the raw water. However, the dam was not completed in time to permit the storage of the soft flood waters of the late winter and early spring months. During 1926 the average daily flow of the river from May 1 to October 31 was 630 000 000 gal., and the average daily demand of the city for the same period was 29 000 000 gal. Consequently, 1926 was not a good year to show the effect of storage, but it is the only one for which data are available (1927).

At the upper end of the O'Shaughnessy Reservoir the influent is made up of the flow from Mill Creek, a tributary having a water-shed of 186 sq. miles, and from the Upper Scioto, which has a water-shed of 770 sq. miles above the confluence with Mill Creek. The water-shed tributary to the reservoir is, therefore, 956 sq. miles; and for further reference it should be stated that the Scioto River has a water-shed of 988 sq. miles at the O'Shaughnessy Dam, 1 052 sq. miles at the Julian Griggs Dam, and 1 076 sq. miles at the water purification works.

Daily samples of water, collected from Mill Creek and the Upper Scioto, were analyzed for mineral content, and the average values weighted on the basis of the contributing water-sheds. The average total hardness of the raw-

water inflow into the O'Shaughnessy Reservoir, from May 1 to September 10, 1926, was 313 parts per million, and the average hardness at the intake to the water purification works, about 22 miles down stream, and with the two reservoirs intervening, which were full all the time and have a total combined storage capacity of 7 120 000 000 gal., was 278 parts per million, a reduction of 35 parts per million in total hardness. During the same period the raw-water draft for the City was 3 911 000 000 gal., and for 1926 the average cost of chemicals for removing 1 part of hardness from 1 000 000 gal. of raw water was $0.104. The apparent saving in the cost of chemicals used in water-softening resulting from storage during the period mentioned, therefore, may be said to be $3\,911 \times 35 \times \$0.104 = \$14\,200$.

Engineering Organization

The engineering work was carried out by the Bureau of Water-Works Extension, a temporary bureau created in the Division of Water and Sewage Disposal by ordinance of the City Council. The Bureau began to function on May 1, 1920. Of the three writers, John H. Gregory, M. Am. Soc. C. E., was Consulting Engineer, and C. B. Hoover, M. Am. Soc. C. E., Engineer in Charge, of the Bureau; C. B. Cornell, M. Am. Soc. C. E., was Construction Engineer in charge of the work at the dam and reservoir. Following the death of Mr. Jerry O'Shaughnessy, Superintendent of the Division of Water and Sewage Disposal, Mr. Hoover was appointed Superintendent of the Division on December 1, 1921, and, in addition to his duties as Superintendent, continued to serve as Engineer in Charge of the Bureau of Water-Works Extension until October 1, 1925, when the work of the Bureau was practically completed. For the first two years, A. R. Holbrook, Assoc. M. Am. Soc. C. E., was Office Engineer, and following his resignation he was succeeded by John C. Prior, M. Am. Soc. C. E. The reservoir surveys were in charge of V. C. Norton, Field Engineer. The Hon. James J. Thomas was Mayor of Columbus and W. H. Duffy, Director of Public Service.

DISCUSSION

J. ERNEST CARMAN,* ESQ. (by letter).—The excavation incident to the construction of the O'Shaughnessy Dam exposed a section of rocks 90 ft. thick in the Valley of the Scioto River and offered a good opportunity for a detailed study of the formations encountered.

The bed-rock exposed along the river valley at the site of the dam is the Columbus limestone of Middle Devonian Age. The excavation for the dam, however, exposed the entire thickness of the Columbus limestone, a few feet of the Delaware limestone above, and about 2 ft. of the Monroe dolomite below, the latter belonging to the Lower Monroe, or Bass Island formation, of Silurian Age. The rocks encountered were correlated by zones with the standard section of the Columbus limestone as determined by Dr. Clinton R. Stauffer.†

The section as seen in the excavation is as follows:

	Thickness, in feet.
Delaware Limestone:	
Bluish limestone in layers of 3 to 6 in.....	3+
Columbus Limestone:	
Zone H. Bluish gray, fossiliferous limestone in layers of 1 ft. to 2 ft. The base is at a very smooth plane.....	7
Zone G. Bluish gray, fossiliferous limestone in layers of 3 to 5 ft.....	19
Zone F. Bluish gray, very fossiliferous limestone with *Spirifer gregarius* (*Spirifer gregarius* Zone).....	4
Zone E. Bluish gray limestone that weathers buff. In layers of 12 to 18 in. Upper half fossiliferous.....	14
Zone D. Grayish brown limestone with bands of chert nodules and some chert layers (Chert Zone). Contains some gastropods.....	12½
Zone C. Missing.	
Zone B. Brown dolomitic limestone with some banding and in thick ledges of 3 to 5 ft. The basal 8 ft. is more compact and contains some sand grains.....	30
Zone A. Arenaceous limestone matrix with pebbles of Monroe dolomite and chert (Conglomerate Zone)....	½
Monroe Dolomite:	
Ashen gray to drab, laminated, argillaceous dolomite in beds of 2 to 8 in. In part, brecciated, with minute fragments	2+

Zone A represents the earliest deposit of the Columbus time as the sea transgressed the eroded, pebble-strewn surface of the Monroe dolomite. The sand grains were either on the surface or were washed in by the encroaching sea. Their characteristics are such as to show that they were derived from the Sylvania sandstone of Northern Ohio. The sand content of this layer at this location is greater than at any other known exposure in Central Ohio.

* Prof. of Geology, Ohio State Univ., Columbus, Ohio.
† *Bulletin No. 10*, Geological Survey of Ohio, 1909.

Zones G, E, and B were broken by vertical and inclined joints, a condition having special significance from an engineering viewpoint, for the foundation of a dam.

Zone H forms the upper few feet of the rock wall on either side of the valley, but the top of the zone is not exposed. At a point 50 yd. east of the east end and at a slightly less distance west of the west end of the concrete portion of the dam the "bone bed" which marks the top of the Columbus limestone was encountered in the excavation for the core walls of the earth embankment sections of the dam. Beyond these points the Delaware limestone was encountered in the core-wall trenches.

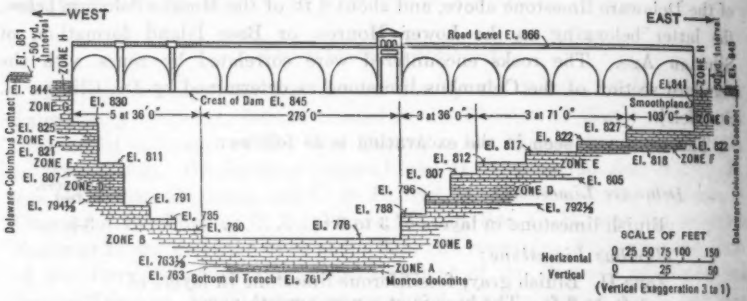

FIG. 25.—CROSS-SECTION OF THE SCIOTO VALLEY AT THE DOWN-STREAM FACE OF THE O'SHAUGHNESSY DAM.

It is of interest to note that the study developed the facts that the Delaware limestone on the east and west sides of the valley is ¼ mile apart and the Delaware-Columbus contact is at about Elevation 850 above sea level; whereas, the geological maps, based on the best information previously available, show a separation between the two areas of Delaware limestone of 1½ miles and a Delaware-Columbus contact about 45 ft. higher than was actually found.

Fig. 25, shows a cross-section of the Scioto Valley at the dam, as one sees it looking up stream (north) from just below the dam. The section shows, to scale, the rock benches just south of the dam and the location of the exposures of the several zones of the Columbus limestone with respect to these benches and to the valley sides.

B. F. JAKOBSEN,* M. AM. SOC. C. E. (by letter).—The paper indicates that the work was carefully planned and executed, as of course it ought to be. The writer notes the absence of any reference to the water-cement ratio in connection with the concrete. It would be interesting to know how the concrete was tested and what strength was found.

Before concreting was started on the Pacoima and Santa Anita Dams of the Los Angeles County Flood Control District, tests on different concretes were made at the Pacoima Testing Laboratory under the writer's direction. At first, hand-mixing was used, but this was found to give such widely varying results, that no conclusions could be drawn. Therefore, a small motor-

* Cons. Engr. (La Rue & Jakobsen), Los Angeles, Calif.

driven mixer was installed, and the results were found to check very closely and consistently with the Abrams curve for strength against water-cement ratio. The results obtained at Pacoima have already been reported.* All the tests showed that the water-cement ratio was by far the most important feature of concrete production and that when this was watched good concrete resulted.

The desirability of strong and durable concrete has been emphasized often enough and there seems also to be a more or less direct relationship between the impermeability of concrete and its strength. In dam construction the writer thinks that shrinkage may be the most important factor, and it seems well established that the leaner the concrete the less will be the shrinkage. Therefore, for equal strength, the leaner concrete is to be preferred, especially in great structures where shrinkage effects may produce high tensile stresses.

Impermeability is also of great importance, especially in cold countries. A Norwegian engineer, Fredrik Vogt, Assoc. M. Am. Soc. C. E., has told the writer, that his experience in Europe indicates that in warm climates porous concrete tightens up with age, whereas in cold climates the reverse is the case. This seems to agree with American experience.†

The main part of the O'Shaughnessy Dam is constructed with Class A concrete (see Fig. 14), but a 12-in. layer of a richer mix (Class C concrete) was added all around the dam. The writer doubts the advisability of adding such a surface coating and is inclined to believe it is detrimental rather than beneficial. This richer mix will shrink more and will probably crack in a great many places, thus tending to produce cracks in the underlying concrete. The writer realizes the desirability of increasing the resistance of the concrete to scour, where it is subject to the action of rapidly moving water, but this ought to be accomplished without increasing the tendency to shrink in setting.

W. H. DITTOE‡ AND G. GALE DIXON,§ MEMBERS, AM. SOC. C. E. (by letter).—For the past twenty years the City of Columbus has presented an outstanding example among the moderately large American cities in its progressive attitude toward public water supply, an example established by the excellent initial development involving softening works completed in 1908, and maintained by further improvements recently finished (1928).

The authors have completed a thorough-going record of the system by adding this paper to the earlier exhaustive description‖ of the initial development.

The architectural effects of the O'Shaughnessy Dam are dignified and appropriate, and evidently the construction work is excellent; the design appears properly conservative in flood-discharging capacity and in the static resistance of the masonry overflow dam.

‖ *Transactions*, Am. Soc. C. E., Vol. LXVII (June, 1910), p. 206.

The "cascade" treatment of the natural rock slopes of the valley below the dam, for returning the spillway discharge to the channel of the river, is of special interest. Under flood condition similar to that of 1913, the spillway will pass a 9.5-ft. depth of water over its crest, and for about 49% of its length will discharge directly upon the unprotected limestone floor surfaces of the cascade at elevations above tail-water level; this discharge will travel over the cascade floor in thin high-velocity sheets at "the lower alternative stage" of flow. During the discharge of smaller flows, this condition will rule over a still greater width of cascade floor, while for the maximum anticipated flood—a depth of 12.5 ft. over the crest of the spillway—the higher stage of tail-water will result in only a small reduction of width of floor unprotected by any back-water.

The writers have been impressed by the excellent opportunity for a full-scale study of the occurrence of the hydraulic jump and related phenomena bearing on the subject of erosion below over-fall dams, which exists at the Julian Griggs Dam. Considerable experimental work with small-scale models has recently been done along these lines, but there is a very definite need for systematic observations by coincident photographs and measurements of the performance of actual structures. The Julian Griggs Dam is of the ogee type, with a uniform height of 33 ft., and is subject to overflow depths which have ranged to 13 ft. Marked erosion of the limestone river bottom beyond the apron has occurred. At the lower stages, a well-defined "standing wave" appears just at the end of the short apron, which at higher stages is drowned out by the natural back-water of the channel.

It is believed by the writers that a far-sighted policy in the management of domestic water supplies in populous districts requires the acquisition of a more liberal width of marginal land surrounding reservoirs than has apparently been considered necessary at Columbus, and also a rigorous control of the use of land and water surface, to afford positive protection against serious pollution. In recent years a growing tendency has manifested itself, in the vicinity of centers of population, toward the development of summer cottage colonies near all bodies of water within easy reach which, in any measure, might afford recreational opportunities. Unless the responsible authorities take steps calculated definitely to discourage such developments in the vicinity of water supply reservoirs, the value of these reservoirs for their primary purpose may, in time, become seriously impaired.

It is the understanding of the writers that the use of the O'Shaughnessy Reservoir for recreational purposes has already gained headway through an ordinance of the Columbus City Council permitting boating and fishing, and that land immediately abutting the reservoir property has been allotted and is being sold by realty companies for residential purposes.

A striking example of the results which may follow the adoption of a lenient policy in regard to recreational use of the water and the marginal lands of a reservoir is to be found in the Milton Reservoir on the Mahoning River in Northeastern Ohio, built by the City of Youngstown in 1917 in connection with its water supply system. The Milton Reservoir is located about

16 miles west of the city and at a distance of about 40 miles up stream from the Youngstown Water-Works Intake from the Mahoning River within the city. The reservoir was constructed for use in regulating the dry-weather flow of the river, not only for the benefit of the municipal supply, but also for industrial purposes and, incidentally, for preventing nuisance from the discharge of the city's untreated sewage into the stream. The purpose of construction was therefore not parallel with that under discussion, but the result of the policy adopted for control of the reservoir is none the less an outstanding lesson.

The Milton Reservoir is formed by a dam 55 ft. high, flooding 1 657 acres of land and impounding 9 000 000 000 gal. of water. The initial purchases of land by the City comprised 3 344 acres, or about double the flooded area. Much of this property was acquired under deeds which reserved to the grantors the right of access to and the use of the reservoir for boating, fishing, bathing, and other uses normal to an ordinary body of water. Subsequently, the City established a "permanent holding line" at a relatively short distance from the water's edge enclosing about 2 500 acres—about one and one-half times the flooded area—and the "salvage land" lying outside this line was divided into blocks and offered for sale. Under these conditions, an extensive development of the surrounding lands for summer-resort purposes has naturally followed, and the reservoir has become an important recreational center. About twenty-five separate allotments offering summer camp and cottage sites have been put on the market, and restaurants, bath and boat houses, dance halls, and other semi-public buildings have been constructed for the service of a summer population of several thousand people.

Meander Creek (proposed)	5 248	2 610	2.6	40	690

The writers have recently had occasion to consider the availability of Milton Reservoir for the purpose of providing a permanent source of public

water supply for the Cities of Youngstown and Niles, Ohio, in connection with the project of the Mahoning Valley Sanitary District for providing a complete modern system of works for these cities. The existing conditions about the reservoir are entirely proper in connection with its present function of general regulation of the river, but radical procedure would be required in preparation for its use as a permanent source of potable supply. Careful estimate indicated that in order to gain the necessary sanitary control of the waters and the marginal lands, the taking of an additional area of 3 000 acres of land over and above that now owned by the City would be required, at a cost exceeding $2 000 000. The original total cost of the reservoir, including land and construction, was $1 321 000.

The Mahoning Valley Sanitary District is now (1928) preparing to develop a relatively uncontaminated upland source of supply for Youngstown and Niles, so that these cities will shortly abandon the use of the badly polluted Mahoning River water. In connection with this project, the writers have examined precedent in the acquisition of land about various important reservoirs, and submit Table 7, as of possible interest.

It should be noted that, with the exception of the Columbus Reservoir, the "mean width of marginal strip", as stated in Table 7, is derived by dividing the area of land taken above reservoir level by the recorded length of flow line; irregularity of shore line, of course, has an important bearing on the practical fixing of taking lines which is not evaluated in the arrangement of Table 7. Thus, the proposed Meander Creek Reservoir has a very irregular shore line, whereas the two Columbus reservoirs are of quite smooth outline, each being confined principally to the main valley of the stream.

JOHN H. GREGORY,* C. B. HOOVER,† AND C. B. CORNELL,‡ MEMBERS, AM. SOC. C. E. (by letter).—In his discussion, Mr. Jakobsen mentions three points which merit further explanation, namely, the absence of any reference to the water-cement ratio, in connection with the mixing of the concrete; the methods of testing the concrete and the results of these tests; and the desirability of facing the lean concrete forming the main body of the dam with a richer mixture of concrete. As bearing on the first point, it should be stated again that concrete was first placed in the dam on November 1, 1922. At that time, engineers were generally of the opinion that there was a direct relation between the compressive strength of concrete and the quantity of water used in mixing. It had also been shown in laboratory experiments that the quantity of mixing water necessary to produce a workable concrete had a direct relation to the grading of the aggregates used, the fineness modulus being the means by which this relation was expressed. The application of these principles to large construction work and the development of satisfactory methods of field control were in the experimental stage. Little, if anything, was known concerning the weather-resisting properties of concrete proportioned according to the new theories, nor of its behavior when exposed to alternate wetting and drying, because long-time proof on these points was still lacking.

* Cons. Engr.; Prof. of Civil and San. Eng., The Johns Hopkins Univ., Baltimore, Md.
† Supt., Water and Sewage Disposal Divisions, Columbus, Ohio.
‡ Field Engr., Mahoning Val. San. Dist., Youngstown, Ohio.

The engineers in charge of the design and construction of the O'Shaughnessy Dam were confronted with the problem of building a structure in which long life, a high degree of imperviousness, the greatest possible weight per unit of volume, and maximum resistance to the effects of temperature and water must be obtained; and, in which, the strength of the main body of the structure was of relatively minor importance, the maximum compressive stress being less than 100 lb. per sq. in.

At the time construction was started, it appeared to be very generally accepted by engineers that concrete proportioned to secure maximum density fulfilled these requirements, and, therefore, this basis of proportioning the concrete mixtures was adopted. In the prosecution of the work the quantity of mixing water was at all times held to the minimum amount which would secure the workability necessary for the satisfactory placing of the concrete, consideration, of course, being given to the location of the concrete being placed; and, furthermore, concrete was not transported by means of chutes because their use was not permitted by the specifications.

Numerous mechanical analyses of the four sizes of aggregates used were made and a large number of combinations of the results secured were plotted for comparison with the practical curve of maximum density, as established by Taylor and Thompson. Trial batches, containing cement, sand, coarse aggregates, and water, mixed by hand, were made up of the combinations which most nearly approached the Taylor and Thompson curve, and of variations from these combinations in which the total volume of aggregates was kept the same while the relative proportions of the several aggregates were changed. Each trial batch was measured for volume by placing the concrete in a pipe, the workability of the batch was observed and recorded, and, also, cylinders 6 in. in diameter and 12 in. long were made and broken, for a check on the compressive strength. From the results of these tests the various mixtures were selected. Throughout the work only slight variations from these proportions were made; for example, a small increase in the fine aggregate with a corresponding decrease in the coarse aggregates was allowed in thin walls and in the arch rings of the bridge; and, in the latter case, the cement, also, was slightly increased to secure greater workability.

From time to time throughout the course of the work test cylinders were made and broken. Cylinders made from concrete containing the two smaller sizes of coarse aggregate showed greater consistency in the test results than those containing the three sizes. It was demonstrated conclusively, in the case of a few of the tests, that cylinders 6 in. in diameter and 12 in. long were not as reliable as larger cylinders for testing concrete containing the 3-in. aggregate.

In addition to the proportioning and strength tests made by the engineers, J. R. Shank, M. Am. Soc. C. E., was commissioned by the contractor to conduct an extensive series of tests, at the beginning of the work, with various combinations of the aggregates which were to be used. Several hundred test cylinders were made and broken and the results were substantially in accord with those secured by the engineers. Since none of the tests was made to set

up a water-cement ratio for the work, a detailed account of the test results is thought to be out of place in this discussion.

A richer concrete facing (1:2:4), 1 ft. thick, was placed on the exposed faces of the dam and bridge piers for the purpose of securing greater resistance to scour, to alternate wetting and drying, and to changes of temperature. Experience with previous work in Columbus, especially the Julian Griggs Dam, convinced the writers that resistance to scour and to temperature and water exposure would be secured best and at a minimum expense by applying a 1:2:4 concrete on the face of the overflow and on the vertical sides of the abutment sections, as well as on other exposed concrete structures. With the facing used no difficulty has been experienced with shrinkage cracks in the Julian Griggs Dam and, to date (1929), none has appeared in the O'Shaughnessy Dam.

The discussion of Messrs. Dittoe and Dixon raises a number of very interesting points. The most important of these has to do with scour at the toe of the two dams mentioned; that is, the Julian Griggs Dam, which was put under construction early in 1904 and practically completed in December, 1905, and the O'Shaughnessy Dam which was put under construction in 1922 and completed, ready for use, on June 1, 1925. Both structures are built on limestone, the geological formations at the two sites being, in general, similar.

Referring first to the Julian Griggs Dam, records have been kept by the City of Columbus since 1904, which show the scour at the toe of the dam. These records include elevations of the original surface of the ground and the top of the rock before construction started. Cross-sections were again taken on September 1, 1908, October 14, 1909, July 14, 1913, October 26, 1920, and the last ones on August 10, 1928.

Scour continued year after year, from the time the dam was completed in 1905 until 1920, that is, for about fifteen years, but, in the last eight years, since 1920, practically no further scour has occurred. On a few of the sections some further small scour has occurred since 1920, whereas, on the other hand, on some of the other sections there appears to have been a filling up. This is probably due to the movement of some loose rock on the bottom of the river. Taking the sections by and large it seems that a condition of practical stability below the toe of the dam was reached in 1920.

Attention should also be called to the fact that the dam, in March, 1913, passed through the most disastrous flood on record in the history of Central Ohio. At the peak of the flood on March 25, the depth of water passing over the 500-ft. spillway was 12.8 ft., with a flood discharge of approximately 80 000 cu. ft. per sec.

A full set of cross-sections was not taken in 1913, but scour occurred between 1909 and 1913. It is not known, however, whether the scour was progressive or whether it took place mainly at the time of the March, 1913, flood. The deepest scour, as of 1913, was at Stations 8 + 96 and 9 + 52 (see Fig. 26), since that time the river bottom has filled up considerably.

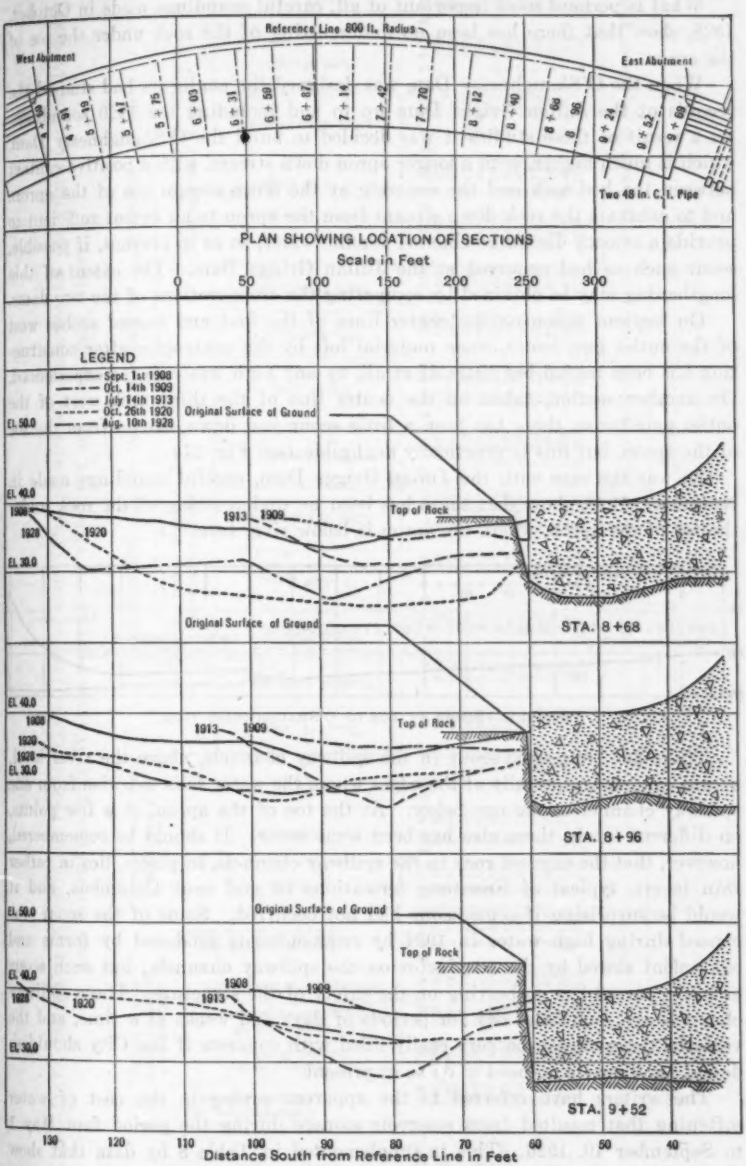

FIG. 26.—SCOUR AT TOE OF JULIAN GRIGGS DAM.

What is perhaps most important of all, careful soundings made in October, 1928, show that there has been no undercutting of the rock under the toe of the apron.

When the O'Shaughnessy Dam was designed the engineers had studied the records of the Julian Griggs Dam up to and including the 1920 soundings. As a result of these studies it was decided to build the O'Shaughnessy Dam, which is much higher, with a longer apron down stream, with a positive contact between the bed-rock and the concrete at the down-stream toe of the apron, and to excavate the rock down stream from the apron to an extent sufficient to provide a smooth discharge channel for the water, so as to prevent, if possible, scour such as had occurred at the Julian Griggs Dam. The extent of this lengthening may be obtained by comparing the cross-sections of the two dams.

On sections taken on the center lines of the first and second arches west of the outlet gate-house, some material left by the contractor after construction has been moved but little, if at all, by any high water so far experienced. On another section, taken on the center line of the third arch west of the outlet gate-house, there has been a little scour just down stream from the toe of the apron, but this is practically negligible (see Fig. 27).

As was the case with the Julian Griggs Dam, careful soundings made in November, 1928, show that there has been no undercutting of the rock under the toe of the apron, where the apron is below river level.

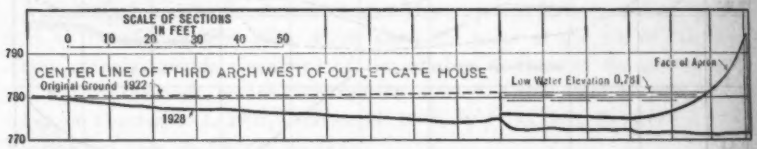

FIG. 27.—SCOUR AT TOE OF O'SHAUGHNESSY DAM.

There has been some scour in the spillway channels, above the river level, as was expected, especially at the edges where the water falls sidewise from one spillway channel to the one below. At the toe of the apron, at a few points, on different levels, there also has been some scour. It should be remembered, however, that the exposed rock in the spillway channels, in places, lies in rather thin layers, typical of limestone formations in and near Columbus, and it would be surprising if some scour had not occurred. Some of the scour was caused during high water in 1924 by cross-currents produced by forms and equipment stored by the contractor on the spillway channels; but such scour as has occurred has no bearing on the safety of the structure. These spillway channels are sometimes dry for periods of days and weeks at a time, and the voids in the rock can be very easily filled with concrete if the City should so desire, but there is no need to do so at present.

The writers have referred to the apparent saving in the cost of water softening that resulted from reservoir storage during the period fom May 1 to September 10, 1926. This is supplemented in Table 8 by data that show the effect of storage in the Julian Griggs and O'Shaughnessy Reservoirs on the cost of purifying and softening the water supply of Columbus for a period of

one full year from July 1, 1927, to July 1, 1928. Samples of water were collected daily from Mill Creek and the Upper Scioto, and at the end of each month composite samples of each were analyzed and the average analysis of the inflow water at the upper end of the O'Shaughnessy Reservoir was then taken as that secured by weighting the separate analyses on the basis of the areas of the contributing water-sheds.

The tons of lime, soda ash, and alum actually used at the Water Purification Works each month, together with the cost of each chemical and the total chemical cost, are given in Table 8. In this table also are given the computed tons of chemicals which the inflow water would have required, and the corresponding chemical cost if the inflow water had been treated so as to produce a water of the same quality as that delivered by the Water Purification Works.

The method of computation used in determining the tons of lime, soda ash, and alum required for the inflow water, when applied to the average monthly composition of the water actually treated, gives chemical tonnage values of about 4% less than those actually used in the treatment of the water, so that the method of computation, as applied to the inflow water, gives a conservative basis for comparison.

The tabulated data show that the annual saving in cost of the three chemicals required, due to reservoir storage, was ($203 205 — $145 813 =) $57 392, and that the saving in cost of lime and soda ash alone was ($186 698 — $123 873 =) $62 825. The difference in cost is due to the increase in the quantity of alum required for the treatment of the water because of the persistence of turbidity for longer periods of time than would have been the case in the absence of reservoir storage. The average cost of lime and soda ash to remove 1 part of total hardness from 1 000 000 gal. for the year was 8 cents. The saving in cost was, therefore, 10 623 000 000 gal. $\times$ 71 parts of total hardness $\times$ $0.08 = $60 339.

The total saving of $57 392 in the cost of chemicals for the period of one year from July 1, 1927, to July 1, 1928, is equal to the annual interest on an investment of approximately $1 150 000 at 5%; also, it represents a reduction of 28% in the cost of softening and purifying chemicals.

More than three years have now (1929) passed since the dam was completed, and a careful inspection of the structure fails to reveal any defects or any visible leakage around or through the dam.

Paper No. 1716

THE TREATMENT OF THE WATER SUPPLY OF THE CITY OF COLUMBUS, OHIO*

By Charles P. Hoover,† Esq.

With Discussion by Messrs. F. H. Waring, George W. Fuller, Robert Spurr Weston, and C. W. Foulk.

Synopsis

A description of construction features of the Water Softening and Purification Works as originally built at Columbus, Ohio, will not be given in this paper. This has been done‡ by John H. Gregory, M. Am. Soc. C. E., who was Engineer in charge of the design of the plant. Operation and new features only will be discussed.

Original Water Supply

Prior to the time the Purification Plant was built, the water supply of Columbus was not safe for drinking. It was badly polluted with sewage, always turbid, and, following heavy rains, extremely muddy. The turbidity of the Scioto River averages 75 parts per million. During floods this rises to 2 250 parts per million, meaning that a day's supply carries from 200 to 300 tons of mud in suspension.

The bacterial count (37° cent., 24 hours) averages 5 665 per cu. cm. The *B. Coli* count sometimes reaches 100 000 per 100 cu. cm. In 1908, the typhoid fever death rate reached 138 per 100 000 population. During the summer of that year there were 1 500 cases of typhoid.

The original supply of water was unsatisfactory for domestic or industrial purposes because it was highly mineralized. The average hardness of the

* Presented at the Fall Meeting of the Society at Columbus, Ohio, October 12, 1927.

present raw water from 1909 to 1926, inclusive, was 272 parts per million, with a maximum of 495 parts per million. This hardness is due to calcium carbonate, magnesium carbonate, calcium sulfate and magnesium sulfate. There are 68 570 lb., or more than a carload, of these compounds in a day's supply. There is enough calcium to make 48 tons of hydrated lime and the magnesium in one day's supply would make 62 500-qt. bottles of milk of magnesia.

Calcium and magnesium salts are very objectionable. They form deposits in boiler tubes and hot-water heating systems, resulting in large heat losses. They also re-act with soap to form slimy, insoluble compounds, which can be seen in the water before lather begins to form. Soap has no cleansing action until it lathers, therefore, much of it is wasted in hard water.

Before the water supply of the city was softened, cistern water was used almost generally for domestic purposes. More than 17 000 cisterns were in use in Columbus, when the municipal plant was built. Cisterns are only makeshifts for a suitable municipal water supply. The water in them is hardly ever adequate, and is almost always dirty and, sometimes, not even soft. They have now been practically abandoned in Columbus.

Water from individual private wells was used for drinking purposes, but many of these wells were contaminated with sewage. They were condemned by the Board of Health after the Purification Plant was put into service.

Status of Water Filtration and Water Softening in 1904

At the time (1904) the Columbus plant was being designed, only two large mechanical water filtration plants of concrete construction were in operation, one at Little Falls, and one at New Milford, N. J. Valuable and helpful experimental work on water purification had been done by George W. Fuller, M. Am. Soc. C. E., who was one of the consulting engineers on the design of the plants, at Louisville, Ky., and Cincinnati, Ohio, on the treatment and filtration of water,* but no large combined water-softening and filtration plant had been built. There was little or no precedent to follow. Under the supervision of George A. Johnson, M. Am. Soc. C. E., bottle and barrel water-softening experiments were made at the Columbus Sewage Testing Station. The results of these experiments were used as a guide in the design of the plant. The demand for the new plant was so urgent that there was no time to investigate the Columbus problem extensively, as was done at Louisville and Cincinnati.

Flexible Plant Built

The plant, as built, was provided with facilities for softening and filtration. The design was so elastic that the operating process could be modified without making elaborate changes. Numerous places for applying the chemicals were provided. The water could be separated and treated in portions, also the time of mixing could be varied. The mixing and settling basins could be operated in series, or parallel, or in series parallel. Raw water could be applied at many points to correct for over-treatment.

* Report of Water Purification at Louisville, Ky.; and Report of Water Purification at Cincinnati, Ohio.

As a result of this flexibility, after twenty years of continuous use, the plant is being operated (1927) as effectively as the most recently built plants. No extensive or costly additions and changes have been required to accomplish this; it has never been necessary to shut down for repairs, changes, or enlargements. The plant has been shut down completely only once since it was put in operation in 1908. This was necessary during the 1913 flood, when one of the force mains, laid in the river bed, was washed out, making it impossible to maintain pressure in the distributing system, and this shut down lasted for only eight hours.

Character of Raw Water Changes Suddenly

The design of the plant was also complicated because the Scioto River, from which Columbus takes its supply, is very flashy. It is sometimes clear, sometimes muddy, sometimes soft, and sometimes hard; and as the waterworks is not provided with large settling basins, in which to store raw water to equalize these fluctuations, the plant must take whatever is flowing in the river. Table 1 shows the fluctuations in the raw-water analysis during a 48-hour period from March 21 to 23, 1916.

TABLE 1.—Character of Scioto River Water.

Date.	Turbidity.	Carbonate hardness.	Non-carbonate hardness.	Total hardness.
March 21.....	22	189	96	285
March 22.....	678	133	63	196
March 23.....	2 250	46	18	64

It was known by those who designed the plant that these sudden changes in the analysis of the raw water would occur. Specially designed and readily adjustable devices, capable of feeding small and large quantities of chemicals, were provided.

These sudden changes require constant supervision to treat the water properly. A chemist is kept on duty day and night making tests once every hour. At plants where only coagulation and filtration are practiced a change in the character of the raw water coming to the plant does not present as serious a problem to the operator as it does at a water-softening plant. In the former it is only necessary to increase the application of the coagulating re-agent; whereas, at a water-softening plant, it is not only necessary to increase the application of the coagulating re-agent, but also to diminish the quantity of softening chemicals.

The addition of too much lime gives the water a caustic reaction. The addition of too small a quantity of lime may prevent the coagulant from completely precipitating, resulting in the passage of alum floc through the filters and the production of a turbid effluent. Lime, unless added in exactly the right quantity, may be detrimental to successful purification and clarification processes.

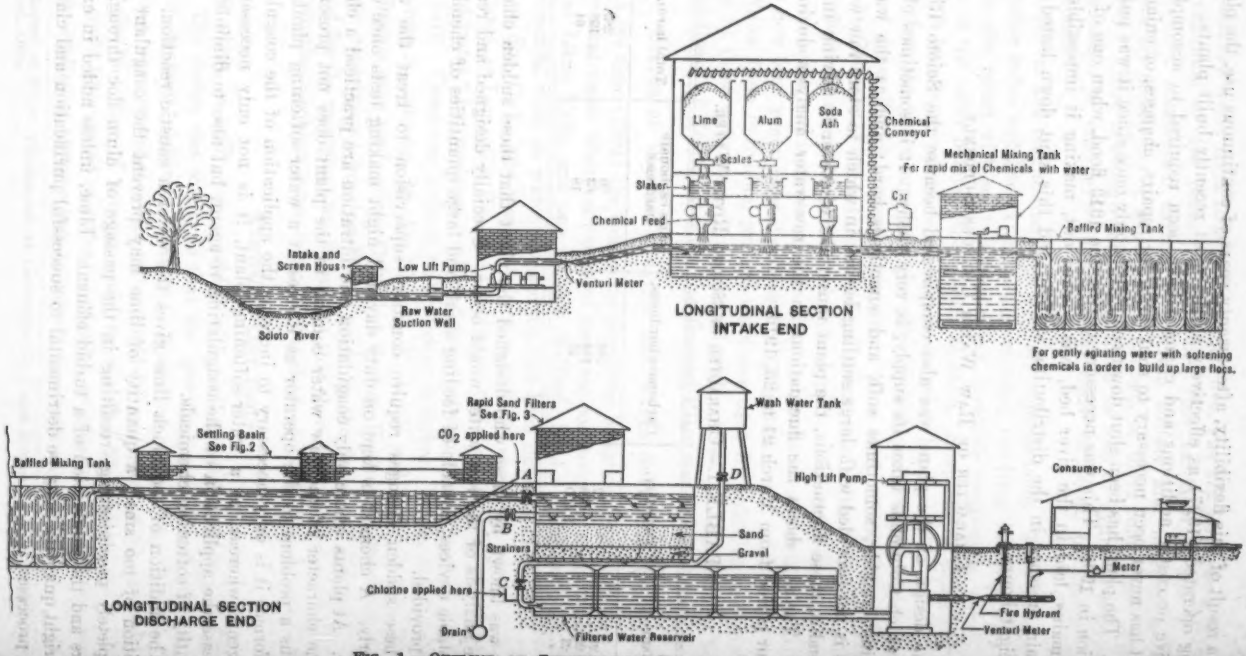

FIG. 1.—OUTLINE OF PURIFICATION PROCESS, COLUMBUS, OHIO.

Process Used in Treatment of Water Supply

The water flows, from the river (Fig. 1), through screens into a suction well. From the well it is pumped through a Venturi meter into the receiving compartment at the Purification Works. Here, it is divided into approximately two equal parts. One part without treatment flows directly to the baffled mixing tanks and the other part, to which is added the entire quantity of lime, soda-ash, and alum solutions necessary to soften and clarify the entire supply, flows to mechanical mixing tanks.

The portion of water receiving the chemical charge is mixed for about 10 min. in square tanks provided with rotating paddles. During this time chemical reactions between the chemicals added to the water and the mineral salts already present in the water are effected. This reaction results in the formation of an extremely heavy gelatinous precipitate, which is largely due to the mass action effect of over-treatment. Under these circumstances the magnesium compounds present in the water are readily precipitated. Lime combines with magnesium to form magnesium hydroxide, a bulky gelatinous precipitate, which coagulates as readily as the precipitates formed by sulfates of alum or iron. It is, however, extremely difficult to precipitate magnesium unless excess lime is applied. This is the reason why separate treatment is used.

This over-treated portion of the water, with floc already formed, joins the other portion of untreated raw water at the entrance of the baffled mixing tanks, and the two are mixed together for about an hour. Floc formation having already been started, further floc-forming reactions take place readily in the baffled mixing tanks. The size of the floc grows as the water rolls over and under the baffles.

From the baffled mixing tanks the water flows to the settling basins (Fig. 2). They are six in number. The mud and precipitated chemicals settle to the bottom of these basins, practically all of it being removed in the first two. It is necessary to wash these basins every three or four weeks. The last four basins are washed only once or twice a year.

Just before the clear softened water leaves the settling basins, carbon-dioxide gas is applied in order to neutralize any excess lime. It also converts the normal carbonates to bi-carbonate form. This reaction stabilizes the water, and prevents after-reactions, or deposits, in the filters or distributing system.

After carbonation, the water discharges from the settling basins into the filters. Here, it is filtered through 24 in. of sand and 18 in. of gravel. As it discharges from the filters into the filtered water reservoir a small quantity of chlorine gas is added, the quantity averaging only 0.15 parts per million. The water meets the U. S. Treasury standards for bacterial purity without the chlorine, but the small quantity mentioned is added as a safeguard. From the filtered reservoir the water is pumped by means of high-lift pumps (Fig. 3) into the distributing system to the consumers.

Advantages of Lime Treatment

Lime is added to water primarily to soften it, but it has been discovered that, when added in sufficient quantity to produce residual or excess lime

(caustic alkalinity), it kills intestinal and pathogenic bacteria, rendering the water safe bacterially.

The lime-softening process also increases the efficiency of sedimentation because better coagulation is effected. The bulk of the precipitate formed by the softening reaction is about twenty times as great as could be obtained by ordinary coagulation processes. This large, bulky precipitate of calcium carbonate and magnesium hydroxide entangles fine particles of suspended matter, bacteria, and other impurities in the water, and settles very rapidly.

Lime-softened and settled water is low in turbidity, color, and organic matter, these having been absorbed or dragged down mechanically by the precipitates. In addition, the water will be free from objectionable gases, such as carbon dioxide and hydrogen sulfide, these having been neutralized. The riddance from bacteria, turbidity, iron, color, organic matter, and objectionable gases by lime treatment, lessens the cost of filtration because filter runs are long, and filtration areas may be reduced.

Lime softening is well adapted to the treatment of a polluted hard water, such as that at Columbus. It is possible during flood times, when tastes and odors are feared, to produce a satisfactory potable water without having to depend on chlorine to kill bacteria.

Application of Chemicals to Water

The lime, soda ash, and alum are now applied to the water at practically one point. When the plant was first put in operation the lime was applied to approximately 25% of the raw water, which was diverted through saturators in order to make a saturated lime water containing 60 grains of calcium oxide per gal. This saturated lime water was then mixed with 50% more of the raw water, making a total of 75% lime-treated water. The soda ash was mixed with the remaining 25% of the raw water for about 20 min. and then mixed with the lime-treated water. This was given up because it was found to be extremely difficult to produce a uniform saturated lime solution.

It was also discovered that considerable lime was lost in the sludge, which deposited in the bottom of the saturators. There was no noticeable advantage in treating the water separately with lime and soda ash and then mixing the two waters together. The resultant reaction is the same as when they are added together. The process was simplified by applying the chemicals at one point, but the split treatment is still used because the hardness of a given quantity of raw water with a given quantity of chemicals will be reduced more than when added in the usual way.

Water not "Doped" with Chemicals

There is a general belief that the use of chemicals for softening water is not desirable. There is usually prejudice against it. Wherever water-softening plants have been built, this prejudice has been almost entirely overcome. The citizens of municipalities operating a water-softening plant, especially in those cities where water softening has been practiced for some years, now understand that the water is not "doped". They have learned there is less mineral matter or chemicals in the softened water than in the raw water.

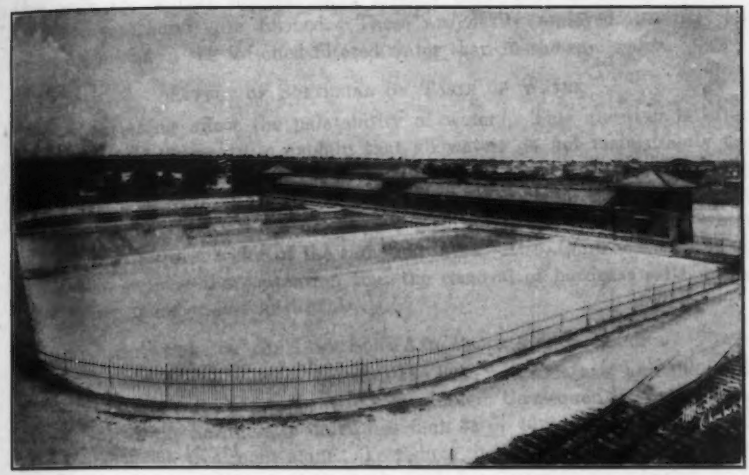

FIG. 2.—VIEW OF SETTLING BASINS, COLUMBUS, OHIO, PURIFICATION WORKS.

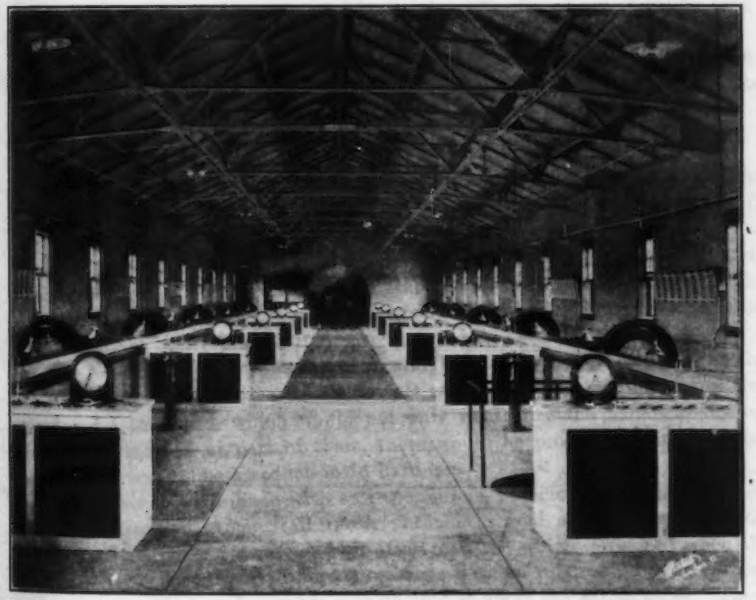

FIG. 3.—VIEW OF INTERIOR OF FILTER ROOM, SHOWING HIGH-LIFT PUMPS, COLUMBUS, OHIO, PURIFICATION PLANT.

The chemicals, which are added in order to soften and purify the water, combine with the soluble mineral salts already present in solution, and new insoluble compounds are formed. These are easily removed, leaving less mineral content in the softened filtered water than in the raw water.

Effect of Softening on Taste of Water

Does softening affect the palatability of water? This question is often asked and it is necessary to explain that all waters do not taste exactly the same. Water highly mineralized, or water that contains iron or sulfur compounds, has a more pronounced taste than water free from these compounds, but there should be no difference in the taste of softened carbonated water and that of a natural water of the same hardness. Also, there seems to be no evidence to support the contention that the removal of hardness salts makes water either more or less healthful.

Limitations of the Lime Soda-Ash Process of Softening

The product of the reaction between the lime and soda ash, and the hardness salts in the water, is not entirely insoluble. Consequently, it is impossible to reduce the hardness to much less than 35 or 40 parts per million with lime and soda-ash treatment alone. To reduce the hardness to this low figure an excess quantity of chemicals must be added.

It has been the experience at Columbus that when the hardness has been reduced to about 85 parts per million, the cost of further removal of hardness is proportionately higher. This is due to the difficulty of precipitating magnesium compounds.

Methods for further reducing hardness by high temperature, excess chemical treatment, split treatment, addition of aluminum salts and excess lime neutralized by carbonation have been described elsewhere by the writer.*

Lime Scale in Pipes and Filters

Lime-softened water is a saturated solution of calcium carbonate, and like any saturated solution is, of course, not stable. Difficulty has resulted from the deposition of calcium and magnesium scale in the filter sand at the plant and in the pipe system of the city. It has long been known that carbon dioxide applied to lime-softened water would stabilize it, because it re-acts with the slightly soluble non-carbonates and changes them to high soluble bi-carbonates, which are not easily precipitated.

For some time doubt was felt as to whether or not carbon dioxide was the best re-agent for corrective treatment. It was realized that if an inexpensive acid could be found, which would not only neutralize the mono-carbonates, but precipitate all or part of them, there would be produced a stable water and at the same time a reduction in hardness.

Experiments were made with sulfuric, silicic, boracic, oxalic, tartaric, and phosphoric acids. Among all these, phosphoric acid seemed best, but was given up because of its cost and an after reaction, which developed when the water was heated. Many different methods may be used to produce carbon-dioxide gas, and several methods may be used to apply the gas to water. These

* *The American City*, Vol. XXXVII, September, 1927.

were investigated over a period of seven years before starting the design of the carbonation plant.

Carbonation of a softened water makes it resemble natural water. If a sample of lime-softened water were submitted to a chemist for analysis, he could very easily tell that it was softened. The results of his analysis would show that the water was different from natural waters. If, however, a sample of lime-softened water that had been carbonated were submitted to him, he could not tell the source of the water from the results of his analysis. This water would be similar in all respects to any natural water of similar hardness.

It should be understood that the recarbonated water does not contain any free carbon dioxide, as only a sufficient amount to combine chemically with the normal carbonates is added, consequently carbonation of water as practised at Columbus should not make it corrosive.

The results of operation and quantities and cost of chemicals used, are given in Tables 2, 3, and 4. Table 5 shows the cost of treatment per 1 000 000 gal. and the cost of removing 1 part per million of hardness from 1 000 000 gal.

Fig. 4 shows the reduction in typhoid fever after filtration. There were five deaths from typhoid fever during 1926, three of which were resident and two non-resident. Assuming the population to be 285 000,* would give the city a total death rate from typhoid fever of 1.7 per 100 000, a resident death rate of 1.0 per 100 000, and a non-resident death rate of 0.7 per 100 000.

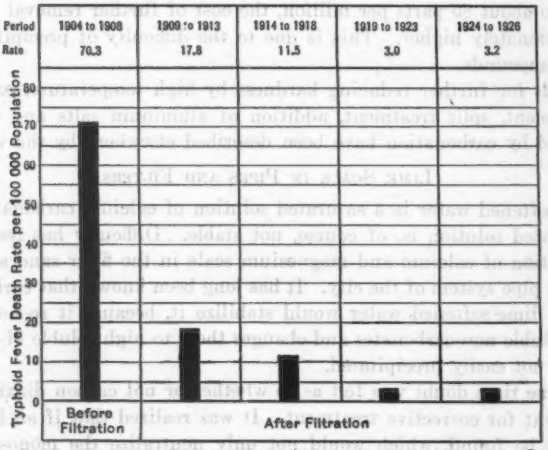

FIG. 4.—REDUCTION IN TYPHOID FEVER DEATH RATE IN COLUMBUS, OHIO, BEFORE AND AFTER FILTRATION.

IMPROVEMENTS AND ADDITIONAL FEATURES ADDED TO THE PLANT

Handling Lime.—Originally, the lime was handled and stored in canvas bags. In order to increase the storage capacity, and to lessen the labor and cost of handling the lime, a concrete storage bin was built. Lime is elevated into it by a conveyor. A cross-conveyor carries it to daily supply hoppers.

From the daily supply hoppers the lime drops into Richardson automatic weighing scales, which automatically weigh it into solution tanks from which it is fed into the water through a chemical feed regulator.

Alum Made at Plant.—It will be noted by examining Table 3 that whereas the cost of lime and soda ash has advanced since 1915, the price of alum is lower. The reason for this is the manufacture of alum at the plant.

Bauxite and sulfuric acid are boiled in lead-lined tanks until a basic solution of aluminum sulfate is obtained. The solution is then diluted with water (usually enough water is added to make 500 gal. of the solution, equivalent to 1 ton of 17% Al_2O_3 alum), and measured as needed into alum solution tanks. There it is diluted with sufficient water to make a standard solution, which is then applied to the water under treatment. By this process five distinct steps in alum making are eliminated—filtering, concentrating, crystallizing, grinding, and re-dissolving. The plant comprising lead-lined boiling tanks, an alum-measuring tank, one acid-measuring tank, storage tanks for sulfuric acid, a pulverizer for bauxite, conveying, elevating, and transmission machinery, bauxite storage bins and weighing device, piping, valves, and fittings, is shown in Fig. 5.

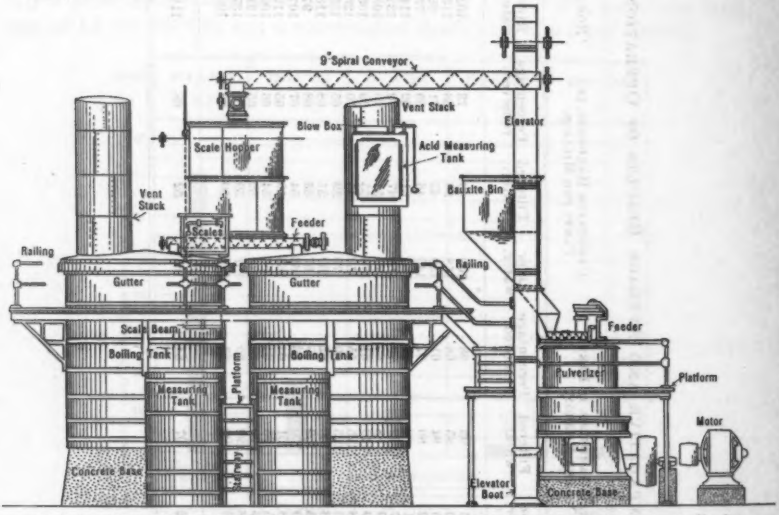

FIG. 5.—CROSS-SECTION OF ALUM PLANT, COLUMBUS, OHIO, WATER PURIFICATION PLANT.

Recarbonation Plant.—The gas-making and distributing plant consists of six principal parts (Fig. 6), a gas producer, a gas burner, a return tubular boiler, a steam-driven air compressor, a combination scrubber and drier, and a diffuser. In operation, coke is burned in the gas producer, which is a closed furnace with a controlled air supply furnished by a blower. The products of combustion pass from the gas producer to a gas burner, where they are mixed with air and burned to complete combustion under a boiler. The steam produced in this boiler is used to drive the air compressor and blower in order

to make a closed cycle for the process. The plant is located in the boiler-room of the pumping station and the steam produced is connected to the main steam line. It has been found that a small amount of steam from the main steam line is required for operating the compressor and blower. The air compressor takes its suction from the boiler stack of the producer gas-burning boiler, through a scrubber and drier, and forces the washed gases through diffusers into the water to be carbonated. Making producer gas from coke, and burning it under a boiler, is perhaps the most economical method of producing carbon-dioxide gas. The steam generated is readily available, and it is possible to produce a gas containing as much as 17 or 18% of carbon dioxide, thus requiring an air compressor of only one-fourth the capacity needed if coke were burned in an open burner.

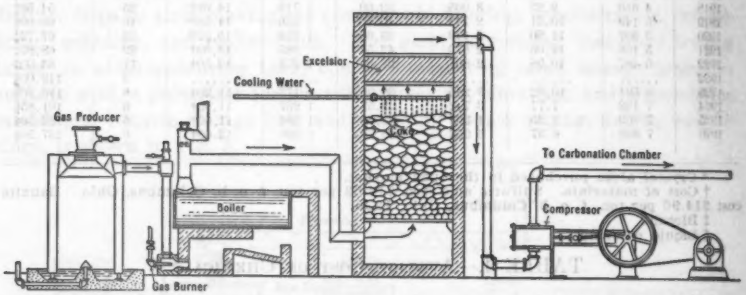

FIG. 6.—CROSS-SECTION THROUGH CARBONATION PLANT, COLUMBUS, OHIO, WATER-WORKS.

Plant Enlarged.—In 1923 the plant was enlarged by the addition of eight 3 000 000-gal. per day filters and the capacity of the filtered water reservoir was increased from 10 000 000 to 16 500 000 gal. With this enlargement it is possible to soften and filter 55 000 000 gal. per day at Columbus. This plant is the largest complete water-softening works in the world.

DISCUSSION

F. H. WARING,* M. AM. SOC. C. E.—An important part of the routine of operation at the Columbus Water Purification Plant should be stressed; namely, the practice of continual research on water-softening conducted both in the laboratory and on a plant-operation basis. Some items have been incorporated into large scale practice in the more recently constructed water-softening plants. Also, some have been used on a large scale at the Columbus plant. Mr. Hoover deserves great credit for the policy of making available to others the results of his experimentation and researches so that they may reap the benefit of his experiences.

The Use of Carbon Dioxide in Water-Softening Practice.—In 1922 it was demonstrated in the laboratory of the Columbus Water Purification Plant that the addition of carbon dioxide to lime-softened water was beneficial. A considerable portion of the calcium and magnesium carbonates was noticeably difficult to precipitate, as a result of which the sand grains of the filters and the water piping became coated. Some of the incrustation tended to pass beyond the filters and cause trouble in meters and hot-water systems. The introduction of carbon dioxide in the settled water passing to the filters destroys the semi-colloidal portion of the calcium carbonate precipitate by dissolving it as calcium bi-carbonate.

In municipal practice in the Middle West full utilization of this feature was not effected until the Defiance, Ohio, plant, designed by Nicholas S. Hill, Jr., M. Am. Soc. C. E., was placed in service in 1921.† Only a brief experience at the Defiance plant was required to demonstrate the efficacy of this feature of water-softening practice. From the start, the Defiance installation was a tremendous success, accomplishing the protection against incrustation of filters, piping, etc., already mentioned.

In Ohio, the custom has been established of an exchange of experiences among operators in charge of water treatment works by means of annual conferences sponsored by the State Department of Health. Thus, the news of the success at Defiance was rapidly spread within the State; and what was perhaps looked upon at first as experimental, namely, the carbon dioxide treatment, was soon viewed as an essential, accepted process in water-softening practice. Based on the early experiments at Columbus and the full scale practical demonstration on the part of the Defiance plant, Mr. Hoover incorporated the carbon dioxide treatment process in his designs for the municipal water-softening plant at Newark, Ohio. Following the Newark installation in 1924 there have been several carbon dioxide installations in Ohio, each based on previous experience, and, except for minor improvements, largely patterned after the Defiance layout. Delaware completed its plant in 1925; Piqua, Girard, and Greenville, in 1926; and Fostoria, Fremont, and Marion constructed new plants in 1927.

It is pertinent to emphasize that, in addition to preventing incrustation, the carbon dioxide treatment deprives the softened water of a taste given to

* Chf. Engr., State Dept. of Health, Columbus, Ohio.

† "The New Water Pumping and Purification Works at Defiance, Ohio," *Journal*. Am. Water Works Assoc., Vol. 7, No. 4, July, 1920.

it by the lime, described by some as a "limey" or caustic taste and by others as a peculiar flat taste. It is practically impossible to tell by taste the difference between any natural water of equivalent hardness and a softened water to which has been applied the proper amount of carbon dioxide gas. From a popular viewpoint, therefore, definite objection to the softening process as applied to municipal practice has been removed.

Bacterial Significance of Softening Treatment.—The promoters of the Columbus plant were pioneers in the field of water-softening. As stated by Mr. Hoover, very little opportunity was available for those in charge of testing station experiments to study fully the several phases of municipal water softening prior to the construction of the works.

A discovery of very great significance was made after the plant had been put into service. It was found that the water leaving the settling basins after softening treatment and prior to filtration was sterile whenever proper amounts of chemicals required for softening were applied. On further inquiry into the nature of this circumstance it was established that bacterial life was entirely destroyed and prevented if the application of the chemicals resulted in a final product that carried caustic alkalinity. Such alkalinity exists only when free hydrate, termed by some as an excess of lime, is present. It is of interest to note that a similar discovery was made almost simultaneously by Sir Alexander Houston, of London, England, who first showed the possible significance of the excess lime method of treatment from the bacterial standpoint.

As a result of the discovery the Columbus plant has been operating steadily from a water-softening standpoint and not with very much regard for the variations in bacterial content of the raw water being treated. From the bacterial standpoint it remained only necessary to be assured that sufficient lime was added so that the treated water was made slightly caustic.

This experience in the removal of bacteria at Columbus was capitalized by the City of Youngstown in 1918. Mr. Hoover was employed to adjust the treatment process at the Youngstown Water Purification Works so that caustic alkalinity would be obtained in the treated water. The Mahoning River at Youngstown, utilized as the source of raw water supply, carries a tremendous burden of bacteria. For example, the yearly average for 1926, measured in terms of *B. coli* per 100 cu. cm., was 9 100; and the maximum monthly average, likewise expressed, was 23 000. Following the introduction of the excess-lime treatment the final effluent of the plant has been acceptable from a bacterial standpoint without the assistance of chlorination or any other disinfection process. For example, the filtered water average for 1926, in terms of *B. coli* per 100 cu. cm., was 0.2; and the maximum monthly average was 0.6. Other water purification works in Ohio have utilized the excess-lime method for bacterial purposes solely, namely, East Liverpool, Ironton, Portsmouth, all on the Ohio River and carrying even heavier bacterial loads than those given for Youngstown. A prime reason for adopting the excess-lime method for bacterial effects at these cities was the necessity of eliminating and preventing chloro-phenol tastes which occurred occasionally, usually together with the high bacterial loads. The excess-lime treatment made it possible to avoid using chlorine

during the intervals that phenol was being experienced in the raw waters at these Ohio River plants.

If raw waters carrying heavy bacterial burdens must be utilized as a source of raw water supply, designing engineers may well give serious thought to the use of the excess-lime treatment to accomplish bacterial reduction, even if no water-softening benefits are desired.

Value of Recently Demonstrated Over-Treatment with Lime from a Softening Standpoint.—One of the features of the Columbus water-softening plant is the over-treatment of a part of the raw-water supply; that is, the raw water is divided into approximately equal parts, one part receiving all the softening re-agents; after thorough mixing this over-treated part is mingled with the part of the raw water that had received no treatment, and the whole is given efficient mixing before entering the settling basins.

The reason for over-treating a part of the supply is commonly known to the chemist by the term, "mass reaction". What really happens is that the extra heavy application of lime in the 50% part of the raw water causes the magnesium to come out of solution as magnesium hydrate, a fluffy flocculent precipitate. The magnesium will not come out of the water in such proportion by the action of the lime when only a slight caustic alkalinity is created by the latter; it takes an excess, or over-treatment of the lime to bring about the precipitation of the magnesium. This precipitation is practically complete for that part of the raw water thus treated in the Columbus plant.

Of course, with the processes originally provided it was early understood that such an excess of lime for all the raw water could not be tolerated if the final water was to be palatable and not have a harsh effect on the users of the supply. Therefore, the part that was over-treated, was neutralized, so to speak, with the remainder of the water receiving no treatment.

The introduction of the carbon dioxide process into water-softening practice has now made it practicable to conduct the mass reaction treatment, or over-treatment with lime, on a 100% scale as applied to the raw water. This is possible because the over-treatment in the lime application is easily compensated by carbon dioxide application and with the resultant precipitation of the excess hydrate alkalinity as crystalline calcium carbonate. In this procedure of water softening, the carbon dioxide is not added in an excess, which would tend to re-dissolve some of the calcium carbonate precipitate, but falls just short of such an amount.

As a result of this system of extra heavy lime treatment, followed by re-carbonation, it is possible to precipitate all the magnesium and to throw down the calcium carbonate in crystalline form. The water then coming to the filters carries practically no material to incrust the sand or piping.

Utilization of this feature on a plant scale of operation has been effected regularly since June, 1927, at the Piqua, Ohio, water-softening works. Reports from James Montgomery, Superintendent of the Piqua plant (formerly of the Columbus and Newark Water Departments), have demonstrated the practicability of this process for bringing about further softening of a water supply, coupled with a more pleasing final product than was heretofore possible. Following closely on the success of the Piqua plant, the treatment has

been installed regularly at the Greenville, Ohio, plant, under the efficient management of Mr. John Q. McGuire (also formerly of the Columbus Water Department). The total hardness of the Miami River water before treatment at the Piqua plant since June, 1927, has averaged 215 parts per million. The total hardness of the treated water since June has averaged about 50 parts per million. Mr. Montgomery estimates that the treated water would have averaged about 80 parts per million if the works had been operated on the usual plan that was in effect before June. The raw water supply at Greenville is taken from wells having an average total hardness of about 450 parts per million, of which approximately one-fourth represents incrustant hardness. The treated water since July, 1927, has averaged about 90 parts per million, whereas before July the treated water had a total hardness of about 120 parts per million.

It is of interest to note that the new softening procedure, using extra heavy lime treatment, made possible by carbon dioxide application, costs no more at the Greenville and Piqua plants than the old lime-soda method; but with the advantage, however, that the treated water is much softer.

The large scale experiences of Piqua and Greenville have demonstrated the additional value of the carbon dioxide process. As the result of the early experiences at Defiance and Newark, followed by the more recent experiences at Piqua and Greenville, a complete carbon dioxide treatment process has now (1927) been installed at Columbus, and probably before very long the new schedule of softening will be adopted there just as it has been at Piqua and Greenville.

The policy of freely exchanging with others the experiences of both research and plant operation has paid Columbus well; and at the same time it has extended great benefit to other municipalities. Mr. Hoover deserves commendation for the liberal application of this policy.

GEORGE W. FULLER,* M. AM. SOC. C. E.—Without intending to discuss this paper from a technical standpoint, it seems appropriate to say a few words in regard to the development of the art of water softening. In the autumn of 1903, when the late Rudolph Hering, M. Am. Soc. C. E., and the speaker were called to Columbus to assist in formulating a program for water supply and sewage disposal, it was thought that the greater difficulty with those two undertakings would relate to sewage treatment; hence, a sewage testing station was operated on a sizable scale for several months. As Mr. Hoover has stated, the tests that led to the basic design of the water purification plant were made in a somewhat haphazard manner so far as anything outside the laboratory itself was concerned. The work was done in carboys and small tanks. At that time there were only three sizable plants in existence, municipally operated; namely, at, McKeesport, Pa., Winnipeg, Man., Canada, and South Hampton, England, although there were quite a number of industrial plants for water softening.

The main purpose of the water-works improvements was to correct a very highly polluted water. Mr. Hoover speaks of 138 deaths per 100 000

* Cons. Engr. (Fuller & McClintock), New York, N. Y.

population from typhoid fever. It should be made plain that that situation has been changed so that there are now less than 5 deaths per 100 000 population per year, which is, of course, very gratifying from the public health standpoint.

In regard to the water-softening installation itself, it was not the ambition of the designers to produce a completely softened water, but rather to make the Columbus water supply approach in hardness that of the Great Lakes. In fact, the policy was expressed of operating the plant so as to produce a water of hardness equal to that of Lake Michigan.

In those days at Columbus, with a very hard water from galleries, the community was led to use many thousands of cisterns. The people were accustomed to rain water. They used their pressure-water supply to a substantial extent for operating water motors, whereby soft cistern water was pumped into the house for laundry purposes.

When the plant went in service it was found that a hardness of 120 parts per million, or about 7 grains per gal., did not suit the citizens. They wanted a softer water. Particularly, on Mondays, there was a constant ringing of the telephones at the City Hall, the Water Department Office, and the plant, to have a much softer water. That led to the experiences which Mr. Hoover has related, and which as the data in his paper will show, resulted in a constantly decreasing hardness down to a point of about 85 parts per million.

With that softening came some burdens, due to the separation of calcium and magnesium carbonates in excess of their natural solubility in water, which is, as the speaker recalls, about 35 parts per million in the absence of carbonic acid. These slowly forming crystalline products accumulated in the pipes, on the sand grains of the filters, in the household plumbing, and actually stopped the meters.

Mr. Hoover has energetically attacked these problems, taking a plant that was intended to be flexible, but not as well prepared in its design as it could be made now. He is entitled to great credit for the persistence with which he has kept up his research work. Every hour during this period of twenty years there has been an analysis made of the water at different stages through this plant, and he has thereby gained experience that entitles his opinion to a great deal of consideration. The speaker is glad to note that this pioneer work has been the forerunner of developments of the art which have been so significant and which have been found to be so well worthy of application in many places in Ohio and elsewhere.

A plant such as Mr. Hoover operates is in a certain sense a manufacturing plant, creating a product which the people like in their private homes, but which is also more suitable for manufacturing and for steam-raising purposes. The speaker is aware that a municipal plant does not always find it desirable or practicable to produce water that best serves various industrial purposes. There are two things here to be considered: First, how far is a municipality justified in producing a better water supply than that which serves, reasonably, the citizens and the water users, at the lowest cost; and, second, to what

extent may those who need water for special purposes expect support and consideration from the producers of the municipal supply?

What is referred to particularly, of course, is water for boiler feed. Without doubt, industrial plants in need of a very soft water can get it by local treatment of a portion of the public supply. When it comes to the question of what is the best manner of operating a municipal water supply, consideration must be given to those things which Mr. Hoover has described; that is, elimination of all the deposits that are annoying to those who control the plant, annoying in the meters and the service piping and household plumbing. On the other hand, the practice of recarbonation is complained of as increasing the corrosion problem when used as the supply to railroad locomotives and for steam raisers in general.

The speaker will not attempt to offer any fixed conclusions as between those two lines of thought. They do exist, however, and he is sure that Mr. Hoover will consider them in the future, as he has in the past, and that there will continue to come from Columbus a vast fund of helpful information.

ROBERT SPURR WESTON,* M. AM. SOC. C. E.—There are not many who realized with what insufficient data the designers of the Columbus plant had to work. Softening processes are about 100 years old, but for the most part they have been applied to small works in England that were supplied largely from wells. The experiences at plants like those at Canterbury and South Hampton, England, therefore, were not altogether applicable to the Columbus problem. Furthermore, the waters were largely calcareous rather than dolomitic and, consequently, difficulties due to slimy deposits of magnesia, and poor crystallization of the precipitate, were not so vital as those at Columbus in the early days.

The plants in the United States designed for industrial softening expressed nothing that was novel in the way of treatment and nothing that was based upon modern physical chemistry. The Columbus designers supplemented the data with the meager available results of experiments made in bottles on a very small scale. Yet, in spite of all difficulties, John H. Gregory, M. Am. Soc. C. E., and his advisers succeeded in designing a plant so flexible that it is operating to-day (1927), with some changes to be sure, but such changes have not vitiated the efficiency of the original design in any way.

It is fortunate that Mr. Hoover has been able to conduct his research work as well as he has. Another fortuitous circumstance is a rapidly changing river, which made necessary the employment of a man of Mr. Hoover's character and caliber to supervise the operation of the plant. One could see on visiting the plant in its early days, when the chalky incrustations on the sand grains were a serious detriment to its operation, that the management was hard put to get good results. Failure was often threatening; yet success was attained.

The work of Mr. Hoover in connection with the recarbonation of water has been mentioned, and one can only add praise of his genius to the com-

* Cons. Engr. (Weston & Sampson), Boston, Mass.

mendations of others. Mr. Hoover is also to be commended for the introduction of what almost every one engaged in water-works practice calls "Hoover alum", which effected, not only an economy of the first order from the standpoint of the Columbus plant, but also a much lower price for sulfate of alumina for other plants.

The foresight of those in charge of the Columbus plant in providing for excellent management and in keeping records which are accurate and informing, is to be greatly praised, and all who have had to consult these records appreciate the care and the skill with which they have been collected.

The tendency of modern standards of quality is toward a softer water. A hardness of 60 to 80 parts per million, the goal of most lime-soda plants, is failing to give satisfaction to critical consumers. In many cases, this means going beyond the lime and soda processes and using zeolite softeners, which can remove all the hardening constituents. The Ohio Valley Water Company has recently installed a large plant of this type at McKees Rocks, Pa., by which the hardness is being lowered to a degree that is more pleasing to the consumer than 60 or 80 parts per million, which, in Massachusetts by the way, is considered an extremely hard water. In Brookline, Mass., the water is called hard at 40 parts per million. The average hardness of the water in Boston, Mass., is 12 to 18 parts per million. The standards will surely rise and the combination of the lime-soda and zeolite processes for hard waters will come into more general use, especially where non-carbonate hardness is high and where salt, for the regeneration of the zeolite, is cheap. Even Mr. Hoover may soon begin to compare the cost of salt for reducing the sulfate content of the hardness of the water at Columbus by the zeolite process with that of soda by the lime-soda process. Surely all engineers are greatly indebted to Mr. Hoover for his paper, and the work that has preceded it.

C. W. Foulk,* Esq.—As a matter of interest the speaker presents the following data to show the advantage of softened water to the average householder. The Columbus plant removes from 180 to 190 parts per million of hardness from the Scioto River water. This, if left in the water, would destroy about $6 worth of soap per year in the average household. (The household price of soap is taken at 10 cents per lb.) On the basis of 50 000 households in Columbus, $300 000 worth of soap would be wasted each year. This waste is eliminated by the softened water.

Considering the positive gains arising from the use of soft water, attention is called to the following items in the construction and operation of a house, which are needed in a hard-water city, but not in one with a soft-water supply:

Hundred-barrel cistern	$110
Electric water pump	120
Installing pump	20
Extra plumbing	50
Total	$300

* Prof. of Analytical Chemistry, Ohio State Univ., Columbus, Ohio.

This means that it costs $300 less to build a house in Columbus than to build the same house under the same conditions in a hard-water city. If interest and depreciation are calculated, it is seen that there is an annual saving of from $25 to $30, because of the soft-water supply.

One more observation is worth making. Mr. Hoover has calculated that 1 ton of this Columbus water costs the housekeeper 4 cents. What other valuable commodity can be had at that price per ton, delivered?

Paper No. 1717

UPWARD PRESSURES UNDER DAMS: EXPERIMENTS BY THE UNITED STATES BUREAU OF RECLAMATION*

By Julian Hinds,† M. Am. Soc. C. E.

With Discussion by Messrs. E. L. Chandler, B. F. Jakobsen, Charles Terzaghi, J. C. Stevens, F. W. Hanna, Ivan E. Houk, C. H. Howell, P. Wilhelm Werner, H. de B. Parsons, E. W. Lane, C. E. Grunsky, and Julian Hinds.

Synopsis

Uplift measurements have been made by the United States Bureau of Reclamation on three gravity diversion dams and one gravity storage dam. Two of the diversion dams, the Colorado River Dam, on the Grand Valley Project, in Colorado, and the Percha Dam, on the Rio Grande Project, in New Mexico, are founded on gravel. The other diversion dam, the Willwood Dam, on the Shoshone Project, in Wyoming, is founded on sandstone and shale, thoroughly grouted. The gravity storage dam, the recently completed American Falls Dam on the Minidoka Project of Idaho, is built on a columnar basalt foundation, also thoroughly grouted.

The measurements at the Colorado River and Percha Dams indicate that the materials deposited above a dam built on porous foundation act somewhat as a filter. When the filter surface is thoroughly seasoned, it offers considerable resistance to the passage of water, and the uplift pressure is partly relieved. When the filter surface is disturbed, as in time of flood, the uplift pressures are greater. The results are too indefinite to permit an attempt to prove, or disprove, any of the theories of flow under dams of this type.

Note.—The Special Committee on Irrigation Hydraulics selected the subject of "Water Movement and Pressure Under Dams" as one of ten for study and research. This paper was submitted to the Committee by the author and the Committee recommended its publication. (See Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1927, Society Affairs, p. 121.)

* Published in March, 1928, *Proceedings*.

† Care, Dept. of Water and Power, Los Angeles, Calif.

The worst uplift conditions occur with a freshly disturbed filter surface, and experimental data taken under any other circumstances should be used with care. A limited area of escape at any point below the filter surface as at the Colorado River Dam, causes an increase in pressure above the constriction, and a decrease below.

At the Willwood Dam there is, generally, no evidence of appreciable uplift for that portion of the dam founded on shale. For sandstone the uplift pressures vary with the up-stream and down-stream water levels, in a reasonably regular way, and the uplift appears to vary, roughly as a straight line, from full tail-water depth at the toe to full tail-water plus one-fourth the difference in tail-water and head-water elevations at the heel.

The results at American Falls are generally similar to those at Willwood. Although there are no shale areas at this site there are a few apparently water-tight holes. The uplift pressure intensities are on the average slightly higher, relatively, than at Willwood.

Colorado River Dam

The type of design and general conditions at the Colorado River Dam are shown in Fig. 1, while the general appearance of the structure is shown in the photograph, Fig. 5. The design contemplated an open gravel foundation throughout, although it was known that rock could be reached at the ends of the structure. When the cut-off trench was opened, the gravel in a large portion of the river bed was found to be fairly tightly cemented, but not of sufficient hardness to justify changing to a standard type of gravity dam. The dam was finally founded on the upper strata of loose gravel, the up-stream cut-off being carried to tighter material except for a short distance in the vicinity of Pier *B*, where the open gravel extended to an undetermined depth, and across the sluice-way, where the percolation distance is such that a deep cut-off was not considered essential. The gravel in the river bed is mostly rather coarse with only a small percentage of sand.

The ogee crest of the dam is divided into six parts, each controlled by a 70 ft. by 10 ft. 3-in. roller crest. An additional 60 ft. by 15 ft. 3-in. roller controls a sluice-way at the west end of the dam. The total height from the top of the down-stream apron to the top of the rollers in the closed position is 18.25 ft., which is the maximum possible unbalanced head. The dam was completed in 1915.

Pier *B* is over the deep gravel portion of the foundation and is provided with two pipes for determining uplift pressures. These pipes are situated as shown in the pier detail, Fig. 1. Details of the pipe and its setting are shown in Fig. 2. One pipe was also installed in Pier *G*, its position being intermediate between the upper and lower pipe locations shown for Pier *B*.

A large number of readings have been recorded from these pipe wells, daily observations having been made throughout several irrigation seasons. Some of the results are given in Table 1. The data shown cover the full range of variations in head, and are typical.

Fig. 3 shows graphically the daily fluctuations in water levels from April 1 to October 30, 1922. A study of the relations shown on this diagram is interesting. The up-stream water level, E_1, is controlled by the roller gates, and is more or less independent of other factors. The tail-water level, E_4, depends on the flow passing over the dam. The fluctuations in the water level in the lower well, E_3, closely follow the changes in the depth of tail-water. The depth in the upper well, E_2, changes promptly with a change in the up-stream water level, and appears to respond more slowly to general changes in the height of tail-water.

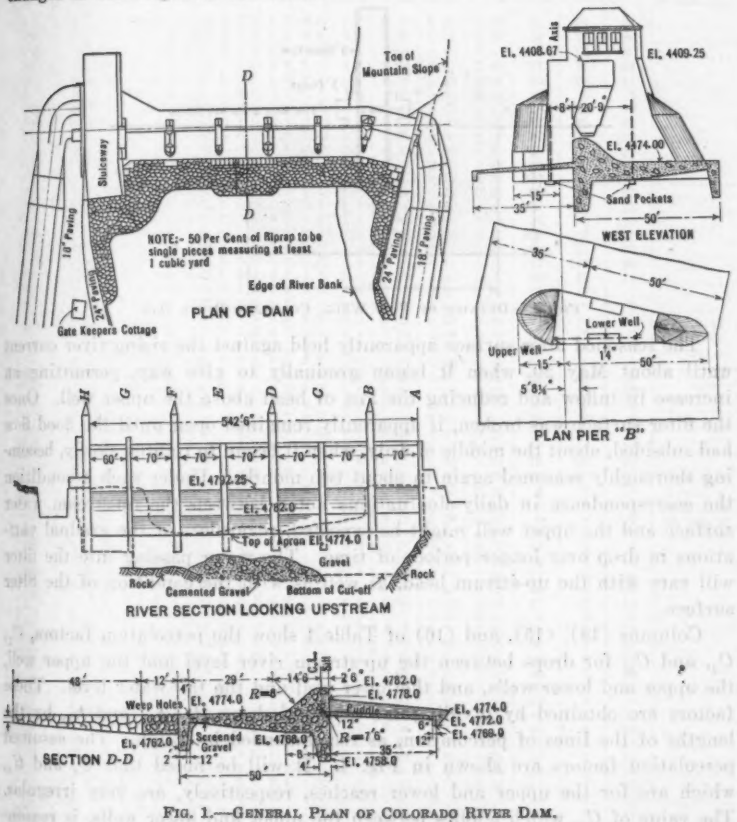

FIG. 1.—GENERAL PLAN OF COLORADO RIVER DAM.

It will be noted that on April 20 a gradual rise in tail-water depth began. The depth in the lower well immediately increased and followed the fluctuations in tail-water levels in detail. The upper well continued to respond in detail to changes in the up-stream level, but did not reflect the change in tail-water level until about thirty days later, when a general rise began. A similar delay occurred when the tail-water started to lower about June 15.

Although the general relation of the two upper curves in Fig. 3 vary widely, the daily fluctuations correspond in a remarkable way.

No entirely adequate explanation of the apparently delayed action of the upper well has been offered. It is probable that this effect is produced by changes in the mechanical or bacterial condition of the up-stream silt blanket, rather than by any hydraulic consideration. Prior to April 20 the discharge had been moderate and steady for a time and the silt bed above the dam, acting as a filter for the percolating water, had probably become well seasoned, causing an appreciable loss of head at the point of entrance.

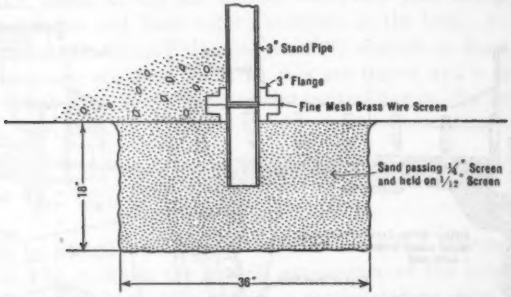

FIG. 2.—DETAILS OF PIPE WELL, COLORADO RIVER DAM.

The seasoned filter surface apparently held against the rising river current until about May 20, when it began gradually to give way, permitting an increase in inflow and reducing the loss of head above the upper well. Once the filter surface was broken, it apparently remained open until the flood flow had subsided, about the middle of July, when it began to tighten slowly, becoming thoroughly seasoned again in about two months. Under such a condition the correspondence in daily fluctuations noted between the up-stream water surface and the upper well might be expected, regardless of the gradual variations in drop over longer periods of time. The water passing into the filter will vary with the up-stream head, as well as with the condition of the filter surface.

Columns (14), (15), and (16) of Table 1 show the percolation factors, C_1, C_2, and C_3, for drops between the up-stream river level and the upper well, the upper and lower wells, and the lower well and the tail-water level. These factors are obtained by dividing the observed drops, h_1, h_2, and h_3, by the lengths of the lines of percolation, as recommended by Bligh. The assumed percolation factors are shown in Fig. 4. It will be noted that C_1 and C_3, which are for the upper and lower reaches, respectively, are very irregular. The value of C_2, which applies between the upper and lower wells, is reasonably consistent, except for measurements made before the rollers were put into service, and when the drop from head-water to tail-water was low. Because the total drop from head-water to tail-water varies, with the percolation distances constant, it is not logical that the percolation factors remain constant, but they might ordinarily be expected to remain proportional to each other, which they fail to do.

The variations in these factors can be accounted for in a general way by considering the physical conditions in connection with Fig. 3. Water can flow under the up-stream apron of the dam across the full width of the river channel, but can escape in appreciable quantity only through the narrow gap of open gravel under Pier *B*. Likewise, after passing the restricted open gravel area under the cut-off, the flow is free to spread laterally, thus reducing

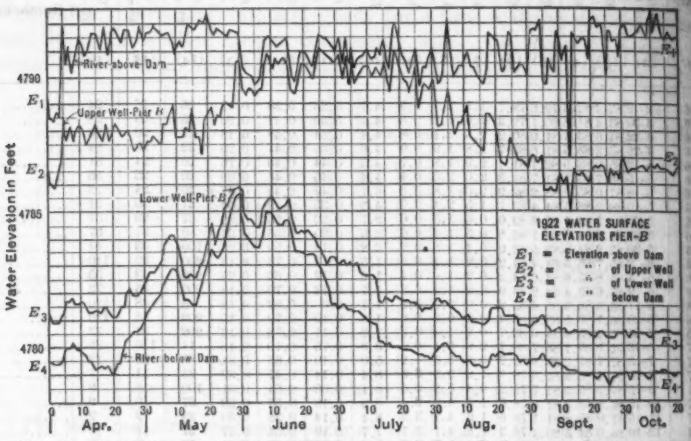

FIG. 3.—OBSERVATIONS OF WATER ELEVATIONS, AT PIER *B*, APRIL TO OCTOBER, 1922, COLORADO RIVER DAM.

the resistance to outflow. It seems logical, therefore, that the greatest loss should occur at the point of passing the cut-off wall. At times like June and July, 1922 (see Fig. 3), the great area open to easy infiltration causes the entrance loss to be small in comparison with the loss under the cut-off. In September and October the filter bed had tightened until, notwithstanding its

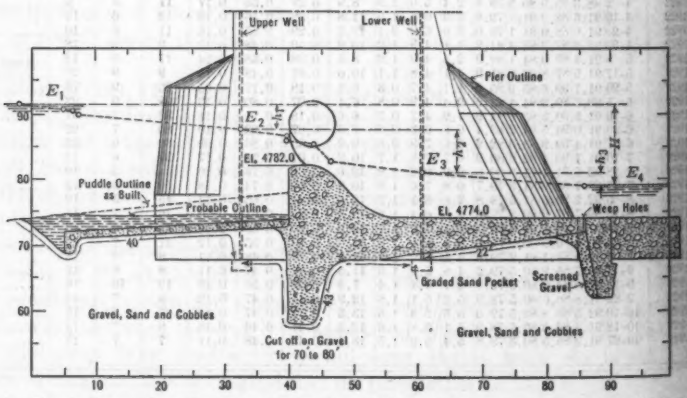

FIG. 4.—CROSS-SECTION OF COLORADO RIVER DAM, SHOWING HYDRAULIC GRADIENT COMPUTED FROM AVERAGE DATA FOR VALUES OF *H* EQUAL TO 12 FEET OR MORE.

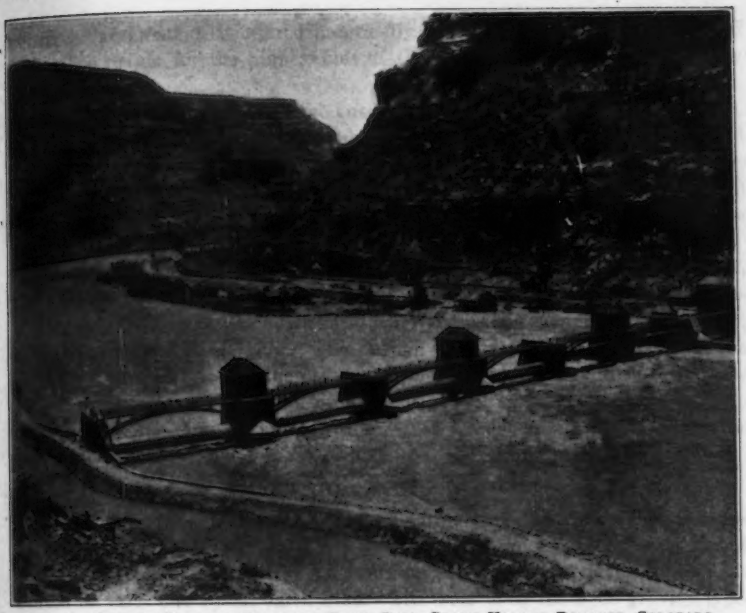

FIG. 5.—GENERAL VIEW OF COLORADO RIVER DAM, GRAND VALLEY PROJECT, COLORADO.

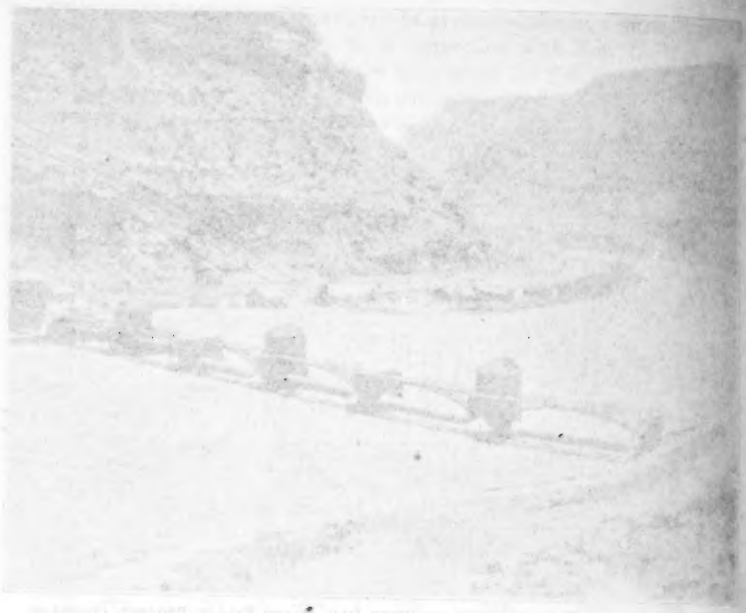
FIG. 6.—GENERAL VIEW OF PERCHA DIVERSION DAM, RIO GRANDE PROJECT, NEW MEXICO.



relatively large extent, it offered practically as much resistance as the cut-off wall. The reason for the high values of C_3 in May and June is not equally apparent.

If open gravel existed below the cut-off wall for the full length of the dam, the drop to the upper well would undoubtedly be materially increased, and that between the two wells would be decreased. Because of the irregular conditions existing at the Colorado River Dam, the data in Table 1 and Fig. 3 neither prove nor disprove Bligh's theory of a uniform pressure drop along the line of creep.

The one pressure well at Pier *G*, is just down stream from the cut-off wall. Observations indicate drops corresponding roughly with the drop to the down-stream well at Pier *B*. Conditions at Pier *G* are too complicated to permit an analysis of the data there. The cut-off wall is founded on rock on one side of the pier, and not on the other, and the long sluice structure introduces further uncertainty in the path of percolation.

A view of the site of the Colorado River Dam, looking down stream, is shown in Fig. 5.

Percha Dam

The Percha Dam is more strictly a floating type, no rock or impervious material being in the vicinity. Its general appearance is shown in Fig. 6 and its dimensions in Fig. 7. An overflow section, in the river channel, is flanked on each end by an earth dike. The weir is of the ogee gravity type, with free overflow crest. Heavy paving and rip-rap below the dam prevent scour and piping. Upward pressure is relieved a short distance below the toe of the gravity section by weep-holes through the rubble concrete apron. Percolation is retarded, and uplift reduced by an up-stream concrete apron, two concrete cut-off walls, and a line of steel sheet-piling under the up-stream cut-off. Construction was completed in 1917. No back-filling above the up-stream apron, to reduce leakage, was done when the dam was constructed, but the river bed promptly silted up, practically to the top of the weir.

* Possible leak in Well No. 5.

The material in the river bed grades from river sand with a small percentage of gravel at the surface to heavy boulders with some gravel and sand

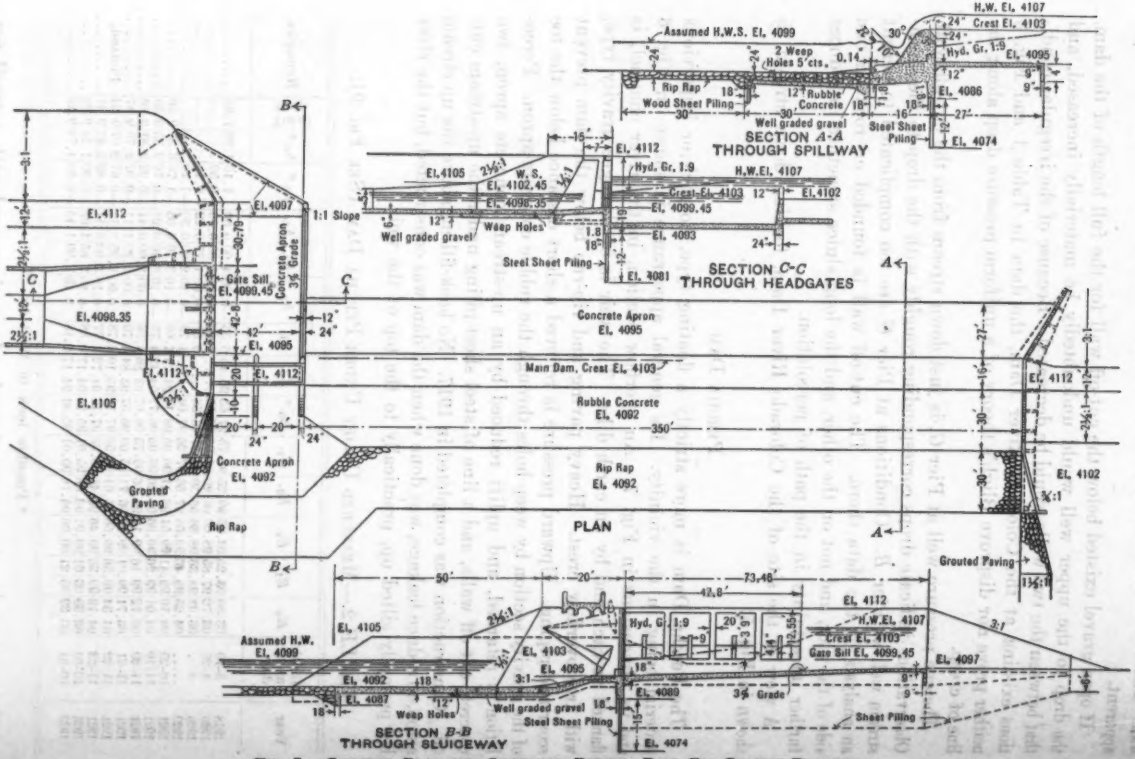

FIG. 7.—GENERAL PLAN AND SECTIONS, PERCHA DAM, RIO GRANDE PROJECT.

at the bottom of the steel sheet-piles. The material is graded and silted until it is reasonably resistant to percolation.

At the time of construction a system of pipes was installed for the measurement of uplift, as illustrated in Figs. 8 and 9. Uplift pressures have since been observed, as recorded in Table 2. The various notations, E_1, E_2, etc., and h_1, h_2, etc., have the same meanings (see Fig. 9) as in the case of Table 1. Inspection of Table 2 shows that except the first and the last two sets of data approximately one-half the total drop occurs between the up-stream water level and Well No. 1, which is just inside the up-stream apron cut-off. A large part of the remainder appears in h_3, which is the drop produced by the sheet-piling cut-off. Losses along the flat surfaces, between Wells Nos. 1 and 2, and Nos. 2 and 4, are small.

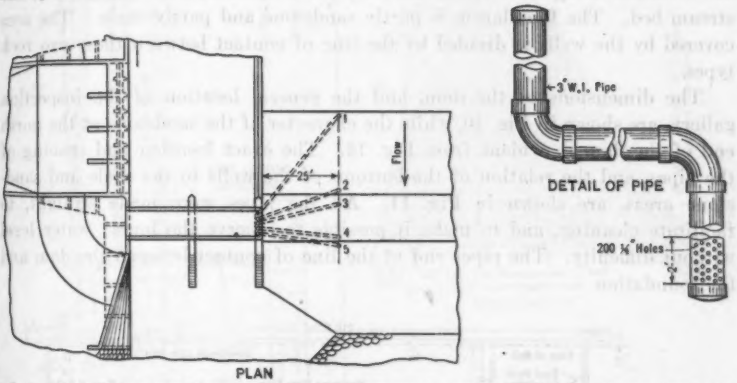

FIG. 8.—PIPE WELLS FOR MEASURING UPWARD PRESSURE, PERCHA DAM, RIO GRANDE PROJECT.

The first set of readings, and the last two, Table 2, show practically no loss at entrance. The first readings were taken soon after the dam was placed, and perhaps before the channel had completely silted and seasoned sufficiently to resist the entrance of water under the apron materially. The second set of readings was taken after the summer flood period, and it is probable that

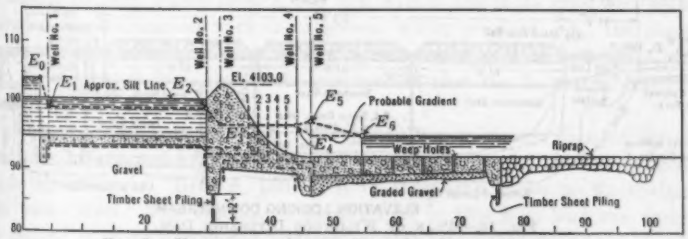

FIG. 9.—UNDERFLOW, PERCHA DAM, RIO GRANDE PROJECT.

the up-stream silt bed had been disturbed or partly removed. The entrance drop, h_1, was accordingly small at these times, the other drops being thereby materially increased. The first reading shows the loss to occur almost entirely at the two cut-off walls, the drop along the horizontal surfaces being small.

FIG. 7.—GENERAL PLAN AND SECTIONS, PERCHA DAM, RIO GRANDE PROJECT.
SECTION B-B THROUGH SLUICEWAY
El. 4074

The last two sets of data correspond reasonably well to Bligh's theory of a uniform drop along the line of creep, considering the steel sheet-piling to be water-tight.

The data presented are too limited to form the basis of any definite conclusion, but support, in a general way, the tentative conclusions drawn from the data for the Colorado River Dam.

Willwood Dam

The Willwood Dam (Figs. 10 and 12) is a low ogee gravity dam founded on rock. At the time of construction twelve pipes were placed in the concrete (Fig. 11) for determining the upward pressure under the dam. These pipes are arranged along three lines, relatively close together, near the center of the stream bed. The foundation is partly sandstone and partly shale. The area covered by the wells is divided by the line of contact between these two rock types.

The dimensions of the dam, and the general location of the inspection gallery, are shown in Fig. 10, while the character of the sandstone at the north end of the dam is evident from Fig. 13. The exact location and spacing of the pipes, and the relation of the bottoms of the wells to the shale and sandstone areas, are shown in Fig. 11. All the pipes were made straight, to facilitate cleaning, and to make it possible to observe the lowest water level without difficulty. The pipes end at the line of contact between the dam and the foundation.

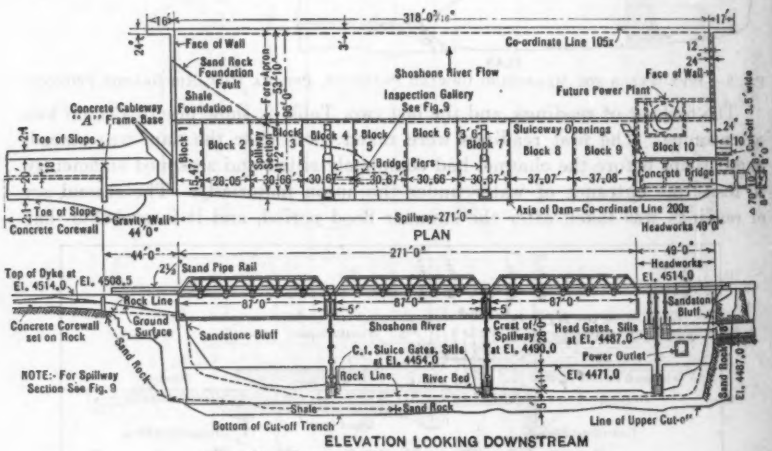

Fig. 10.—Plan of Willwood Diversion Dam.

The sandstone is somewhat broken and porous. The shale is reasonably good, and when protected from the air is amply strong for the expected bearing pressures. The foundation was thoroughly grouted along the up-stream cut-off. The results obtained to 1926 are shown in Table 3 and on Fig. 14. From

a study of Fig. 14, it appears that in the sandstone areas the uplift pressures vary in a regular way with the heights of the head- and tail-waters. Pressures in the shale areas are erratic.

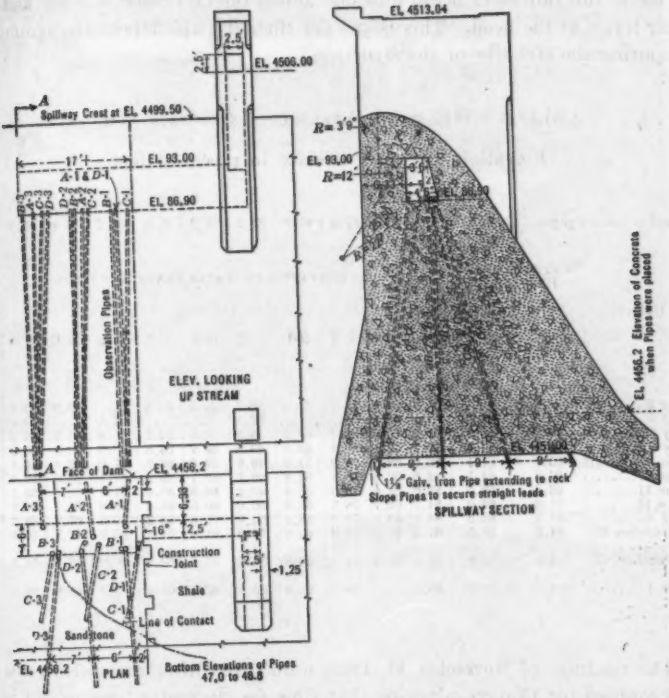

FIG. 11.—PLAN SHOWING LOCATION OF PRESSURE PIPES, WILLWOOD DIVERSION DAM.

Holes *B*, Line 1 and Line 2, are well within the shale area, and seem to have no communication with the reservoir water pressure. All the observed levels in these holes are below both the head-water and the tail-water, which can be accounted for only on the assumption that the holes are entirely or almost entirely water-tight.

Hole *A*, Line 1, is in shale, but is near the up-stream face of the dam, and may be reached by a crevice, which accounts for the evident connection with the reservoir. Hole *A*, Line 2, is in shale, and shows no fluctuation in the water level. The absence of fluctuations in this hole lead the observers to believe it to be obstructed. However, this was not definitely determined, and tightness may be due entirely to the shale bottom.

Hole *C*, Line 1, is in shale, but near the line of contact between the shale and sandstone. It appears to communicate with the pressures in the sandstone. Hole *C*, Line 3, is reported to be plugged, and no measurements for it are recorded.

Line 3 is entirely in sandstone, and shows a reasonably definite variation in uplift pressure as the head- and tail-water levels vary. The uplift pressure appears to vary, approximately as a straight line, from full tail-water depth at the toe to full tail-water depth plus one-fourth the difference in head- and tail-water levels at the head. This is smaller than the uplift pressure assumed in computing the stability of the structure.

The readings of November 11, 1925, were taken after the sluice-gates had been lowered for 15 days, allowing that time for the water level to fall in the wells. It should be noted that the water level in Holes *A* is high in all three lines. After these observations were taken, the water was artificially removed from all wells. Readings were again taken on July 1, 1926, after the gates had been closed since February 12. The readings were taken at high water, with the dam overtopped. The head-water had not, at any time since the unwatering of the wells, been more than 2 ft. higher than at the time of the observation.

The maximum uplift pressures observed at the Willwood Dam up to the present observations are plotted in Fig. 15. Uplift curves at Lines 1, 2, and 3 have been arbitrarily extended as straight lines from the values observed at the *A*-pipes to the maximum observed reservoir head at the up-stream edge of the dam; also, as straight lines from the values observed at the *D*-pipes to the maximum observed tail-water head at the down-stream edge. The latter is probably an accurate assumption. The former may indicate uplift pressures greater than those actually existing due to the thorough grouting of the foundation.

FIG. 12.—GENERAL VIEW OF WILLWOOD DAM, SHOSHONE PROJECT, WYOMING.

FIG. 13.—VIEW SHOWING CHARACTER OF SANDSTONE AT NORTH ABUTMENT, WILLWOOD DAM, SHOSHONE PROJECT, WYOMING.

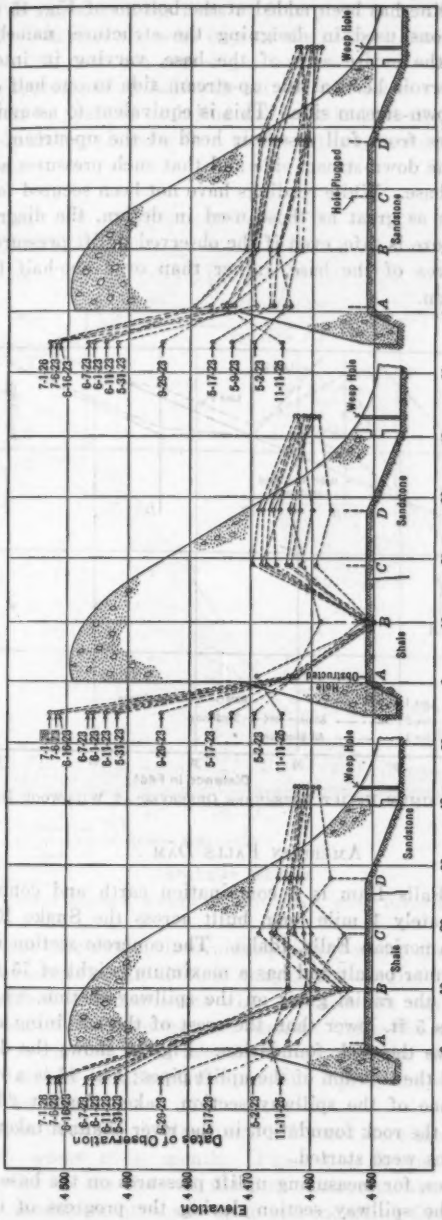

FIG. 14.—UPLIFT PRESSURES OBSERVED AT WILLWOOD DIVERSION DAM.

A full diagonal line has been added at the bottom of Fig. 15 to illustrate the uplift assumptions used in designing the structure, namely, that the pressures act over the entire area of the base, varying in intensity from one-half of full reservoir head at the up-stream side to one-half of full tail-water head at the down-stream side. This is equivalent to assuming that the uplift pressure varies from full reservoir head at the up-stream side to full tail-water head at the down-stream side and that such pressures act over one-half the area of the base. While readings have not been secured for head- and tail-water elevations as great as those used in design, the diagrams clearly show that the structure is safe, even if the observed uplift pressure intensities act over the full area of the base, rather than over one-half the area, as assumed in the design.

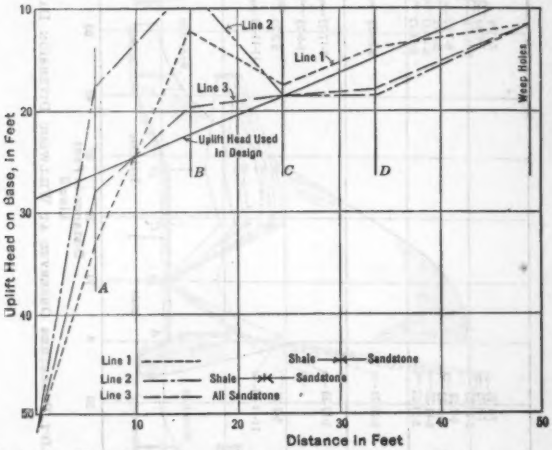

FIG. 15.—MAXIMUM UPLIFT PRESSURES OBSERVED AT WILLWOOD DAM.

AMERICAN FALLS DAM

The American Falls Dam is a combination earth and concrete gravity structure, approximately 1 mile long, built across the Snake River Valley, near the Town of American Falls, Idaho. The concrete section is built on a foundation of columnar basalt and has a maximum height of 75 ft. above the rock. The crest of the radial gates on the spillway section, which occupies the river channel, is 5 ft. lower than the crest of the adjoining concrete sections, or 70 ft. above the rock foundation. Fig. 16 shows the design of the spillway section and the location of the uplift pipes; Fig. 17 is a view showing the down-stream face of the spillway section, taken August 26, 1927; and Fig. 18 is a view of the rock foundation in the river channel taken just before concreting operations were started.

Twelve 3-in. pipes, for measuring uplift pressures on the base of the dam, were installed in the spillway section during the progress of construction.

These were arranged in three lines of four pipes each. One line was located at Station 9 + 00 near the west edge of the river channel; one was placed at Station 13 + 00, near the east edge; and the third was located at Station 11 + 10, or approximately half-way between the other two. Individual pipes were spaced 12 ft. apart in each line and were located as shown in Fig. 16, the up-stream pipe being placed 6 ft. 6 in. from the up-stream face of the dam in each instance.

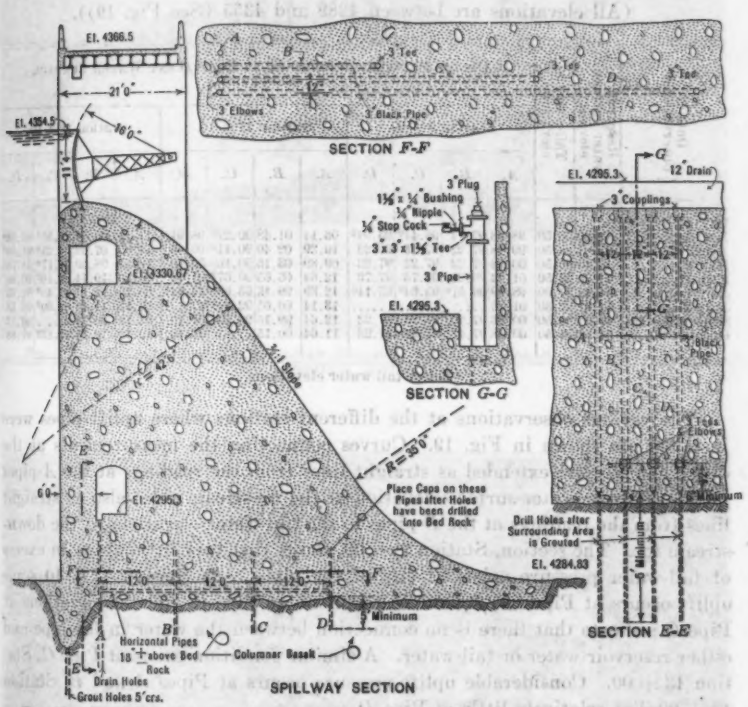

FIG. 16.—SPILLWAY SECTION, AMERICAN FALLS DAM, WITH PIPES FOR UPLIFT PRESSURE.

All the pipes were run to the drainage gallery where observations were made by reading pressures on an altitude gauge, or by sounding in the pipes. The pipes were placed in the concrete when the first lift was poured, leaving the lower ends about 6 in. above the rock surface. After the up-stream part of the foundation was grouted, holes were drilled through the vertical pipes approximately 5 ft. into the rock formation and the tops of the vertical pipes capped, as indicated on Fig. 16.

Observations were begun March 25, 1927, and were then taken at intervals of from two weeks to a month. Pipes not flowing were pumped out three days prior to the date of the first measurements. Table 4 gives the results of all measurements made up to and including October 20, 1927, uplift

pressures at the base of the dam being expressed as equivalent water-surface elevations. In Table 4 elevations below the tail-water level show that the water surfaces in the pipes were not being affected by either reservoir or tail-water pressures; or, in other words, that the foundation at these locations was tight on the dates such elevations were measured.

TABLE 4.—MEASURED UPLIFT ON BASE OF AMERICAN FALLS DAM.

(All elevations are between 4289 and 4355 (See Fig. 19)).

* Below tail-water elevations.

The various observations at the different stations where uplift pipes were installed are shown in Fig. 19. Curves connecting the measurements at the different pipes are extended as straight lines from the readings at the *A*-pipes to the reservoir water-surface elevation at the up-stream side; also as straight lines from the readings at the *D*-pipes to the tail-water elevations at the down-stream toe. The section, Station 9 + 00, shows that very little uplift in excess of tail-water pressure exists at any of the pipes. At Station 11 + 10 some uplift occurs at Pipes *A*, *B*, and *D*, but none at Pipe *C*. The observations at Pipe *C* indicate that there is no connection between the water in the pipe and either reservoir water or tail-water. A similar condition exists at Pipe *C*, Station 13 + 00. Considerable uplift pressure occurs at Pipes *A* and *B*, Station 13 + 00, but relatively little at Pipe *D*.

In Fig. 20 is shown a summary of maximum uplift observations at the American Falls Dam. In designing this dam, it was assumed that uplift pressures would act over one-third the area of the base and that the variation in pressure would be as a straight line running from full reservoir head at the up-stream side of the dam to full tail-water head at the down-stream side. Line 1, Fig. 20, shows the assumption of uplift-pressure variation, while Line 2 shows the equivalent line which would give similar uplift forces if applied to the entire area of the base. Line 3 shows the design assumptions used at the Willwood Dam, namely, that the pressure represented by Line 1 is applied over one-half the area of the base. Line 4 shows the uplift assumptions being used in the design of a high arch dam for an irrigation project in the Northwest, the pressures shown by this line being applied over the full area of the base.

FIG. 17.—GENERAL VIEW OF SPILLWAY SECTION, AMERICAN FALLS DAM, MINIDOKA PROJECT, IDAHO.

FIG. 18.—VIEW OF ROCKY FOUNDATION OF SPILLWAY SECTION, AMERICAN FALLS DAM.

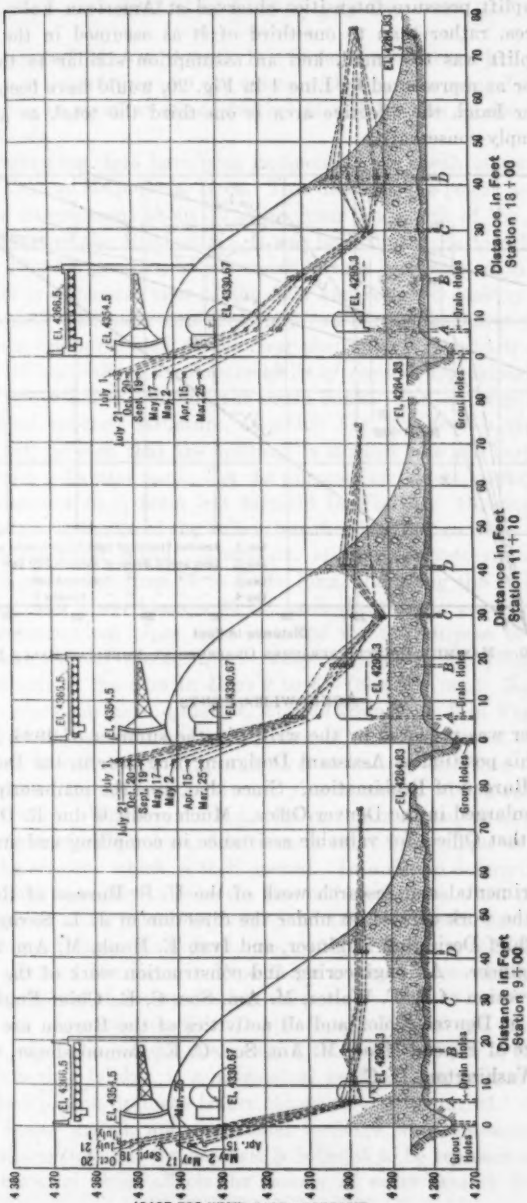

FIG. 19.—UPLIFT PRESSURES OBSERVED AT AMERICAN FALLS DAM.

If the uplift pressure intensities observed at American Falls apply to all the base area, rather than to one-third of it as assumed in the design, the assumed uplift was too small, and an assumption similar to that made at Willwood, or as represented by Line 4 in Fig. 20, would have been better. If, on the other hand, the effective area is one-third the total, as assumed, the design is amply conservative.

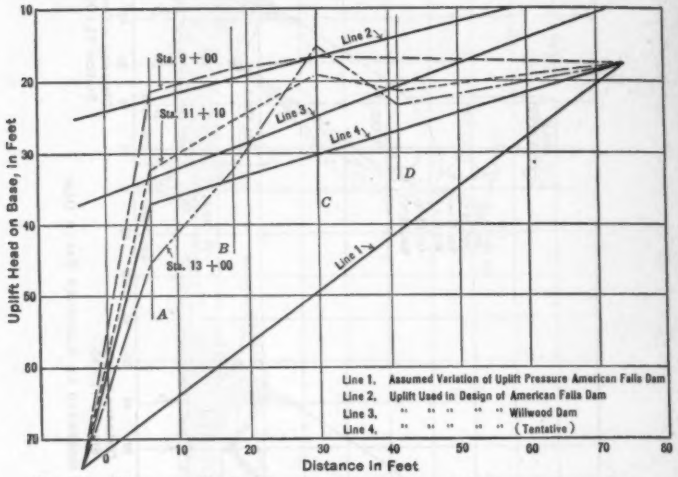

FIG. 20.—MAXIMUM UPLIFT PRESSURES OBSERVED AT AMERICAN FALLS DAM.

ACKNOWLEDGMENTS

This paper was prepared by the writer in the summer of 1926, just before he resigned his position as Assistant Designing Engineer in the Denver Office of the U. S. Bureau of Reclamation. Since that time the manuscript has been revised and enlarged in the Denver Office. Much credit is due R. D. Hubbard, Engineer of that Office, for valuable assistance in compiling and studying the data.

The experimental and research work of the U. S. Bureau of Reclamation is a part of the work carried on under the direction of J. L. Savage, M. Am. Soc. C. E., Chief Designing Engineer, and Ivan E. Houk, M. Am. Soc. C. E., Research Engineer. All engineering and construction work of the Bureau is under the direction of R. F. Walter, M. Am. Soc. C. E., Chief Engineer, with headquarters at Denver, Colo., and all activities of the Bureau are under the general charge of Elwood Mead, M. Am. Soc. C. E., Commissioner, with headquarters at Washington, D. C.

DISCUSSION

E. L. CHANDLER,* M. AM. SOC. C. E. (by letter).—The subject covered by this paper is very interesting and the writer wishes to offer some data from his own observations in an effort to add further material to the excellent contribution of Mr. Hinds.

Some enlightening data have been gathered as the result of work done on the Pinhook Dam at Maquoketa, Iowa. This dam and the power house form a hydro-electric development about 30 miles from the mouth of the Maquoketa River, a tributary of the Mississippi. It was built by the Eastern Iowa Power Company in 1923-24, ponding of the water having been started in December, 1923. Fig. 21 is a general view of the dam and reservoir looking up stream toward the west. The structure consists of an earth dike about 20 ft. high, extending from the north bank of the river about 400 ft. northerly to the hills on that side of the valley; a concrete spillway section approximately 160 ft. long; and a power house abutting the south bank. The spillway is a hollow deck, reinforced concrete structure, of which Fig. 22 shows a typical cross-section. It will be seen that the spillway is divided into six bays, each bay being fitted with a Taintor gate. For the purposes of this description, the bays will be numbered 1 to 6, from left to right in Fig. 21. Outcropping limestone is found on each side of the valley, but the river bed consists of sand and gravel to an unknown depth. Therefore, all the concrete structures were founded on timber piles from 20 to 30 ft. long, and along the up-stream line of the spillway and power house a 30-ft., steel, sheet-piling cut-off was driven.

During construction, pipes were installed for the purpose of measuring upward pressures under the spillway. They were placed in systems at right angles to the axis of the dam in Bays 2 to 6. (See Fig. 21.) Each set consisted of five pipes, 1½ in. in diameter, lettered from *A* to *E* in Fig. 23. Each pipe terminates at its lower end in a pocket of sand and gravel so graded as to permit easy flow of water. Pipes *A* to *D* extend upward into the chamber under the deck of the spillway, and each pipe is capped with a reducer and a ¼-in. brass air-cock. Whenever it is desired to obtain a reading at any station, a suitable length of rubber hose, fitted over a short ¼-in. nipple at one end, is coupled to the air-cock which is then opened. In order to determine the head acting, it is only necessary to raise the free end of the hose until the elevation is found at which water ceases to escape, and then, by measuring up from the known elevation of the concrete floor, it is a simple matter to reduce the results to a known datum. Readings in Pipe *E* are made by direct measurement in the pipe from the top of the tumble-bay weir.

The amount of percolation through any deposit of sand and gravel depends considerably, of course, on the character of the finer portions of the material. The tabulation that follows, is a mechanical analysis of a sample taken from the site of the Pinhook Spillway before construction was started. Considerable intermixed larger gravel, and occasional boulders were encountered in the course of construction, but the analysis is believed to be representative of that part of the material which affects the passage of water beneath the structure.

Readings were taken in the pipes at intervals during the filling of the reservoir and after the full head had been raised, the last one having been made in April, 1926. (See Fig. 23(*c*).) Results obtained only in Bays 3, 4, and 5 are considered herein, although other observations were made. Table 5 shows the results obtained. For the sake of comparison, the tabulation is made in a manner similar to that used by the author in Table 1. The nomenclature is somewhat different, but will be apparent from a study of Fig. 23. In studying Table 5, the first four groups of readings should be considered together. They represent conditions with wide variations of head, before the silt had accumulated over the bottom of the reservoir. The derived values for these groups, shown in Columns (10) to (19), inclusive, seem very consistent except for the values of the percolation factor, C_2. Variations for that factor are not surprising. Pressure readings were determined to the nearest 0.1 ft. only, and very slight errors in the values of h_2 would result in large variations in the corresponding values of C_2.

The fifth group represents conditions under which evidently there was a sealing of the bottom of the reservoir. The results show little relation between actual conditions and theory. In Bays 2 and 3 (Fig. 21), the pressures in Pipe *A* are actually less than the corresponding pressures in Pipes *B* and *C*. Quantities for Columns (15), (16), and (18), of Table 5, are not shown for this group as it is not considered that they would have any value under the circumstances.

For the purpose of making comparison between the pressures found and the theoretical values that would obtain if the "line-of-creep" theory were true, the curves of Fig. 23 are shown. These are based on readings given in Table 5 for Bay 4. It will be seen from this table that the results for this bay are typical. Computations for the theoretical piezometric line are based on the assumption of free communication between tail-water and the under side of the block apron, through the joint at the down-stream line of the tumble-bay weir. Fig. 23(*a*) and Fig. 23(*b*) represent conditions before any appreciable silting of the lake bottom had occurred, and would seem to offer excellent evidence in support of the "line-of-creep" theory under considerable variation of head. Fig. 23(*c*) is based on conditions existing more than two years after the completion of the dam. A mud blanket approximately 2 ft. deep had been deposited up stream. The very noticeable drop in the pressures for Pipes *A*, *B*, *C*, and *D*, as com-

FIG. 21.—VIEW OF PINHOOK DAM AND POWER HOUSE.

pared with previous readings for the same pipes, is perfect evidence of the value of an up-stream apron in reducing the upward pressure under such a structure.

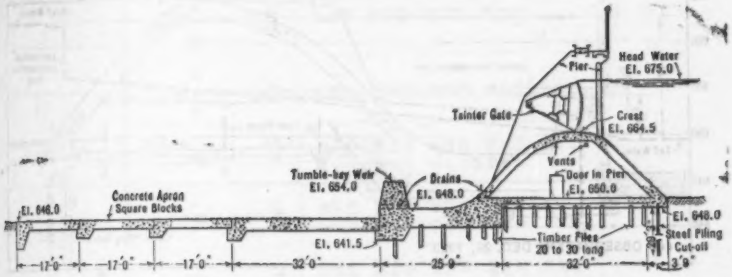

FIG. 22.—CROSS-SECTION OF PINHOOK DAM SPILLWAY, BAYS 2 TO 6.

It is found in each case that the inclination with the horizontal of the actual piezometric line is less than that of the theoretical line as computed, and that in Figs. 23(*a*) and (*b*), the two lines cross between the test pipes, *B* and *C*. A possible explanation for the fact that the pressures in Pipes *C*, *D*, and *E* are greater than those computed theoretically, might be that it is erroneous to assume that the theoretical line meets the tail-water elevation at the down-stream face of the tumble-bay weir. If it should be assumed that the concrete block apron confines the flow sufficiently to cause upward pressure under it, then it would be necessary to assume some point farther down stream at which the pressure would become zero. Such an assumption would lessen the amount of drop at the steel piling cut-off and would flatten the remaining part of the line, tending to make it approach the slope of the actual line.

A second assumption would be that, although the results afford a good substantiation of the theory, it is not strictly true that all the flow follows down the up-stream side of the steel piling and up the other side. It is probable that some of the flow diffuses through the pervious sub-strata, following a course leading diagonally upward from the bottom of the piling, and reaching the under side of the concrete farther down-stream. This would help to account for the comparatively lower pressures in Pipes *A* and *B*. Such would probably be the case in any pervious material of uniform structure, and would certainly be true if the piling extends through or into a stratum more open in nature than the overlying material.

An unfortunate feature of the Pinhook installation is the fact that no readings can be taken during a period of high tail-water because the water level under the spillway deck communicates freely with the tail-water through drain holes and when the tail-water rises it becomes impossible to reach the test pipes.

The author attributes the rather irregular nature of the results obtained from readings on the Colorado River Dam to the fact that while water enters beneath the dam through a considerable area up stream, it "can escape in appreciable quantity only through the narrow gap of open gravel under Pier

B", and that "after passing the restricted open gravel area under the cut-off, the flow is free to spread laterally, thus reducing the resistance to outflow". This is very probably the case. A fairly analogous condition was created artificially in a series of tests conducted by E. W. Lane, M. Am. Soc. C. E., and the writer, on the Island Park Dam at Dayton, Ohio.*

Island Park Dam is part of the park system of the City of Dayton. It is a gravity type, concrete, overflow structure, across the Miami River, developing a head of 7 ft. at low-water flow. Conditions are very similar to those shown in Fig. 9, except that the timber sheet-piling is at the up-stream line of the fore apron, and that one of the test pipes extends into the bed of the pond up stream. Tests were made after a mud blanket had sealed the bottom of the pond, and in every instance the readings were far below the theoretical pressures based on the "line-of-creep" theory. An attempt was then made to approximate conditions which existed before the silt deposit had formed. This was done by removing the mud from a small area in the vicinity of the up-stream pipe. As a result, the pressure in the up-stream pipe increased to nearly the full theoretical head, although there was slight change in any of the others. This was, no doubt, due to the diffusion of flow after passing through the comparatively small opening near the pipe intake.

The foregoing experiments indicate that, for the design of structures on sand and gravel foundations, it is not wise to assume pressures less than those that apply under the "line-of-creep" theory, although that theory probably errs somewhat on the side of safety. With the depositing of silt over the bottom of a reservoir, the factor of safety increases very materially. As the author indicates, in the case of a low structure, this margin of safety may be diminished in a time of high water if velocities are developed high enough to disturb the bottom up stream from the dam. In a case where no appreciable disturbance of the bottom will occur, it might be reasonable to assume less than the total amount of upward pressure, if the pond can be filled by easy stages and the bottom can be allowed time for partial sealing before the full head accumulates behind the dam. For economic reasons, however, it is generally desired to develop the full head as soon as possible, and such assumptions might lead to trouble.

Installations of apparatus of the nature described by the author can be accomplished at very little cost at the time of construction, and are advocated as serving two worthy purposes. The value of data obtained as a basis for theory and design is obvious. Furthermore, periodic observations will either give assurance of continued stability, or may indicate extraordinary conditions developing under a structure in time to avert serious damage or even failure.

B. F. Jakobsen,† M. Am. Soc. C. E. (by letter).—This paper is an interesting account of some measurements of uplift pressures under dams. A study of Tables 3 and 4 shows a progressive increase in uplift pressure

* *Engineering News-Record*, May 20, 1920.

† Cons. Engr. (La Rue & Jakobsen), Los Angeles, Calif.

intensities in nearly all the holes, except those nearest the down-stream face. This is very significant, and it appears that the water makes channels under the dam, progressing slowly until these channels finally reach the down-stream tail-water. Referring to Table 3 and comparing the values for May 2, 1923, with those of November 11, 1925, it will be noted that both the reservoir and tail-water elevations were lower on November 11, 1925, but most of the uplift pressures were higher, except in the holes, *D*, where these pressures have decreased and approached closer to the tail-water elevations.

It is also interesting to note in Fig. 19, that in spite of grouting holes spaced 5 ft. apart under the cut-off wall and in spite of the drain pipe, *A*, the uplift pressure intensities in Pipe *B* are considerably higher than at the tail-water (see especially Station 13 + 00). Reading Column (*D*) under Station 13 + 00 in Table 4 and comparing these readings with the water elevation in the reservoir and the tail-water elevation, the gradual increase followed by a decrease, may be explained by the fact that the water slowly penetrates under the dam until it finally reaches the tail-water.

It would have been desirable if several pipes could have been located in fairly close proximity to each other; say, in groups, so that some information might have been gathered as to how regularly the uplift pressure occurs and how it is distributed under the dam. In the absence of any specific knowledge it would seem to the writer that the measured uplift should be assumed as acting under the entire base, although this would be an upper limit that cannot be reached, but can be approached.

It would be interesting to have these measurements continued because it is possible that silting might occur, the water might scour larger and larger channels as time goes on, or uplift might increase at one section and decrease at another.

All that experience can teach is that uplift does occur. It will undoubtedly vary for each particular site and may vary from section to section at any site. It is quite possible that some uplift may occur even in good rock and in spite of such precautions as grouting under the cut-off wall and by drainage wells close to the wall.

If it were not for the possibility of uplift, the design of a gravity dam, simple as it is, might be classed almost as an exact science. In reality, the first step toward the design of such a dam, is to make an assumption as to how much uplift may be expected. If the base width of the gravity dam is less than about 85% of the height, some assumption as to uplift is involved. If the designer is too optimistic, an unsafe dam is likely to be the result.

Taken as a whole, the paper shows that uplift is a serious matter under gravity dams and that drainage and grouting cannot be relied on to eliminate it entirely.

CHARLES TERZAGHI,* M. AM. SOC. C. E. (by letter).—Data like those presented in Mr. Hinds' paper are among the most precious that the engineer could possibly obtain because they create a unique opportunity to check current conceptions against observed facts.

* Prof., Foundation Eng., Mass. Inst. Tech., Cambridge, Mass.

The first group of data concerns dams on a more or less permeable sand and gravel foundation. According to Bligh's empirical rule* a row of sheet-piles should increase the effective distance of percolation by an amount equal to twice the depth of the sheet-piles. During the past years, Bligh's rule has been also confirmed by both theory and laboratory experiment. Engineers should realize, however, that the theoretical and the empirical rule is only valid when the underground is perfectly homogeneous; that is, when the permeability of the underground is the same in a vertical and in a horizontal sense, and, in Nature, such simple conditions almost never exist. If the underground includes a single layer of feebly permeable material which is penetrated by the sheet-piles, the piling becomes far more effective than it would be otherwise.

Another important question concerns the processes which lead to piping. According to the results of the experimental and theoretical investigations performed by the writer a few years ago concerning the mechanics of piping in uniform sands, the material located beneath the structure remains strictly in equilibrium unless, at some point down stream from the weir, the hydraulic gradient exceeds the critical value, unity.† There is not even a shadow of a possibility for underground erosion. The structure either is safe or else it fails, but there is no possibility for the continued movement of particles. In contrast to this, wherever the underground consists of strata of widely different grain composition, every surface of contact between two different layers represents a zone of weakness. The seepage produced by storage starts an extensive migration of material within the underground. As a result of this migration, the quality of the underground gradually becomes either better or worse, but it certainly does not remain stationary and it may take many years until a state of relative equilibrium is reached. Tables 1 and 2 seem to furnish very instructive illustrations for these gradual changes. The results of experimental investigation of the migration of material in stratified underground were recently published by Dr. A. Läufer, in Vienna.‡ The factor of safety of a dam against piping depends in a large extent on minor geological circumstances which cannot possibly be anticipated, such as the area and form of lens-shaped beds of more permeable material. Therefore the gradual transformation of the underground on every dam should be watched for a couple of years by means of stand-pipe observations, such as those reported by Mr. Hinds. On some weirs in the Alps that were equipped with a foundation patented by the writer, provisions were made for checking or releasing the flow of seepage according to the results of stand-pipe observations after the weir was built.

Very uncertain, also, are the current assumptions concerning the hydrostatic uplift below masonry dams founded on solid rock. It should be realized that a solid rock foundation with fairly wide groutable fissures may be far less unfavorable than another one, equally solid, with many but very nar-

row fissures which cannot be grouted. Fig. 24 shows a cross-section through the Oestertal Dam, in Germany, and the distribution of the hydrostatic upward pressure as disclosed by measurements on May 6, 1910, at full reservoir.* The upward pressure was measured by means of pressure gauges connected through pipe lines with chambers 4 in. in diameter, arranged along the surface of contact between the dam and the rock. The pressures, AB (Fig. 24), were measured along a section where, during construction, the rock appeared to be tight and dry; while the pressures, AE, were measured along a section where the rock was somewhat scattered and contained conspicuous water-bearing seams. According to Fig. 24, along the first section, the upward pressure was almost twice as high as it was along the second one. The diagram shows, in addition, how extremely variable the distribution of pressures can be over the base of the same dam.

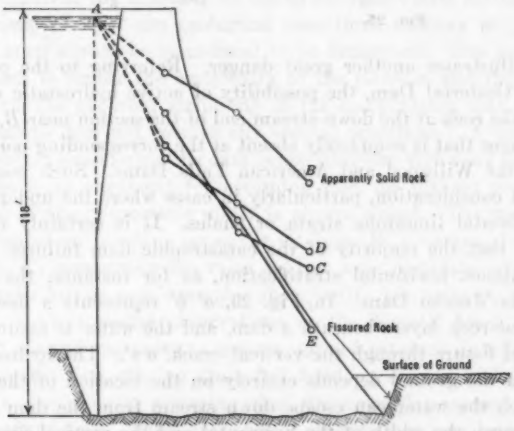

FIG. 24.—HYDROSTATIC UPWARD PRESSURE ACTING ON THE OESTERTAL DAM IN GERMANY.

Still more uncertain are the accepted assumptions concerning the percentage of the area of the base over which the pressure acts. The narrowest seams which can be grouted have a width of about $\frac{1}{20}$ in., while the narrowest seams through which hydrostatic pressure can still be transmitted, have a width of about $\frac{1}{500}$ to $\frac{1}{1000}$ in. Under the geological conditions found at the site of the American Falls Dam, in Idaho, it seems to the writer that the assumption of the pressure acting over one-third the area might have been fairly conservative. On the other hand, there are geological conditions which present the possibility that the pressure may act over more than four-fifths of the base area. This is particularly true in cases where the valley was carved out by erosion through rocks with a low modulus of elasticity. Due to the removal (by erosion) of the rock which formerly occupied the shaded area in Fig. 25, the remaining rock underwent unequal elastic expansion associated

* "Unterdruck bei Staumauern," by R. Schäfer, *Zeitschrift für Bauwesen*, 1913, p. 101.

with the formation of cracks and slight mutual displacement of the rock fragments. As a result of such a displacement, the area of actual contact between the rock fragments may be reduced to a small fraction of the area of the base of the dam, leaving between the rock faces both horizontal and inclined fissures too narrow to yield a visible amount of seepage, yet wide enough to transmit hydrostatic pressure.

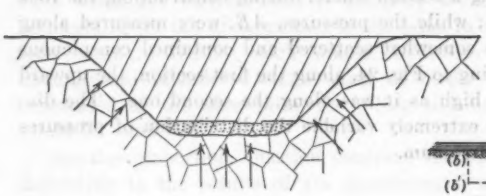

FIG. 25.

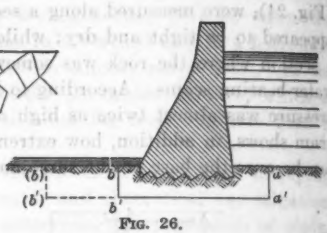

FIG. 26.

Fig. 24 illustrates another great danger. Referring to the pressure line, *AB*, for the Oestertal Dam, the possibility of active hydrostatic uplift occurring within the rock at the down-stream end of the section near *B*, is apparent. This is a danger that is completely absent at the corresponding points (near *E*, Fig. 24) at the Willwood and American Falls Dams. Such possibilities require careful consideration, particularly in cases where the underground consists of horizontal limestone strata or shales. It is certainly more than a mere chance that the majority of the catastrophic dam failures occurred on rocks with almost horizontal stratification, as for instance, the two Austin Dams and the Jumbo Dam. In Fig. 26, $a'\ b'$ represents a fissure between two horizontal rock layers beneath a dam, and the water is assumed to enter the horizontal fissure through the vertical crack, $a\ a'$. The hydrostatic uplift acting within the ground depends entirely on the location of the crack, $b\ b'$, through which the water can escape down stream from the dam and also on the ratio between the width of the horizontal and the vertical fissures. Since these important circumstances cannot possibly be investigated, either by inspection of the dam site, or by test borings, the design should be based on the most unfavorable possibilities. In a case like the one represented in Fig. 26, the greatest danger obviously consists, not in the action of the uplift on the base of the dam, but in the possibility that the upward pressure will lift the weaker roof of rock down stream from the dam.

Obviously, then, the intensity of the upward pressure acting on dams depends to a very large extent on the element of chance; that is, on circumstances which cannot possibly be predicted except in a very general way. The most dependable rocks are obviously those that contain a moderate amount of irregular groutable fissures, such as those that form the underground of the Willwood and the American Falls Dams. The grout curtain creates a considerable drop of the hydrostatic head at the place where it intersects the current of seepage water; while, down stream from the curtain, the open fissures facilitate the free escape of the seepage water toward the down-stream toe.

On the other hand, the most hazardous foundation conditions should be expected in almost undisturbed limestone and shale rocks that have very few vertical cracks. In such rocks, there exists, the additional danger that the horizontal fissures may be open over a large percentage of their area. This is due in part to the dissolving action of the seepage water and in part to the possibility of unequal expansion of the shale beds or of the gradual removal (by erosion) of soft material contained in the seams. To pass judgment on the quality of a dam foundation is one of the most difficult and responsible tasks. It requires both careful consideration of the geological conditions and the capacity for evaluating the hydraulic importance of the geological facts which can only be obtained by a thorough training in the hydraulics of seepage.

Many textbooks on engineering contain simple and alleged empirical rules for computing the intensity of the hydrostatic uplift acting on the base of dams, irrespective of the geological conditions existing at the dam site. Such rules must always be considered to be dangerous. The young engineer is led by them to ignore the complexity of the problem and the layman may conclude from the apparent simplicity of the computation that the design of dam foundations does not require any special expertness. A warning should be issued against considering the data concerning the Willwood and the Austin Dams as one more argument for assuming that the present practice for the computation of the hydrostatic uplift is always sound. The warnings which have been issued on previous occasions by John R. Freeman, Past-President, Am. Soc. C. E., concerning the same subject were certainly not exaggerated, and every year brings new examples that justify his opinion. Prompted by the results of his pressure observations at the Neyetal Dam, in Germany, R. Schäfer* advised engineers to assume upward pressure distribution according to a straight line, sloping from full head up stream to half head down stream. He recommends assuming that the upward pressure acts over the entire area of the base. Thus, every set of observations may lead to other conclusions. Nevertheless, if placed in the hands of cautious and experienced engineers, data such as those presented by Mr. Hinds are of inestimable value. In Europe, studying the uplift and the seepage conditions of dams continuously until they become stationary has become a fairly common practice; and it would be of great value if the same practice would become a routine custom in the United States.

J. C. Stevens,† M. Am. Soc. C. E. (by letter).—The data presented in this paper are invaluable and will aid greatly in the design of dams as regards uplift pressures. The simplified presentation of the maximum uplift pressures observed, compared with those used in design as in Figs. 15 and 20, is particularly to be commended. These show the pressure areas over the entire base of the dam. The writer believes this is the proper manner to treat such uplift pressures in design and also to present experimental data relative thereto.

† Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

The author fails to describe the drain-holes in the American Falls Dam. Presumably, they are independent holes in line with the pressure pipes, *A*, but their spacing and depth are not indicated. Their effect, however, is quite apparent in Fig. 20. It is hardly possible that the pressure lines are straight from the *A*-line to the free-water surface, since this ignores the effect of the cut-off wall. Similarly, it is not likely that they are straight between rows of holes or between the *D*-line and tail-water. This shows that while unit uplift pressures may be measured at many points in the dam, engineers are yet almost entirely ignorant of the area to which these unit pressures apply.

It would seem that uplift in the mass of the concrete itself is possible, particularly along horizontal planes between pours and especially when the dam is loaded, so that there is practically no pressure in the masonry itself at the face of the dam.

If dams could be designed so that the pressure in the masonry at all points equals or exceeds the water pressure at that point, uplift would be taken care of automatically. This is impracticable in high dams, however, and uplift pressures must be reduced, first, by adequate cut-off walls and, second, by effective drainage down stream therefrom.

F. W. HANNA,* M. AM. SOC. C. E. (by letter).—There is probably no other question arising in the design of a dam, on which there is so much guesswork, as on the proper uplift to assume in order to meet actual conditions that occur in the foundation of the structure. This paper, therefore, is timely and valuable in the present period of extensive dam building. The fact that the U. S. Reclamation Service has provided facilities for observing pressures in three different types of foundation materials, is commendable, and additional similar facilities in other foundations are desirable.

The author's contention that filter bed action exists in the stream beds above overflow dams is undoubtedly correct, but it is of relatively small importance in the designs of dams made to withstand the worst uplift conditions. It is of extreme importance, however, when it comes to a proper interpretation of seepage data. The paper brings out this fact clearly. The erodability of the filter film, where the dam is relatively low, is well illustrated by the Colorado River and Percha Dams.

The author shows that the data at the Colorado River Dam neither prove nor disprove Bligh's theory of uniform pressure drop along the line of creep, and he properly ascribes this to the irregular foundation conditions at the dam. In this connection it is important to observe that conditions of such uniformity as to give results in conformity with Bligh's theory rarely occur in the foundations of dams. Of the four dams discussed by the author, only one has a fairly uniform foundation throughout. The Colorado River Dam is founded on loose, coarse gravel of varying thickness, with parts of the cut-off wall extending to tighter material. The foundation of the Willwood Dam is partly shale and partly sandstone; and the American Falls Dam rests on columnar basalt. In the foundations of all these dams, there is opportunity for lateral movement of the seepage water due to variations in the depth or character of the materials under them, thus destroying the conformity of

* Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

pressure creep theory with the Bligh theory. On the other hand, the Percha Dam is founded on rather uniform material as regards horizontal layers parallel to the axis of the dam; and at this project there is a more reasonable conformity with Bligh's theory, as might be expected. The sandstone section of the Willwood foundation also shows reasonable conformity with Bligh's theory.

Another interesting point brought out by the data presented by the author is the distribution of pressure on the base of the dam. In the design of dams it is customary to assume the uplift pressure to act either on all, or on a fractional part, of the base. The lack of uniform distribution of pressure is well indicated by the points, *B*, in Lines 1 and 2 of the Willwood Dam and the points, *C*, at Stations 11+10 and 13+00 in the American Falls Dam. The foundation materials of these dams are such as to make these results subject to anticipation. On the other hand the foundation materials of the Percha Dam and the sandstone parts of the foundation of the Willwood Dam are such as to lead to the assumption of uniform distribution. In this connection the experiment* of H. de B. Parsons, M. Am. Soc. C. E., is of interest. In carefully conducted experiments, Mr. Parsons found, for confined clay, sand, and gravel, that the effective area of the base is approximately 100 per cent. This indicates that the pressure is applied to the base, not only by direct water contact, but by the points of contact of the soil particles with the base. This result is for uniform hydrostatic head on the entire base and is not to be confused with the variation of head from heel to toe of dam.

Ivan E. Houk,† M. Am. Soc. C. E. (by letter).—Some additional measurements and studies of upward pressures under the American Falls and Willwood Dams have been made since this paper was published. In view of the fact that one or two additional points of interest are exemplified, and also because it is desirable to furnish as complete data as possible for the use of interested engineers, it seems advisable to present the results of the more recent investigations in this discussion.

Table 6 gives the results of measurements made at the American Falls Dam since October, 1927, the arrangement of the data being the same as in Table 4. It will be noticed that observations have been made about once a month during the last year (1927-28). Present plans are to continue the readings at about the same interval for at least another year, and then at somewhat greater intervals for some time in the future. By such readings it is hoped to observe any increase or decrease in uplift pressures which may occur as time progresses. Thus far, no general conclusions as regards a time effect seem to be warranted.

Any thorough study of uplift pressure variations resulting from elapse of time should be based either on observations taken with the same reservoir and tail-water surface elevations, or on observations properly corrected for variations in total head. Variations in the total head at the American Falls Dam are essentially variations in reservoir levels, inasmuch as the tail-water elevation is kept practically constant in connection with the operation of the plant

† Below tail-water elevation.

of the Idaho Power Company about 600 ft. down stream from the dam. Keeping this in mind a cursory inspection of Tables 4 and 6 would indicate that for the same total head the elapse of time at the American Falls Dam has resulted in increased pressures at some of the pipes and in decreased pressures at others.

. Where uplift pressures are affected by both reservoir and tail-water levels, or, in other words, where the bottoms of the pipes are connected with percolation passageways leading to both up-stream and down-stream edges of the base, the increases in pressure may be caused by either a loosening of the passageways leading through the grouted rock to the up-stream edge of the base, or by a tightening of those leading to the down-stream edge of the apron or to the open drains. Likewise, decreases in uplift pressure may be caused by a tightening of the passageways above the wells or by a loosening of the ones below. Probably both actions have been occurring to some extent at the American Falls Dam. Approximate measurements of total flow of the drains have been made at times of observing uplift pressures, but the results are somewhat erratic and show no definite increase or decrease in drainage since the reservoir was first filled. Tightening of the percolation passageways may be caused by deposition of salts from the percolating water. Such an action is believed to be responsible for a reduction in drainage flow which has been observed during recent years at the Elephant Butte Dam on the Rio Grande Project of New Mexico and Texas.

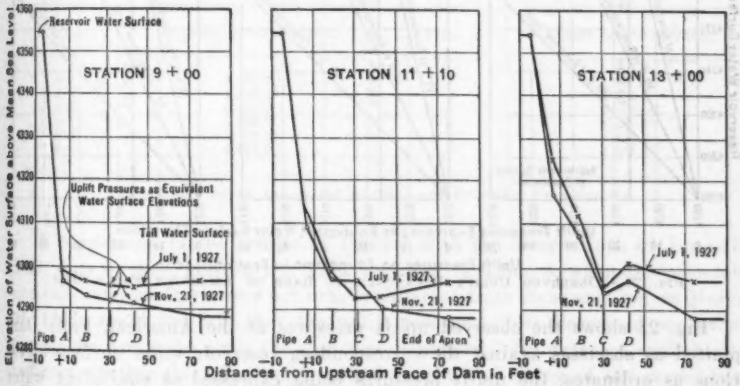

FIG. 27.—EFFECT OF VARIATION IN TAIL-WATER ELEVATION ON UPWARD PRESSURES UNDER AMERICAN FALLS DAM.

The series of uplift pressure observations at the American Falls Dam on November 21, 1927 (the first set of observations recorded in Table 6), is of special interest because of the relatively low tail-water elevation (4 286.6) which existed at that time. Such a stage is approximately 10 ft. lower than the elevation usually maintained. At the time of the November measurements the tail-water had been lowered for several days because of some gate repairs required by the Power Company. Fig. 27 shows the readings of November 21,

1927, platted with those of July 1, 1927, when the reservoir water surface was at almost exactly the same elevation, but when the tail-water level was at Elevation 4 297.0; that is, 10.4 ft. higher than on November 21. Water surface elevations are platted as ordinates, and distances from the up-stream face of the dam as abscissas—the down-stream direction being taken as positive. The diagrams show that the uplift pressures on November 21 were considerably lower than on July 1, the differences being from 3 to 4 ft. at several of the pipes and as much as 8.0 ft. at Pipe *A*, Station 13 + 00. (See Fig. 16.) The diagrams in Fig. 27, together with the data in Tables 4 and 6, would indicate that Pipes *C*, Stations 11 + 10 and 13 + 00, are relatively tight as regards connections with either reservoir or tail-water conditions, as stated by the author. No explanation can be offered for the sudden increase in pressure at Pipe *C*, Station 11 + 10, between July 21 and September 19, 1927. The other pipes, some of which have at times shown water elevations slightly lower than the tail-water levels, apparently are affected to some extent at least by both reservoir and tail-water conditions.

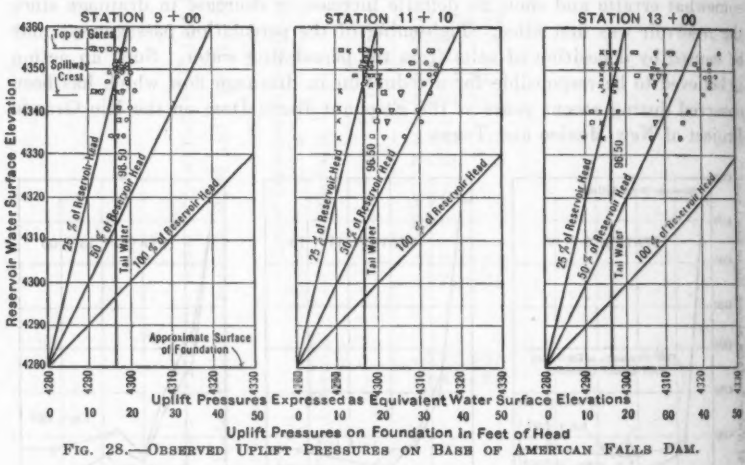

FIG. 28.—OBSERVED UPLIFT PRESSURES ON BASE OF AMERICAN FALLS DAM.

Fig. 28 shows the observed uplift pressures at the American Falls Dam platted as abscissas against the corresponding reservoir water surface elevations as ordinates, the uplift pressures being expressed as equivalent water surface elevations, as in Tables 4 and 6, no corrections being made for differences in tail-water levels. The elevation, 4 280, at the bottom of the diagrams is the approximate surface of the rock at the locations of the uplift pipes. Elevations of the spillway crest and the top of the radial gates are indicated on the diagrams by short horizontal lines, while the normal tail-water elevation, 4 296.5, is indicated by vertical lines. Diagonal lines represent uplift pressures of 25, 50, and 100% of the reservoir pressures at the up-stream edge of the base.

While the observations shown in Fig. 28 are naturally somewhat erratic, the diagrams indicate, in a general way, the variation of uplift pressures with

changes in elevation of reservoir water surface. It will be noticed that in most cases the uplift pressures fall between the 25 and 50% lines. Pressures at Pipe *A*, Station 13 + 00, are practically the only ones that fall definitely above the 50% line. These pressures fall on a diagonal line representing about 60% of full reservoir water pressure. Uplift pressures observed at Pipe *B*, Station 11 + 10, seemed to increase gradually as the reservoir filled until May 17, 1927, then to drop back about 6½ ft. by July 1, although the reservoir water surface continued to rise, reading an elevation of 4 354.46 by July 1—a total of 9.7 ft. higher than on May 17. Since July 1, 1927, the uplift pressure at this pipe seems to have remained almost constant, thus indicating that the foundation rock surrounding the bottom of the pipe has tightened appreciably. Observations at Pipe *A*, Station 9 + 00, seem to show a somewhat similar condition.

Measurements of uplift pressure at the Willwood Dam have not been made periodically for some time. In fact, only one set of observations has been secured since the paper was published. This was on March 31, 1928, when the reservoir water surface elevation was 4 500.55 and the tail-water elevation, 4 458.50. Uplift pressures at the various pipes on March 31, expressed as equivalent water surface elevations, are given in Table 7.

TABLE 7.—UPLIFT PRESSURES EXPRESSED AS EQUIVALENT WATER SURFACE ELEVATIONS.

Pipe.	Uplift, water surface.	Pipe.	Uplift, water surface.
A-1	4 467.2	*C*-1	4 461.3
A-2	4 458.4*	*C*-2	4 462.8
A-3	4 468.8	*C*-3	Plugged
B-1	4 452.9*	*D*-1	4 456.6*

B-3	4 464.0	*D*-3	4 459.1

* Elevations below tail-water surface are indicated by asterisks.

A comparison of the results in Table 7 with the observations of June 16, 1923, July 6, 1923, and July 1, 1926, recorded in Table 3, when the reservoir and tail-water surfaces were not greatly different from those existing on March 31, 1928, would indicate that the uplift pressures have decreased somewhat during the five years since the dam was completed. No data are available to indicate whether this effect has resulted from a tightening of the percolation passageways above the pipes, from a loosening of the drainage passageways below, or from both.

It may be interesting to discuss briefly the methods of installing the uplift pressure pipes at the American Falls and Willwood Dams. At the latter the pipes ended at the line of contact between the rock and the concrete. The pipes were placed in holes drilled through the concrete after the body of the dam had been poured to Elevation 4 456.2, approximately 5 ft. above the surface of the rock foundation. It is presumed that the drill holes did not extend more than a few inches into the rock inasmuch as no mention of the matter

is made in the installation records. At the American Falls Dam the pipes were placed before concreting, leaving the lower ends 6 in. above the rock, as shown in Section *E-E* of Fig. 16. After the concrete was poured to a height of a few feet above bed-rock, holes were drilled through the concrete at the lower ends of the pipes and approximately 5 ft. into the foundation.

Whether or not holes should be drilled from the ends of the pipes into the foundation is a debatable question. If they should extend into the rock, how far should they go? If there are horizontal seams, or percolation passageways, in the foundation within relatively short distances of the base of the dam, the uplift pressures in such places may exert some uplift on the concrete, since the weight of the intervening rock would probably be considerably less than the uplift. Drilling into the rock may intercept such areas, or passageways, and result in the measurement of uplift pressures where otherwise no uplift would be recorded. At the Gibson Dam, which is a concrete arch type, 200 ft. high, now (1928) being built by the U. S. Bureau of Reclamation on the Sun River Project of Montana, the uplift pipes are being installed in the same manner as at the American Falls Dam, but the holes at the ends of the pipes are being drilled approximately 18 in. into the rock instead of 5 ft. The depth in the foundation to which such holes should be drilled, or whether they should be drilled at all, is a problem which is not susceptible of exact solution. It must be decided on the basis of engineering judgment. Of course, the pipes might be set directly on the rock, and the ends surrounded by gravel before concreting. However, such methods would tend to intercept uplift conditions from horizontal areas considerably larger than the areas of the pipes. In most cases the writer would favor drilling into the rock about 18 in., as is being done at the Gibson Dam. Probably the depth of drilling should be decreased for comparatively low dams and increased for comparatively high dams.

As regards the proportionate area of the base on which the uplift pressures should be considered to act when designing a dam, the writer is inclined to favor using the entire area, especially if the uplift pressure curve is based on actual measurements instead of on arbitrary assumptions. Thus far, no practicable method of measuring the areas on the base of a dam on which uplift pressures are actually exerted, has been developed. Naturally, the extent of such areas will depend on the character of the foundation, the thoroughness of the grouting operations, and the efficiency of the drains. If the dam is built on a solid rock foundation, the rock thoroughly grouted along the up-stream edge of the base, and an adequate system of drains installed, the writer would expect large areas of the base to be entirely free from uplift pressure. The existence of such areas at the Willwood and American Falls Dams is indicated by the zero uplift pressures observed at several of the pipes. However, if these pressures are taken into account in determining an average uplift pressure curve, no further consideration of such areas is necessary. As far as such areas are concerned the average pressure curve should be applied to the full area of the base. If estimates of the actual areas subjected to uplift pressure are to be made and used in calculating the total uplift force, the observations which indicate zero pressure should be omitted from the diagrams used in determining the intensity of the uplift pressure.

Of course, there remains the question as to what proportion of the rock surface is in contact with the concrete in the areas where uplift pressure is observed; or, more exactly, what proportion of the areas where uplift pressure is observed should be considered as capable of transmitting uplift pressure to the base of the dam? Here, again, the writer would favor using the entire area. If a crack has formed between the foundation and the dam, as was the case at the up-stream side of the Stevenson Creek Test Dam, the full area would be effective as far as the crack extended. If the rock is of a stratified nature and a horizontal seam exists a short distance below the base, uplift pressure may be transmitted through the rock layer to the full area of the concrete even if a large proportion of the rock surface is in actual contact with the concrete. If the dam has been built on a sandstone foundation and uplift pressure exists in the sandstone, the pressure may be effective over nearly the full area of the base even if a large proportion of the sand grains are in actual contact with the concrete. In such a case the pressures would be transmitted through the sand grains from pore spaces below. In this connection it is interesting to note that H. de B. Parsons, M. Am. Soc. C. E., as the results of a large number of experiments made under varying conditions of head, depth of sand, etc., concluded* that:

"* * * it would not be safe to estimate an uplift in pervious soil of less than full pressure head acting on the total area of the base, when there is no flow of water through the soil; nor less than the full pressure head indicated by the hydraulic gradient when there is flow through the soil."

The writer's idea of the most practicable method of investigating upward pressure under dams would be to install a large number of measuring pipes, uniformly distributed over the entire area of the base. He would then plat the pressure measurements, including the observations of zero pressure, and would apply the resulting intensity curves to the full area. Such a method would make proper allowances for the areas in which no uplift pressure exists. As regards the areas subjected to uplift pressure it would be slightly on the safe side. The pressure intensities would be accurately measured, but the effective area would be assumed as equal to the maximum possible. However, the writer believes that the question of effective area where there is uplift pressure is not so important as the question of what areas are entirely free from uplift. In other words, he believes that it is important at this time to secure a large number of uplift pressure measurements uniformly distributed over the base of the dam. When such investigations have been made at a large number of dams, built on different types of foundation, the designing engineer can make a much better estimate of the uplift to be expected at a given site than is possible at present.

C. H. HOWELL,† M. AM. SOC. C. E. (by letter).—This paper gives additional information on the intensity of uplift under certain existing dams. The effect of uplift is due to two factors: One of which is the intensity of the pressure; and the other, the area of the base on which the pressure is applied.

* See p. 1331.

† Chf. Engr., The J. G. White Eng. Corporation, S. en C., City of Mexico, Mexico.

As the author states the observations recorded do not prove or disprove the theory and assumptions ordinarily used in considering the problem. The fact that dams that have been investigated continue to stand, however, proves that the assumptions made in their designs were adequate.

The writer knows of no experiments or investigations as to the area subjected to uplift on rock foundations. This factor is just as important as that of the intensity. Its exact determination would be difficult if not impossible for the whole of any given dam site. Even if exact measurements could be obtained for one site the results would not necessarily be applicable to any other.

Water may develop pressure on the bottom area of a dam in one or both of two ways. One of these is through a faulty contact between the concrete and the top of the rock. The area thus affected must always be less than the total area as shown in Fig. 29(*a*). This is true, because otherwise there would be no contact between the concrete and the foundation, which would be an impossibility. The section, $C\,L$, is the part of the unit length, L, of the base receiving uplift from faulty contact. The factor, C, may vary from zero to anything less than 1.

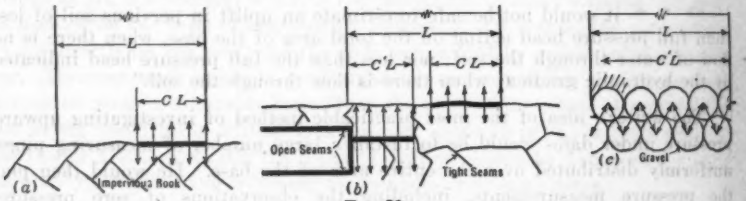

FIG. 29.

The other way for uplift to be developed is through open seams in the rock below the base of the dam (see Fig. 29(*b*)). The area thus affected may easily be 100% of any given unit of area; that is, the factor, C' (in Fig. 29(*b*)) may vary from 0 to 1.0. Likewise, $C'\,L$ is the section of unit length, L, of the base receiving uplift through open seams. It seems to the writer, however, that it is unreasonably conservative to assume 100% over the entire base of the whole dam.

Fig. 29(*a*) and Fig. 29(*b*) also illustrates the difficulty of making a quantitative determination of this part of the problem. In addition to the separate action of these two conditions the uplifting force may be the result of a combination of the two. The area subject to uplift on gravelly foundations has been shown by the author to be approximately 100 per cent. Fig. 29(*c*) shows this condition digrammatically. In this case, C' may vary from 0.9 to 1.0.

Until the areas affected by uplift can be determined the treatment of the problem on rock or similar foundations will continue to be a matter of judgment rather than mathematics. The multiplication of intensity observations alone will not serve to solve it.

P. WILHELM WERNER,* ASSOC. M. AM. SOC. C. E. (by letter).—The measurements at the Colorado River Dam, although indefinite, are of a very interesting nature. The author attributes most of the irregular character of the results obtained to a variable seasoning of the filter surface. For this special case, the explanation may be exactly true, or, at least, nearly so. The writer believes, however, that in many cases the "time effect" accounts for the observed irregularities in the pressure line to an appreciable extent. A certain retardation will occur in the formation of the state of equilibrium corresponding to a new head or differential pressure.

In general, the time effect is, evidently, a condition that is rather favorable to the stability of a dam, and the writer is of the opinion that it often adds materially to the safety of the structure. This is especially true if the flood peaks are of comparatively short duration and the "retardation coefficient" of the foundation is high. The time effect is of a universal nature, and applies to soils as well as rock strata where the water is creeping in very narrow channels. Sufficient data are not yet available, however, to accomplish a general study of its character and magnitude for different materials. It is to be hoped that the problem will soon be taken up in full and given the attention it deserves among engineers.

The readings at the Willwood Dam show that uplift under dams on rock foundation is a really serious matter and that extreme care must be exercised in selecting the dam site with regard to the actual geological and hydrogeological formations. If the shale and the sandstone in this case were located in the reverse order, there would probably have been a considerably more unfavorable condition of uplift under certain parts of the dam. When a dam is to be built on a rock foundation composed of very different strata, there is every reason to test the foundation hydraulically in order to prevent any unexpected eventuality.

For several reasons it would be of great value to have these experiments made over a rather long period of time. It would be especially interesting to know how the uplift pressure varies with the distance to the vertical construction and contraction joints. The results at the Willwood Dam seem to give some indication of this, but sufficient data are not available to justify a conclusion.

The writer believes that a vertical contraction joint, at least when it opens up, acts somewhat as a drainage well, thus decreasing the uplift under the base of the dam. The necessary requirement is, of course, that the joint shall not become clogged and that the seepage can freely issue into the tail-water. As contraction joints in solid gravity dams are usually constructed, however, it seems rather doubtful whether it is safe to assume an effective drainage, although it is more than probable that in many cases such joints have had an appreciable effect on the stability of dams. The writer is of the opinion that this question involves an economic factor of importance, and, therefore (assuming that there are favorable conditions at the dam site), he would suggest a solid gravity dam as shown in Fig. 30.

* Stockholm, Sweden.

This dam would be built in sections of ordinary length. The blocks would be separated by permanent contraction joints, extending down to rock, which would be made wide enough to permit the removal of the forms. This arrangement would cause an increased expense for shutterings, but would mean a considerable saving in concrete due to the decrease in uplift. Preliminary estimates indicate that for dams of ordinary size a saving of at least 5% of the total cost is quite feasible even under the assumption that the value of the ratio between the unit prices of shutterings and concrete is unfavorable.

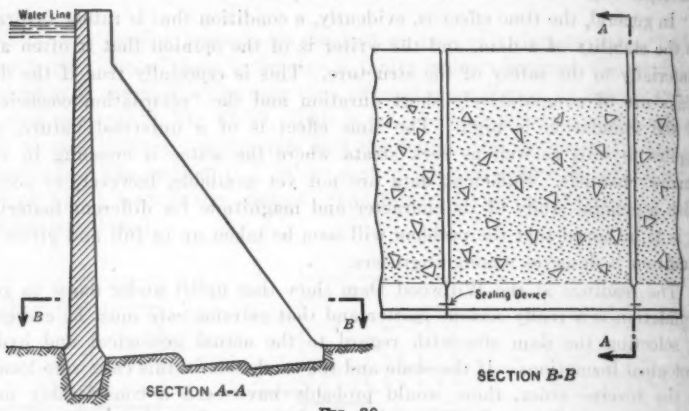

FIG. 30.

The writer is well aware of the fact that, in certain respects, this suggestion is somewhat against present common practice, and a discussion would probably involve many of the most important questions relating to the design of solid gravity dams. Some of these points are in distinct favor of the new design; that is, the possibility of a convenient inspection of the joints and the facilitated dissipation of the chemical heat in the masonry. Other points seem to be more or less a matter of opinion; for example, the hypothetical mutual support between different parts of a solid gravity dam as a means of preventing ultimate failure. Whatever the judgment may be, the writer thinks the idea is worth considering.

H. DE B. PARSONS,* M. AM. SOC. C. E. (by letter).—As knowledge regarding hydrostatic uplift pressure under dams is meager, all records of actual pressures are welcome. The profession is indebted to the U. S. Bureau of Reclamation for making the experiments reported by the author.

There is an upward pressure on the base of every structure founded below water level on fissured or pervious material. The intensity of this pressure undoubtedly would vary with differences in foundation material—its granular structure, grading of particles, fineness or coarseness, compactness, solidity, etc.

* Prof. Emeritus, Rensselaer Polytechnic Inst.; Cons. Engr., New York, N. Y.

Because all the factors involved are not appraised, it is to be expected that measurements of upward pressures will often appear inconsistent, that is, will apparently lack proper relationship. The water column in a test pipe only records static head. One pipe of a series may enter a firmly compacted pocket through which there is little or no flow, while another pipe in the same series may end in loosely compacted and coarse material, or in a crevice in the rock through which there is considerable and rapid flow. The water column in the first pipe would measure practically total head, while that in the latter would record only the static head. When plotted, the points representing the upward pressures, as measured in these pipes, would lack correlation with each other.

The work of preparing the site for a dam and the laying of the base masonry disturb Nature's placement of the foundation material. Water flowing through the foundation material will seek lanes or paths of least resistance, and these lanes may be neither straight nor at the surfaces of the foundation under the base. Consequently, observations of upward pressures in pipes arranged in a row normal to the axis of the dam may not show consistent relations, nor be such as to indicate a smooth hydraulic grade line. Furthermore, cut-offs will affect the uplift observations and produce results that may appear erratic.

Cut-offs made of sheet-piles may not be water-tight. The piling might be tight for some distance and then have an opening caused by a boulder or other sub-surface obstruction. The path of the water passing through such an opening cannot be predicted.

Deposit of silt will tend to close the voids between the soil particles, and thereby diminish the flow through the foundation. This silting process may divert the flow from some observation pipes and not from others. The silt blanket in a reservoir behind a dam, the crest of which is high above the river bed, will not be disturbed ordinarily by flood discharges, as mentioned by the author for the Colorado River Dam the crest of which was only 8 ft. high.

Considering the complexity that exists, the writer does not think that the quotients obtained by dividing the distances, as measured along the base of a structure in the direction of river flow, by their corresponding losses of static head (the percolation factors of Bligh), should be proportional in every instance. While the losses of static head may be measured with fair accuracy by the test pipes, the lengths of the paths along which the underground water flows is not known with any certainty.

The hydrostatic head in the pipes will be affected by the distance the perforations or pipe ends are below the base of a dam. Thus, if one pipe is deep and another shallow, the hydrostatic heads may lack correlation. It is the writer's opinion that, under ordinary conditions, the pipe openings should be not less than 18 in. and not more than 6 ft. below the base. This would place the openings of the pipes below the irregularities of the base masonry and still near enough to record the uplift pressures in the layer of foundation material on which the base rests. The chance for consistent and correlating records will be improved by care in placing the pipes.

The writer's plans for the Sherman Island Dam*, across the Hudson River, near Glens Falls, N. Y., contemplated thirteen rows of three pipes each; that

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), Fig. 18, p. 1287.

is, one row in alternate bays of the multiple arches, or about 38 ft. apart as measured across the river. Unfortunately, as constructed, only seventeen pipes were placed, with four bays having two pipes, and three bays, three pipes, each. In one bay there was a defective pipe. All of them were on the down-stream side of the 55-ft. interlocking steel sheet-pile cut-off. The foundation material under the dam was sand of varying sizes, containing some boulders. The geologic rock floor, except at the abutments, was not reached by 80-ft. borings.

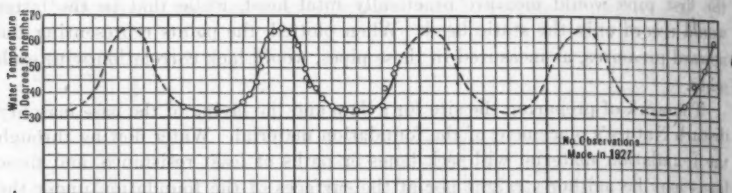

FIG. 31.—SEASONAL VARIATION OF UPLIFT HEAD UNDER MAIN DAM AND WATER TEMPERATURES, SHERMAN ISLAND DAM.

The upward pressures were fairly consistent in the pipes of each row, but were not always correlated when comparing one row with another. The uplift records showed an annual periodic variation which fluctuated with the changes in temperature of the river water. Thus, the average uplift head above water below the dam became greater as the temperature of the water increased and less as the temperature lowered. This seasonal variation is shown in Fig. 31. It was noticed that the up-stream cut-off of sheet-piling caused a large diminution in uplift, after which the uplift diminished toward the down-stream edge of the apron along a curved line. The low uplifts for 1925 may be due to low-water temperatures, as no temperature observations were recorded in that year during the summer months.

E. W. LANE,* M. AM. SOC. C. E. (by letter).—The data on upward pressure under dams presented by Mr. Hinds is a valuable addition to the present knowledge of this subject. The writer believes strongly in the necessity of such experiments because unsupported theoretical deductions are apt to be considerably in error.

He has collected some similar data which may throw additional "light on the subject". With E. L. Chandler, M. Am. Soc. C. E., he measured the upward pressure on the Island Park Dam in the Miami River at Dayton, Ohio. In these tests the effect of the blanket of silt which formed in the pool

* Engr., U. S. Bureau of Reclamation, Denver, Colo.

above the dam was especially noticeable, as it cut off nearly all upward pressure, as shown in Fig. 32 (*a*) and Fig. 32 (*b*). Another example of very slight upward pressure, probably due to the same cause, is that on the dam in the Miami River at Hamilton, Ohio. This dam is founded on gravel of good grading between sand and 9-in. cobblestones. The pipes were installed and the closure made in November, 1921, and the readings were taken in the following July by C. H. Schwartz, Assoc. M. Am. Soc. C. E. The results are shown on Fig. 32 (*c*) and Fig. 32 (*d*). Between the time of the closure of the dam and the date on which the readings were taken, several freshets occurred, which deposited a layer of mud above the dam. About 100 to 200 ft. above the dam, however, a gravel plant had excavated a hole 20 to 30 ft. deep.

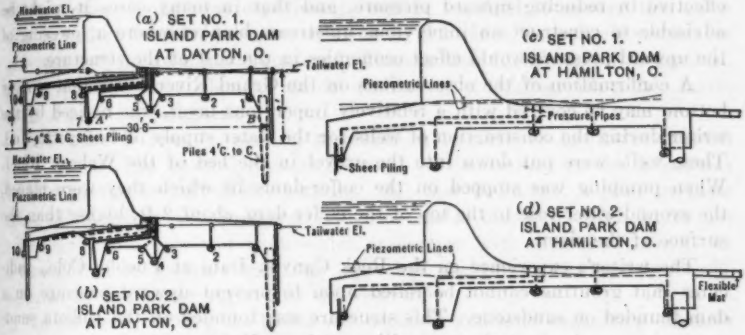

FIG. 32.—OBSERVATIONS ON UPWARD PRESSURE.

Another case showing upward pressure which was probably somewhat reduced by silting is that of the hydro-electric plant at Hamilton, Ohio (Fig. 33). The observations were made by Mr. Schwartz and Mr. W. P. Watson, three months after the water was turned into the head-race. The

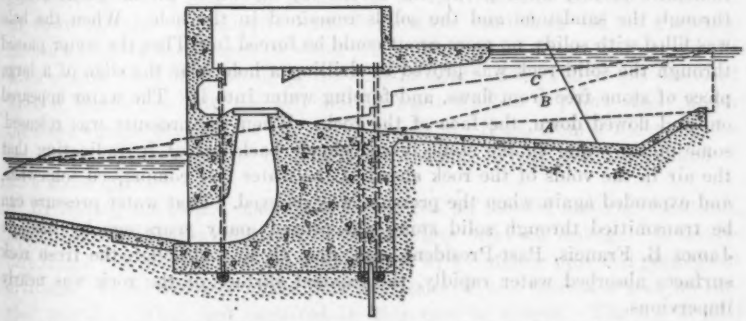

FIG. 33.—UPWARD PRESSURE EXPERIMENTS, HYDRO-ELECTRIC PLANT, AT HAMILTON, OHIO.

dotted line shows the upward pressure under the main part of the structure. The extension (*B*) of this line represents the assumption that the pressure at the up-stream edge of the structure is equal to the full depth of water at that point. Another assumption, represented by Line (*A*), is that the rate of

loss of pressure per foot of length of line of creep was the same under the up-stream part of the structure as under the part where it was established by the observations, and that the difference between Lines (*A*) and (*B*) at the up-stream edge represents the loss of pressure due to silting. The true condition is probably between the two assumptions. Since the length of the power house was relatively small in proportion to the effective head, it is probable that some of the water that entered the ground from the head-race passed around the ends of the power house and thus lowered the pressure more than it would have if all the water had passed under it. The dashed line (*C*) shows the upward pressure under the commonly used "line-of-creep" theory.

These examples show that an earth blanket up stream from a dam is very effective in reducing upward pressure, and that in many cases it might be advisable to construct an impervious up-stream blanket where a lowering of the upward pressure would effect economies in the cost of the structure.

A confirmation of the observations on the Grand River Dam, that a river bottom may be covered with a relatively impervious layer, was noticed by the writer during the construction of wells for the water supply of Lafayette, Ind. These wells were put down into the gravel in the bed of the Wabash River. When pumping was stopped on the coffer-dams in which they were placed, the ground-water rose to the top of the coffer-dam, about 2 ft. higher than the surface of the river.

The writer's experience on the Rock Canyon Dam at Pueblo, Colo., indicates that grouting cannot be relied upon to prevent upward pressure on a dam founded on sandstone. This structure was founded on the Dakota sandstone, composed of nearly pure silica grains. Holes on 10-ft. centers were drilled near the up-stream face of the dam into the rock to an average depth of about 10 ft. and were vented to the down-stream side of the dam to relieve upward pressure. The possibility of grouting these holes was investigated, but it was found that, although water could be poured into them slowly for an indefinite period, when grout was forced in, the water in the grout filtered through the sandstone and the solids remained in the hole. When the hole was filled with solids, no more grout could be forced in. That the water passed through the solid rock was proved by drilling a hole near the edge of a large piece of stone free from flaws, and forcing water into it. The water appeared on, and flowed down, the face of the rock. When the pressure was released, some of the water in the stone flowed slowly back out of it, indicating that the air in the voids of the rock ahead of the water was compressed somewhat, and expanded again when the pressure was relieved. That water pressure can be transmitted through solid stone was proved many years ago by the late James B. Francis, Past-President, Am. Soc. C. E. Although the fresh rock surfaces absorbed water rapidly, the exposed surface of the rock was nearly impervious.

C. E. GRUNSKY,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The results of such studies as presented in this paper are of unquestioned value to the Engineering Profession. The same may be said of the great mass of research work and refined studies now in progress throughout the country for the ascer-

* Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

tainment of stresses in structural members and shapes under all manner of loading. It should not be forgotten, however, that actual conditions at completed structures cannot always be reproduced in the laboratory and that in the design of important works much relating to adequacy must frequently be left to personal judgment based on knowledge of past experience.

Thus, for example, the writer holds that experience has not yet demonstrated the effect on the quality and serviceability of concrete through which there is percolation of moisture in sufficient quantity to leach out carbonate of lime. The resulting efflorescence or deposit is frequently seen on the under surfaces of short-radius, multiple-arch concrete dams. Does concrete through which moisture is penetrating under high pressure lose strength? and, if so, at what rate? Long-time experiments will be required to answer this question as well as further questions relating to the effect in such circumstances of waters varying in mineral content. The engineer in this case is compelled, for the present, to supplement his determination of strains with a fair increment of personal judgment.

The same is true in making assumptions relating to hydrostatic uplift under dams. The upward pressures cannot be determined in the laboratory for any particular full-sized structure. All that is known, is that in those spots of uncertain and indeterminate area under dams to which water has relatively free access and from which it escapes with difficulty there is an accumulation of pressure that may approach the full hydrostatic head represented by the water surface of the reservoir.

To illustrate, in 1892 the writer was engineer and later consulting engineer on a California water supply project which involved the erection of an earth dam. It was built on a foundation of fissured volcanic tufa. The earth available for construction could not be called first-class. It lacked homogeneity. The earth fill extended from the dam for some distance along the top of a low ridge. Soon after the reservoir was filled, a part of this low extension where it had a height of perhaps 10 or 12 ft. became soft and sloughed off down stream. Familiarity with foundation conditions led to a speedy determination of the source of water which had caused the saturation of the down-stream third of a section of the embankment. This source was disclosed when a trench cut into the soft sliding mass reached a point about under the down-stream edge of the flat top of the dam. Here, from a fissure in the bed-rock a minute quantity of water was flowing. There was not enough to fill a goose quill.

By leaving the trench open for a day or two all the wet material dried out, and it became apparent that there was no other bed-rock leakage. A miniature trench cut into the bed-rock and covered with concrete provided permanent drainage. Then, the slope of the dam was restored, and there has been no further trouble. What had occurred in this case is simple. The fill at and near its toe had been well compacted, was fairly impervious, and in good contact with the foundation. Consequently, the water issuing from the fissure acquiring practically full hydrostatic pressure rose upward in the earth fill and gradually saturated a considerable mass of the down-stream slope and caused the slide.

Sound personal judgment is of great importance when the sufficiency of a foundation for a storage dam is to be ascertained. Moreover, there will nearly always be much doubt as to the distribution and magnitude of the upward pressure under storage dams and no generally applicable law can be laid down. The upward pressure is not necessarily confined to the joint between the structure and its supporting foundation, nor to horizontal cracks, but may find greatest development at some depth below the base of the structure.

The safe procedure does not lie in assumptions as to its magnitude, but rather in thorough drainage, not only of the material of which a massive dam is constructed, but also of the rock or other material on which it rests. Thus, for example, in the case of the earth dam of 1892 already referred to, a masonry wall was constructed across the creek channel about under the center line of the dam and a sump of broken rock was provided at the up-stream face of this wall, from which a pipe in a hillside trench led off the intercepted water. Months after the reservoir came into use, the discharge from this pipe was 186 drops per min. This is a very small quantity of water and yet, in the course of time, it might have saturated quite a mass of material within the dam if an outlet for it had not been provided.

JULIAN HINDS,* M. AM. SOC. C. E. (by letter).—It is gratifying to note the volume of useful material that the discussion of this paper has brought forth; it will be of great help in the solution of uplift problems. The constructive and helpful spirit of all the discussors is appreciated. The discussions are clear and complete and require few closing comments.

Mr. Chandler submits a complete and interesting set of data for the Pinhook Dam, which is founded entirely on gravel. These data indicate Bligh's "line-of-creep" theory to be safe for this structure. The blanketing effect of a mud deposit over the river bed, as found at the Percha and Grand Valley Dams, is again encountered here.

Mr. Jakobsen calls particular attention to the evidence that grouting and drainage do not entirely relieve uplift pressures in the case of rock foundations. This fact is believed to be generally recognized, but it is worthy of further emphasis, as a caution to those who may have too great confidence in the effectiveness of grouting.

The discussion presented by Professor Terzaghi is evidently the result of a very thorough comprehension of the status of the uplift problem. It amplifies the original paper, explains some of the observed phenomena and cautions against overconfident use of the data. It is noted that the uplift shown (Fig. 24) for the Oestertal Dam is high and drops approximately along a straight line. The tail-water level is not shown. Apparently, this dam is not grouted.

Mr. Stevens notes that the drainage provisions at American Falls are not properly described. Unfortunately, the writer does not have at hand data showing the spacing and depth of the drain holes as actually drilled. The construction drawings specify holes on 5-ft. centers, or as required by the engineer.

* Care, Dept. of Water and Power, Los Angeles, Calif.

Mr. Hanna agrees in general with the analysis of the original data, but joins some of the others in pointing out the improbability of finding exact agreement between Bligh's theory and actual pressures, because of lack of homogeneity in the underlying strata.

Mr. Houk brings the original data up to date by submitting subsequent measurements at the Willwood and American Falls Dams. He also adds much to the theoretical discussion. He recommends more closely spaced pipes in order to obtain an idea of the extent of the area subject to uplift which is believed to be good.

Mr. Howell is inclined to the theory that even in areas known to be subject to uplift on rock foundations, the presence of a 100% pressure area is impossible except in small pockets, because there must be some water-tight contact between the dam and the foundations. His discussion serves as a check on those who may be inclined to favor the assumption of a 100% effective area. It seems reasonable to assume that when one solid body rests upon another there must be some parts of the adjacent areas in water-tight contact, but until more information is available on the subject it is believed that the burden of proving that such areas necessarily constitute an important percentage of the total area must fall on those advocating the theory.

Mr. Werner suggests the possibility of time effects on the measured values of upward pressure. Undoubtedly, such effects exist, but the data at hand are not sufficient for their determination. It is, perhaps, unnecessary that there shall always be a marked lag in pressure changes with variations in head, after all the pressure cavities have been filled with water. Attention is called to the possibility that a change of strata, as at the Willwood Dam, may occur in such a way as to increase materially the uplift pressure. For example, a dam founded generally on a porous rock, but with a strata of tight rock along its down-stream toe, would probably be subjected to high uplift pressure. Such a condition should be avoided.

Mr. Werner's suggestion as to the relief of uplift* by means of wide open contraction joints, as illustrated in Fig. 30, is of particular interest to the writer because of certain supplementary studies made along this line. The security of many of the old Spanish dams found in Mexico is believed to be due to this principle. In these dams the separation is carried further than indicated in Fig. 30, the dam becoming a wall supported by heavy buttresses. By inclining the up-stream face, and with conservatively thick buttresses and walls, a theoretical saving of much more than the 5% suggested by Mr. Werner can be made with this type of construction.

Mr. Parsons emphasizes a number of reasons why a given set of uplift observations cannot be expected to agree within themselves, or to show exact conformity with any given theory of computation. This part of the discussion is followed by the presentation of data showing the effect of water temperature changes on the uplift at Sherman Island Dam. It is surprising to

* This principle of uplift relief, combined with other advantages and disadvantages, reaches its ultimate development for a gravity type of structure, in Noetzli's "Round Head Buttress Dam," as described in the latest edition of "Design and Construction of Masonry Dams," by Edward Wegmann, M. Am. Soc. C. E.

note that almost 100% increase in pressure is shown from the lowest to the highest temperatures.

Mr. Lane submits valuable new data and discusses, in some detail, the effectiveness of a silt blanket in the stream bed for reducing the uplift under a dam founded on gravel. The possibility of taking advantage of such an apron in design is suggested. Such a procedure is practicable in places where the blanket is not subject to disturbance by floods. The discussion of the impossibility of grouting sandstone to prevent filtration of water through the body of the rock is interesting. Apparently, grout can be used only to close fissures and not to tighten a naturally porous rock.

Mr. Grunsky again warns against the possibility of placing too much confidence in experimental data. He thinks that it is better to eliminate uplift than to make assumptions concerning its magnitude. Certainly no issue can be taken with this attitude, but all the available evidence seems to indicate that present good practice in the grouting and draining of foundations does not eliminate uplift.

Because so many of the discussions have warned against over-confident use of experimental data a word of counter caution may not be out of place. To discredit research work too seriously is unwise, and militates against progress. Data of the kind submitted in this paper are intended to add to the store of knowledge of past experiences, and in this way to assist in the rendering of "sound personal judgment".

With an intricate and variable problem of this kind it is too much to expect that a simple set of rules can be formulated which will enable an inexperienced man to pass on the foundation for an important dam. This is the possibility which seems to be causing anxiety, and it is right that it should be guarded against; but in doing so it should not be forgotten that depending too implicitly upon "personal judgment" has led to more than one disaster.

The most essential new points brought out in the discussions may be summarized as follows:

1.—Foundation conditions at a given site are likely to vary widely, often preventing concordance of observations. This can only be counterbalanced by a large number of observations. Readings taken at one or two points are not dependable, as they may contain local influences.

2.—When a new dam site is being investigated it is largely a matter of judgment whether or not it is similar to another site for which uplift conditions have been determined. With a greater accumulation of data engineers may be able to judge this factor with more assurance.

3.—An attempt should be made to improve present knowledge of means for controlling underflow and uplift. Grouting and drainage, as ordinarily practiced, reduce uplift, but do not eliminate it.

Paper No. 1718

HYDRAULIC STUDIES AND OPERATING RESULTS ON THE MIAMI FLOOD CONTROL SYSTEM*

By C. H. Eiffert,† M. Am. Soc. C. E.

With Discussion by Messrs. C. S. Bennett, Morris Knowles, Walter M. Smith, B. F. Jakobsen, K. L. De Blois, E. S. Lindley, C. S. Jarvis, E. W. Lane, Charles H. Paul, and C. H. Eiffert.

Synopsis

The flood control system of the Miami Conservancy District, a description of which has been published,‡ consists of a combination of retarding basins and channel improvements. The dams and retarding basins are five in number, while channel improvements were carried out in eight cities and towns. The purpose of this paper is to state as fully as possible the results obtained thus far (1928) in the operation of the works of the District. The observations and measurements made to check the design are recorded.

The complete system has been in operation since 1922. Sufficient time therefore has not elapsed to make definite conclusions possible in all respects; but it is thought best to report at the present time and make known such information as is now available.

In general, the assumptions on which the designs of dams, conduits, and channels were based, have been confirmed. The discharge of the conduits under given heads has been somewhat larger than the quantities used in the calculations, but this was expected while the conduits were new. The outlet structures have fully met the requirements for dissipating the energy of the water as it leaves the conduits.

The improved channels at Dayton and Hamilton, Ohio, have maintained themselves better than was anticipated. The construction of cut-off channels

* Published in May, 1928, *Proceedings*.
† Chf. Engr., The Miami Conservancy Dist., Dayton, Ohio.
‡ *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1503.

has been justified. The dams at Dayton and Hamilton together with the gravel plants have greatly reduced the cost of channel maintenance.

Valuable information has been secured from the rainfall and run-off records. Additional information could be secured by the use of a number of recording rain gauges and recording back-water gauges at the dams.

Design

The flood-control works of the Miami Conservancy District are designed for a maximum flood 40% greater than that of 1913, although the studies which were made indicated that this maximum was larger than could occur in this locality. Should such a flood occur, however, it would just reach the spillways of the dams and in the improved channels it would reach maximum heights about 3 ft. below the tops of the levees. The system is so balanced that the maximum discharge through the conduits in the dams will not be greater than can be carried safely by the improved channels below. An important feature of the design is the fact that the flow through the conduits is not controlled by gates. These conduits are smooth open tunnels, the discharge being entirely automatic.

Some of the assumptions used in the design of the conduits and of the improved channels will be restated as it was to check these that measurements, observations, and investigations have been carried on.

Conduits.—The value of the roughness factor, n, in Kutter's formula used in the design of the conduits was 0.013. It was well known, of course, that the value for smooth concrete conduits was often lower than this, even as low as 0.010. It was thought possible, however, that the concrete surfaces would deteriorate somewhat in time, therefore 0.013 was considered a proper mean between conditions in the newly built conduits and those that might exist in the future.

In calculating the discharge through the conduits it was assumed that the only loss of head necessary to be considered was that due to friction. Every effort was made to design entrance and outlet portions of the structure to eliminate losses at these points.

In making the original discharge calculations the head was calculated from the top of the outlet end of the conduits. S. M. Woodward, M. Am. Soc. C. E., has reached the conclusion* that this head should be computed from a point somewhere between the extreme top and the average top of the outlet, although the exact point cannot be determined. In recalculating the discharge curves an elevation half way between the top and the average top has been used.

River Channels.—In designing the channel improvements, values of n from 0.0225 to 0.025 were adopted after a careful study of available data. The cross-section of the improved channels, in the more extensive channel improvements at Hamilton and Dayton, is a modified trapezoid (Fig. 1). This shape concentrates the low-water flow and is also satisfactory for high water. On the Miami River channel the width, *B-E*, varies from 530 to 650

* Technical Repts., The Miami Conservancy Dist., Pt. VII, p. 144.

ft.; the width, *C-D*, is 150 ft. in nearly all cases. The depth of maximum flow between Lines *A-F* and *C-D* is from 20 to 34 ft. Points *B* and *E* are, as a rule, 8 ft. above Line *C-D*. The low bottom, Line *C-D*, varies in its location relative to the sides. Where the channel is straight, it is in the center; on curves, it is nearer the concave bank.

Stream Flow Measurements

A most important factor in the hydraulic computations are the stream flow measurements. On this work the latest improved methods, as developed by the U. S. Geological Survey, are being used throughout. Measurements are made from cableways at the dams and from bridges in the cities. Price current meters with 50-lb. weights of the new low-resistance shape are used. Meter and weight are suspended by a single $\frac{1}{8}$-in. airplane cable, which greatly reduces the resistance due to the former double insulated cable. As the weight and meter cannot be raised and lowered conveniently by hand with a $\frac{1}{8}$-in. wire, a small windlass is attached to each of the cable cars and a light, portable, folding derrick with a windlass is used on the bridges.

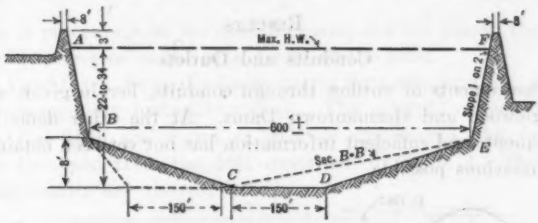

Fig. 1.—Typical Section of Improved Channel, The Miami Conservancy District.

Two men are required to take flood measurements. In most cases the use of the heavy weight and small cable eliminates the necessity of making corrections for the vertical angle; such corrections, however, are made when necessary. Current-meter readings are taken at 0.2 and 0.8 of the depth at 8 or 10-ft. intervals. Every possible precaution has been taken to eliminate error and the results appear to be very consistent.

In co-operation with the U. S. Geological Survey automatic recording gauges have been installed below the five dams and at the City of Hamilton. An automatic long-distance recorder for the river stage at Dayton is located in the District Office. Ordinary staff gauges, which are read daily, are maintained at a number of other locations by the District, the U. S. Geological Survey, and the U. S. Weather Bureau. The locations of all rain and river gauges are shown on Fig. 12.

The automatic gauges at the dams and at Hamilton are placed in concrete houses. The cost of these houses with their pipe intakes varies from $400 to $800, according to the nature of the excavation, length of intake, and height of house. The instruments themselves, known as the Au type of water-stage recorder, cost $200 each. They are very reliable, requiring attention not more than once a month. The pencil making the record is moved by

a float in the well under the gauge house and the motion of the paper on which the record is made, is controlled by a weight-driven clock.

The first two installations were made at the expense of the District. Later ones were made by the District while the instruments were furnished by the U. S. Geological Survey. All records obtained are used jointly by the District and the U. S. Geological Survey, the same being true of records obtained by the Geological Survey in other parts of the valley. Thus, more complete records are obtained than would be possible with either organization working alone.

The automatic recorder in the Dayton Office is a Stevens long-distance water-stage recorder. It consists of a sending apparatus located on a pier of the Main Street Bridge, with a recording apparatus located in the office of the District, all operated by 110-volt current. This instrument, while it is fairly satisfactory, requires more attention than the others.

Some special staff gauges have been installed in Dayton and Hamilton for the purpose of obtaining surface slopes during high water. The results will be used for making further calculations of the coefficient of roughness, n.

RESULTS

Conduits and Outlets

The measurements of outflow through conduits, herein given, are confined to the Englewood and Germantown Dams. At the other dams high stages are less frequent, and sufficient information has not yet been obtained to make definite conclusions possible.

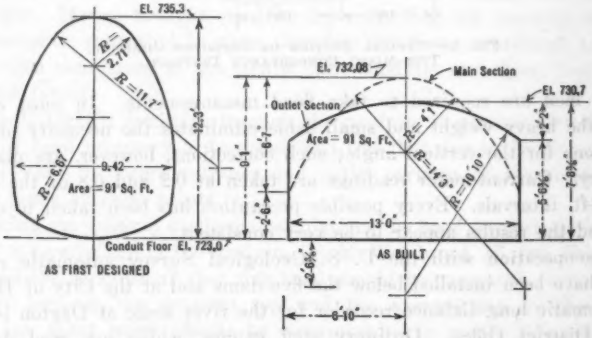

FIG. 2.—GERMANTOWN CONDUITS.

In Figs. 2 and 3 are shown comparisons of the shapes and sizes of the conduits used in the calculations for the Official Plan of the District, with those that were finally adopted and built. The areas are practically the same but, in the conduits as built at the Englewood and Germantown Dams, the sections change near the outlets (to help spread the jet) so that the top of the end of the conduit is 4.6 ft. lower at Germantown, and 4.44 ft. lower at Englewood, than in the original computations. This change, together with the fact that the point of zero head is being taken a little below the top of the

outlet portal rather than at the top, as was done originally, gives a greater head and, consequently, greater velocity and discharge for the same headwater elevations. The difference is most apparent for the lower heads. It

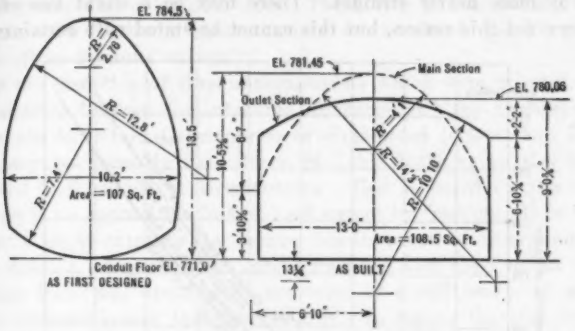

FIG. 3.—ENGLEWOOD CONDUITS.

becomes less in percentage as the head increases, for the reason that the theoretical velocity increases as the square root of the head.

In Figs. 4 and 5 are shown discharge curves for these conduits, and Table 1 gives the corresponding hydraulic values. The original curves used in the design with $n = 0.013$ are shown as well as new curves, the formulas for which were developed from the data contained in Table 2. The results of actual measurements are also platted.

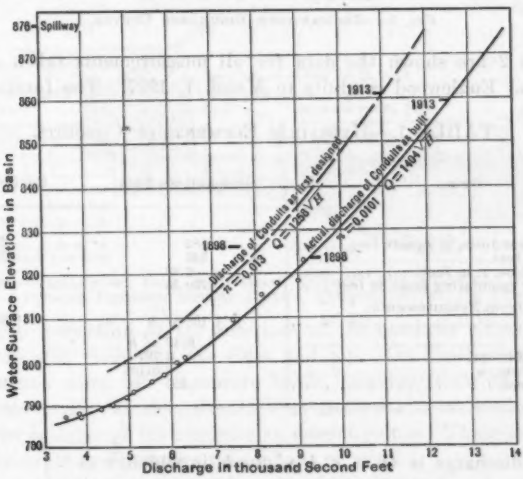

FIG. 4.—ENGLEWOOD DISCHARGE CURVES.

The roughness coefficient, n, is slightly greater for the Germantown than for the Englewood conduits (Table 1). This fact is difficult to explain,

as the interiors of the conduits at the two dams appear to be equally smooth. The entrance to the conduits at Germantown, however, is at one side of the valley and is curved; while that at Englewood is near the middle of the dam and is more nearly straight. There may be a slight loss of head at Germantown for this reason, but this cannot be stated with certainty.

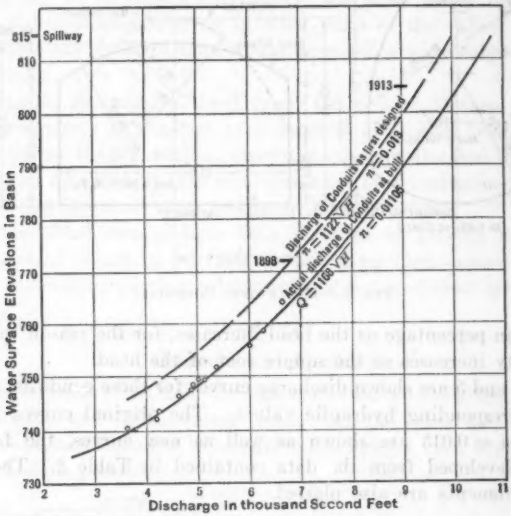

FIG. 5.—GERMANTOWN DISCHARGE CURVES.

In Table 2 are shown the data for all measurements taken at the Germantown and Englewood conduits to March 1, 1927. The formula used for

TABLE 1.—HYDRAULIC ELEMENTS OF CONDUITS.

Item.	Germantown Dam.	Englewood Dam.
Given Data:		
Area, A, two conduits, in square feet	182	217
Length, L, in feet	546	712
Hydraulic radius, r, in feet	2.43	2.71
Zero point for calculating head, in feet	730.35	779.7
Values Derived from Measurements:		
Discharge, Q	$1\ 168\sqrt{h}$	$1\ 404\sqrt{h}$
Velocity, V	$6.42\sqrt{h}$	$6.47\sqrt{h}$
Discharge coefficient, c	0.797	0.804
Kutter coefficient, n	0.01105	0.0101
Chezy coefficient, C	159	176

the conduit discharge is $Q = c\,A\sqrt{2\,g\,h}$, in which, $c = \sqrt{\dfrac{1}{1 + \dfrac{2\,g\,L}{C^2\,r}}}$; A is the cross-sectional area of the conduits, in square feet; h is the head; L, the length of the conduits, in feet; C, the Chezy coefficient; g, the acceleration

due to gravity; and r, the hydraulic radius. The values of c in Table 2 were obtained from the other factors, all of which were known. The values of n were then calculated. The final discharge formulas were developed by using the average value of c for each dam. These may be changed slightly in the future as more discharge measurements are obtained and as the interior surfaces of the conduits change.

With the exception of three measurements which were rejected, the maximum variation between the measured discharge and the discharge given by the formula for either Germantown or Englewood is less than 3 per cent.

As computed from the data shown in Table 2, the value of n is 0.0105 at Englewood and 0.01105 at Germantown. This is based on the assumption that there is no appreciable loss of head except by friction. It is quite probable that a slight entrance loss occurs, but its practical determination would be very difficult. Any such loss is now included with the friction loss and its separation therefrom would make the value of n still lower. A much lower value is improbable and, therefore, it is fair to assume that the entrance loss is insignificant.

The dissipation of the energy of the water as it leaves the conduits at a high velocity has been satisfactorily accomplished by means of the hydraulic jump and the outlet structure. For instance, at the Germantown dam, in the flood of September 2, 1926, the velocity in the conduits at the time the discharge measurement was taken, was 34.6 ft. per sec. At the end of the outlet structure the average velocity was only 7.9 ft. per sec. In Fig. 6 are shown the elevations of the tail-water for various heads at the Germantown Dam.

FIG. 6.—GERMANTOWN DAM, THE MIAMI CONSERVANCY DISTRICT, HIGH-WATER PROFILE THROUGH OUTLET WORKS, SHOWING HYDRAULIC JUMP.

A careful inspection of the interiors of the conduits shows the finishers' brush marks still visible on the sides and top. On the bottom, the surface finish has been worn off. Accurate levels, however, show that the wear is scarcely measurable at this time. Very accurate cross-sections have been taken of the interior of the conduits at several points. These will be repeated annually in order to determine the amount of wear.

Re-Routing Floods.—In making the original studies for the retarding basins a number of past floods were routed through these basins.* The

* A complete description of the routing of floods is given in "Hydraulics of the Miami Flood Control Project", by Prof. Sherman M. Woodward, Technical Repts., The Miami Conservancy Dist., Pt. VII.

maximum elevations reached and the length of time required for the basin to empty were calculated for each flood.

From the information now available it is evident that, due to the greater capacity of the conduits, these floods would not rise as high in the basins as calculated and that the time required to empty the reservoirs would be reduced. The 1913 and the 1898 floods, therefore, were re-routed through the Englewood Basin. The calculations show that the maximum elevation for the 1913 flood would be reduced 1.9 ft. and for the 1898 flood, 2.7 ft.

Drift.—When the plans for the dams were first developed, it was thought that some kind of drift barriers would have to be provided above the con-

duits, but, later, it was decided that these would be unnecessary. Experience thus far indicates that they are not needed. Drift reaches the conduits mostly during the early stages of a flood. During the intermediate and high stages the velocity in the basin is very low and the drift is carried about by the wind. That reaching the conduits during the first stages is usually light material and passes through easily. By the time the water is deep enough to carry large trees, the velocity has been reduced so that very few of these reach the dam.

There has never been any tendency to clog up the conduits. A number of times, as a flood went down, drift was left on the center wall. In all cases, however, this material would easily have passed through the conduits under a considerable head. As an extra precaution against the accumulation of drift, the caretakers go over their respective basins during the fall and winter and cut all "down timber" into short lengths that will pass through without difficulty.

Channel Improvements

The most extensive channel improvements were made at Dayton and Hamilton. The waterways were straightened, widened, and deepened and made more uniform in cross-section and regular in alignment. The condition of the channels at present is excellent, although there have been some slight changes. The stability of these channels has been greatly increased by the low concrete dams at Island Park and Wolf Creek, in Dayton, and at Twomile Creek, in Hamilton; and by the operation of gravel plants in both cities. These plants, above the limits of the improvements, dig large quantities of gravel from the river bed. The excavations thus made serve to catch most of the gravel carried down stream during floods and prevent its deposit in the improved channel. Besides saving maintenance expense, the District obtains some revenue from the sale of the gravel.

Some of the changes in cross-section of the improved channels are illustrated in Figs. 7 and 8. In Dayton there has been considerable deposit above the Island Park Dam. Fig. 7 shows a section 100 ft. above the dam (taken in 1916 before the dam was built), another in 1923, and a third in 1926. The progressive filling indicates that it will not be long until material will begin to pass over this dam and enter the channel below. However, the material deposited here seems to be rather fine and possibly may be carried on through the improved channel. Small bars have formed at other points in Dayton but, taken as a whole, the sections show the remainder of the channel to be practically as built.

At Hamilton a bar has formed below the dam, probably due partly to the gravel carried over. This material is now being removed by the Hamilton Gravel Company as part of its regular operations. Below the railroad bridge the channel widens causing a considerable deposit along the west side (Fig. 8). The alignment here was made to fit the original bank for economy in construction. Such a deposit would not occur in a channel of uniform width and more regular alignment. A flood somewhat larger than those which have occurred, may remove it.

A flexible revetment is used as protection against erosion. This consists of concrete blocks, 5 by 12 by 24 in., each reinforced and cast with two transverse holes. The blocks were manufactured at a central plant. They are held together by ½-in. galvanized steel cables, the ends of which are embedded in the toe-wall of the monolithic slope revetment on the land side, and in the larger blocks, cast in place, on the river side. A detail drawing of this revetment has been published.* As scouring occurs, this revetment settles to a depth where further scour is prevented.

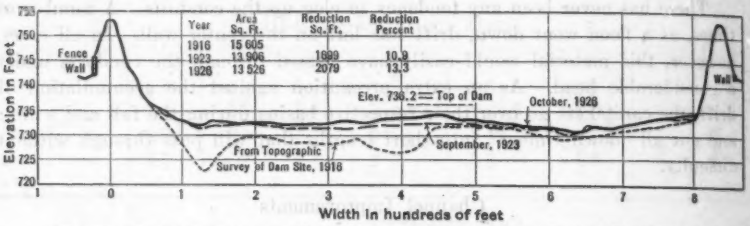

FIG. 7.—CROSS-SECTIONS OF MIAMI RIVER 100 FEET ABOVE ISLAND PARK DAM.

Value of n for Channels.—The discharge measurements made thus far in Dayton and Hamilton show the coefficient of friction, n, to vary from approximately 0.015 to 0.0285. The larger value was obtained at Dayton with a gauge height of 9 ft. At this stage the water just covered the entire bottom from toe to toe of the levees, the depth varying from 0 at the sides to 8 or 10 ft. in the center, over a width of about 600 ft. The lowest value of n obtained was 0.015; this was above the Main Street Bridge, at Hamilton, at a 12.4-ft. stage. The channel here is straight, has a uniform width of 520 ft., and a smooth bottom practically free from grass or weeds, with concrete revetment on the slopes.

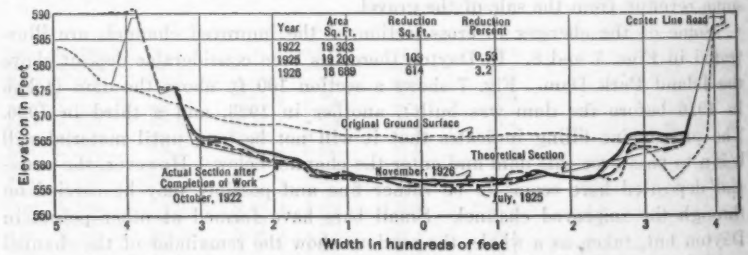

FIG. 8.—CROSS-SECTIONS OF MIAMI RIVER AT STATION 72 + 00, HAMILTON, OHIO.

The detailed procedure in making two determinations of the value of n was as follows: In the storm of March 19 to 21, 1927, the stage of the river at Dayton stayed close to the 12-ft. mark for about two days. The discharge was measured at the Main Street Bridge while the average gauge height was 12 ft. This discharge, 38 300 sec-ft., was used in the computations. Permanent gauges reading to sea-level elevations had previously been installed above and below the Main Street Bridge as shown in Fig. 9(*a*). These gauges were

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), Fig. 35, p. 1508.

read before, during, and after the discharge measurement, the entire set being read five times; three times by the man who took the discharge measurements, and once each by two other men independently.

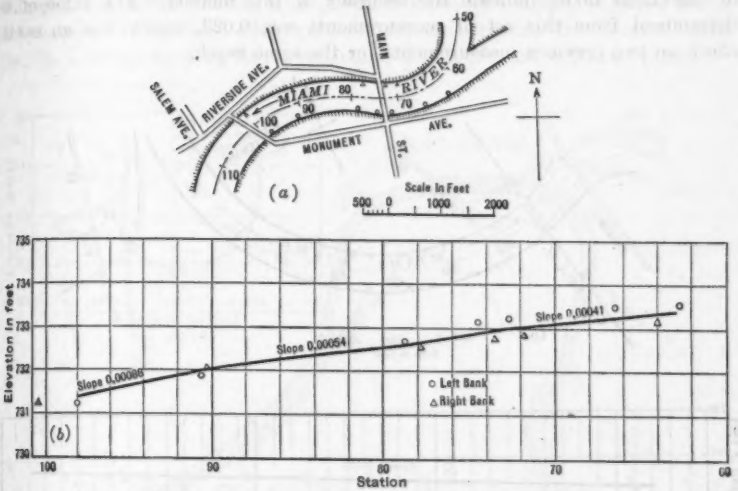

FIG. 9.—HIGH-WATER PROFILE, STATION 63 + 00 TO STATION 98 + 00, THE MIAMI CONSERVANCY DISTRICT, MARCH 21, 1927.

It was recognized that the chief difficulty lay in obtaining accurate slope measurements, and considerable care was taken in obtaining the readings. As each set of slope gauge readings was made, the Main Street river gauge was also read. As there was only a small variation in the gauge height during this time, the surface slopes were practically parallel. Therefore, all slope gauge readings were corrected by addition or subtraction to reduce them to a 12-ft. stage. The five readings for each gauge were then averaged to obtain the final figure. The slope profile was then platted for both sides of the channel, and the slope used in the determination of n was taken as a mean between the surface elevations on the two sides.

This surface slope was used in determining the cross-sectional areas. Accurate cross-sections at 100-ft. intervals were available. Only part of these were used, however, as the areas are quite uniform and the changes gradual. Fig. 9(*b*) shows the final water surface profile. To determine n, three reaches were used, as shown. The slope, hydraulic radius, and velocity having been determined, the value of n was taken from a diagram for the solution of Kutter's formula. For this part of the river it averaged 0.027.

Perhaps the most satisfactory determination was made on a reach of about 3 000 ft. below Stewart Street, at Dayton. Here, the channel is of uniform section throughout and of uniform curvature, with a radius of 4 093 ft. on the center line. The profile in this case was determined by driving stakes flush with the water surface every 200 or 300 ft. on both sides of the channel. While these stakes were being driven the gauge height at Main Street was

11.9 ft. Levels were read on the stakes and the elevations corrected for the 12-ft. stage at which the discharge measurement was taken. The resulting profile is shown in Fig. 10(*b*). The uniformity of the slope and the number of elevations taken indicate the accuracy of this method. The value of n determined from this set of measurements was 0.023, which was an exact check on two previous measurements for the same reach.

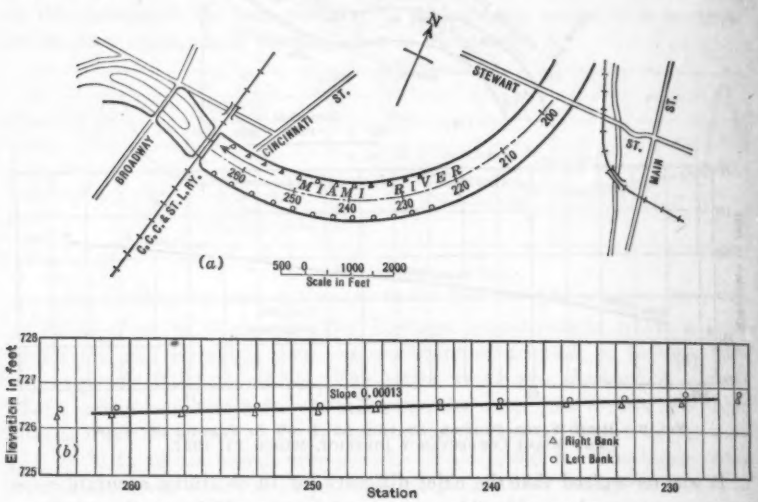

FIG. 10.—HIGH-WATER PROFILE, DAYTON, OHIO, MARCH 21, 1927.

Taking the channels at Dayton and Hamilton as a whole, the average value of n appears to be below that used in the design, and therefore the channel capacity will be somewhat greater than provided by the plan. It is reasonable to assume that at higher stages the values of n will be less than those obtained from the measurements made thus far.

Cut-Off Channels.—At a number of points where more extensive channel improvements were not warranted, cut-off channels were required to facilitate the flow. These were built of small cross-section on the assumption that they would be enlarged by scouring. Each of them reduces the length of the channel, thereby increasing the grade and the velocity. Such channels are located at Troy, Dayton, Poasttown, Middletown, and Hamilton.

The Troy cut-off channel (Fig. 11) is 4 000 ft. long. The original bottom width was 40 ft. which has increased to about 65 ft. Depth and alignment have been well maintained. It assists greatly in passing the water through the City of Troy and its capacity, of course, will continue to increase. The protection levee for the city is located close to this channel for some distance and as the channel is widening about equally on both sides some bank protection may be necessary along the levee.

In constructing this channel the bank nearest the levee was cut on a 2 to 1 slope while the other bank was made vertical. It was thought that cutting

would occur mostly on the vertical side and that the 2 to 1 slope would remain intact. The cutting has actually been about equal on the two sides.

The cut-off channel at the Broadway Bridge, just below Dayton, has not enlarged, due to the fact that it is rather close, and nearly parallel, to the old channel. It has been effective, however, in increasing the channel capacity. In a severe flood no doubt considerable enlargement will take place.

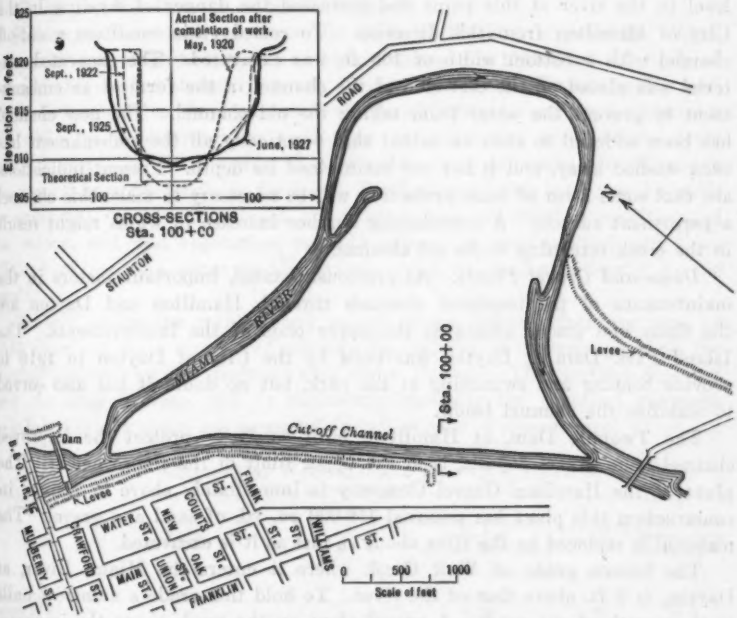

FIG. 11.—CUT-OFF CHANNEL, TROY, OHIO.

A rather remarkable result was obtained north of Middletown on a bend in the river just above the Poasttown Bridge. Here, no excavating was done. The timber was cleared from a strip where a cut-off channel would naturally be located and the river has cleared the remainder. This channel gives the river a more direct approach to the bridge and protects the road on the east, which otherwise would be endangered by scouring.

Opposite Middletown, the Miami River is in the form of a big bend. The overflow area is large, extending, in high water, to the railroad on the west. A concrete bridge about 1 800 ft. long crosses almost the entire bottom. The alignment of the old channel greatly retarded the flow and considerable scour was taking place along the east bank. A cut-off channel with a bottom width of 40 ft. was constructed. At first, only a small part of the flow passed through this channel, but it has been enlarged by floods to such an extent that the cross-sectional area has increased 110% and it now carries the entire low-

water flow and a large proportion of the flood flow. It has also eliminated the scouring along the east bank of the old channel. In this case the results have probably exceeded the expectations of the designers.

Prior to the execution of the District's plan a bad situation existed north of Hamilton, near the mouth of Fourmile Creek, which has a drainage area of 178 sq. miles. The direction of flow of this creek was almost directly opposite that of the river. The retarding action resulting raised the water level in the river at this point and increased the danger of flooding in the City of Hamilton from this direction. To remedy this condition a cut-off channel with a bottom width of 100 ft. was excavated. The excavated material was placed on the east side of the channel in the form of an embankment to prevent the water from taking the old channel. The new channel has been widened to such an extent that practically all the embankment has been washed away, and it has not maintained its depth. Present indications are that some form of bank protection will be necessary to make this channel a permanent success. A considerable further increase in width might result in the creek returning to its old channel.

Dams and Gravel Plants.—As previously stated, important factors in the maintenance of the improved channels through Hamilton and Dayton are the dams and gravel plants at the upper ends of the improvements. The Island Park Dam at Dayton was built by the City of Dayton in 1916 to provide boating and swimming at the park, but no doubt it has also served to stabilize the channel below.

The Twomile Dam, at Hamilton, built solely to protect the improved channel from gravel deposit, is at the upper limit of the improvement. The plant of the Hamilton Gravel Company is immediately above it. Since its construction this plant has removed 156 000 cu. yd. of sand and gravel. The material is replaced by the river about as fast as it is excavated.

The bottom grade of Wolf Creek where it enters the Miami River, at Dayton, is 5 ft. above that of the river. To hold this grade a dam was built at the mouth of the creek. A gravel plant on the creek above the improvement helped to maintain the channel. This plant was abandoned after about 42 000 cu. yd. had been removed. Gravel was not carried down fast enough to supply the plant, for the reason that material was being taken out in large quantities about ½ mile farther up stream.

Gravel plants were located also on Mad River, below Webster Street and below Findlay Street in Dayton. The former has been abandoned, at least temporarily, because the supply was exhausted. It removed a total of about 57 000 cu. yd. Two plants are operating below Findlay Street. They have moved approximately 222 000 cu. yd. to date (1928).

The plants operating on District property have removed from the river a total of 477 000 cu. yd. since the early part of 1922. There can be no doubt that much of this gravel would have passed down stream had it not been removed. A large part of it would certainly have stopped in the improved channels and its removal would cost probably not less than 75 cents per cu. yd.

Rainfall and Run-Off

The District maintains rain gauges at all the dams and at a number of other points. The U. S. Weather Bureau also has gauges in various cities in the Miami Valley. The reports from all these stations are used co-operatively by the District and the Weather Bureau. All rainfalls of more than 1 in. in 24 hours are reported by telephone or telegraph. Other rainfall reports are sent in weekly or monthly by mail. The map, Fig. 12, shows the location of all the gauging stations in the water-shed.

No storms have occurred, since the works of the District were completed, approaching in magnitude the one which produced the 1913 flood. A study of some of the smaller storms, however, is of value. The difference in the percentage of run-off in these storms is of special interest, because it illustrates the difficulty encountered in predicting or estimating river stages from rainfall data. In other words, it shows that it is impossible to determine the run-off by a fixed rule or formula. Predictions of this kind may be made by using the records of the past, but in each case the existing conditions of the season, soil, and vegetation, must be taken into consideration and a coefficient of common sense and judgment must be applied liberally to the result.

Table 3 shows the rainfall and run-off above Dayton, from an area of 2 525 sq. miles, for a number of storms. The rainfall is the average of all the rainfall stations on the drainage area above Dayton. This method does not give the true average, but is sufficiently accurate for practical purposes. Rainfall contour maps are prepared for all storms of importance.

TABLE 3.—Relation of Rainfall and Run-Off, Dayton, Ohio.

Date.	Average rainfall, in inches, above Dayton.	Run-off, in inches.	Run-off, in percentage of rainfall.
March 23-27, 1913	9.60	8.76	91.0
March 28-29, 1924	2.06	1.16	56.0
June 8, 1924	2.22	1.73	78.0
Sept. 12-13, 1925	3.20	0.04	1.25
Nov. 12, 1925	1.43	0.66	46.0
Nov. 26-27, 1925	1.29	0.20	15.6
April 7-8, 1926	1.23	0.84	68.0
March 19-21, 1927	3.44	2.31	67.0

The run-off is determined by reducing the daily gauge heights at Dayton to discharges, in cubic feet per second, and platting a curve of the daily discharges for the storm period. The area included between this curve and a line showing the normal discharge is then measured and the result reduced to inches of rainfall over the drainage area.

A study of the records of the storms of September 12 and 13, 1925, and March 19 to 21, 1927, discloses a remarkable contrast. The average rainfall above Dayton for the two storms was 3.20 and 3.44 in., respectively. The run-off for the storm of September 12 and 13, 1925, was 0.04 in., or 1.25% of the rainfall. For the storm of March 19 to 21, 1927, the run-off was 2.31 in., or 67% of the rainfall.

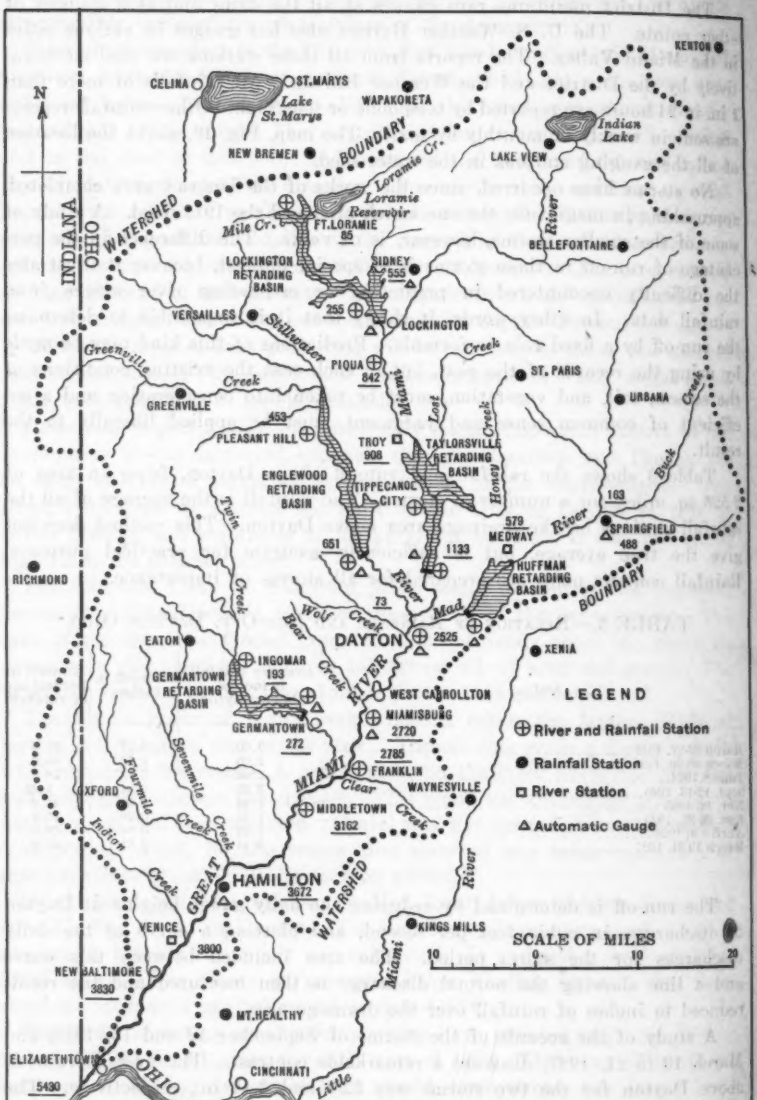

FIG. 12.—DRAINAGE AREA, SHOWING GAUGING STATIONS, MIAMI RIVER, OHIO.

The storm of September 12 and 13, 1925, was of shorter duration. The precipitation for 24 hours at several stations was greater than for any 24-hour period of the 1913 flood. Other things being equal, this would have caused the run-off for this storm to be the greater of the two. However, there was no back-water at any of the dams and the maximum stage reached at Dayton was 2.9 ft.

After the storm of March 19 to 21, 1927, all the dams had back-water, the depths being, at Englewood 48 ft.; Taylorsville, 26 ft.; Huffman, 16 ft.; Lockington, 32 ft.; and Germantown, 29 ft. The maximum stage recorded at Dayton was 12.8 ft. and at Hamilton, 14.3 ft.

The rainfall and run-off curves for both storms are shown in Fig. 13. Unquestionably the difference in run-off was due to the difference in soil conditions. The storm of September, 1925, came at the end of the growing season and following a dry period during which the transpiration and evaporation had been abnormally great. At the beginning of this period there was a deficiency in rainfall of about 5 in. These factors combined to give the soil a tremendous storage capacity. Preceding the storm of March, 1927, there had been little evaporation and there was no growing vegetation to consume moisture. To November 1, 1926, there had been an excess of 5.79 in. in rainfall since the beginning of the year.

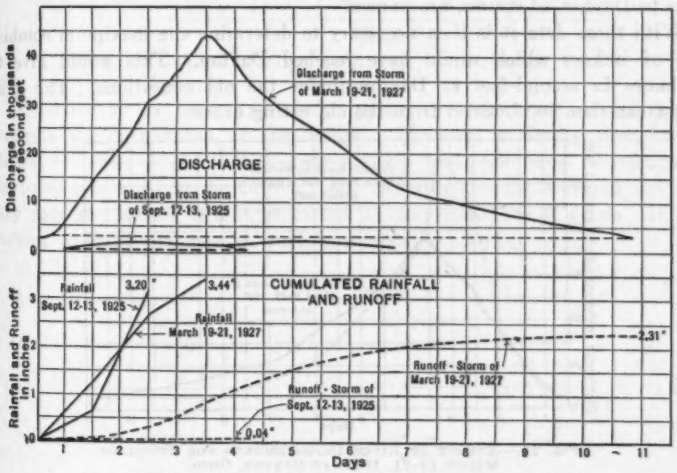

FIG. 13.—STUDY OF RAINFALL AND RUN-OFF, DAYTON, OHIO.

On October 2, 1925, an unusually heavy rain occurred over the drainage area of Clear Creek. This creek, which enters the Miami River just below Franklin, has a drainage area of 52 sq. miles. Following the storm numerous inquiries were made from residents and the information obtained showed the average rainfall for the area to be 4.3 in., with a maximum of 5¼ in. The rainfall occurred between midnight and 9:00 A. M. Surface slopes were determined from high-water marks west of the Dixie Highway Bridge, at Franklin,

and the maximum discharge was calculated to be 10 000 sec-ft., or about 200 sec-ft. per sq. mile. It was not possible to obtain sufficient data to determine the total amount or percentage of run-off.

After high water under present conditions the question is often asked: "What would have happened under the old conditions?" The answer involves an interesting study. It is assumed that the maximum stage at Dayton would be produced by the maximum combination of the inflows into the Englewood, Taylorsville, and Huffman Basins. The run-off from the area below these basins, which would affect the maximum stage at Dayton, will, in most cases, be negligible. In practically all storms this run-off passes Dayton before the maximum stage is reached. It is, therefore, disregarded in these calculations.

During high water the back-water gauges at the dams are read every 2 hours. From the contour maps of the basins a tabulation of the storage capacities of each basin, for various elevations, has been made. From these and the 2-hour readings, together with the outflow record, the total amount of inflow for each 2-hour period can be determined. From this the maximum inflow, in second-feet, is obtained.

From former studies the rate of flow in these rivers was found to be from 3½ to 4 miles per hour. The distances along the rivers from the three dams to Dayton, of course, are known.

With these data it is then necessary to determine the maximum combination of inflows which would have reached Dayton. This would give the discharge in second-feet at Dayton under the old conditions. The gauge height can then be obtained from the old rating curve.

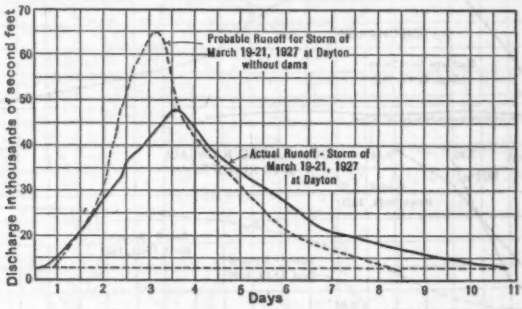

FIG. 14.—EFFECT OF RIVER IMPROVEMENTS FOR STORM OF MARCH 19-21, 1927, AT DAYTON, OHIO.

This method was applied to the storm of March 19 to 21, 1927, the results being shown in Fig. 14. The solid line shows the run-off as it actually occurred at Dayton; the dotted line represents the run-off as it would have taken place before the flood-control works were built. It is to be noted that the peak discharge under former conditions would have been 45% greater and would have occurred about 5 hours earlier.

The maximum gauge height at Dayton was 12.8 ft. In the old channel the actual elevation of the water surface would have been 6.9 ft. higher

The difference in the two peaks at Dayton will be much more pronounced in a larger flood for the reason that the velocities and discharges through the conduits at the dams vary approximately as the square roots of the heads.

Fig. 15 shows the inflow, outflow, and elevation curves for the March, 1927, storm at Englewood. These curves show that at this point alone the peak discharge was reduced from 22 300 to 9 000 sec-ft.

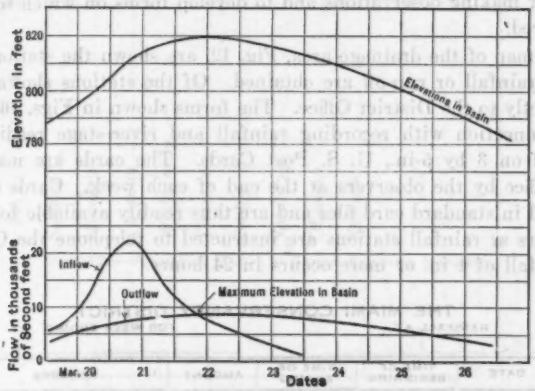

FIG. 15.—FLOOD OF MARCH 19-21, 1927, AT ENGLEWOOD, OHIO.

As stated at the beginning of this paper, the experience gained thus far confirms the correctness of the design. However, sufficient time has not elapsed to make definite conclusions possible along all lines. Investigations are to be continued in the future. The opportunities for securing the necessary data are limited to a large extent by the occurrence of floods. It is the purpose to make the most of such opportunities as they occur.

DISCUSSION

C. S. BENNETT,* M. AM. SOC. C. E. (by letter).—Some details of the manner of obtaining and recording data for use in studies of the operation of the flood control system of the Miami Conservancy District may be of interest. In order to systematize the work it became necessary to adopt certain standard methods for making observations and to develop forms on which to record the data gathered.

On the map of the drainage area, Fig. 12, are shown the stations at which records of rainfall or run-off are obtained. Of the stations shown, seventeen report directly to the District Office. The forms shown in Figs. 16 and 17 are used in connection with recording rainfall and river-stage readings. They are printed on 3 by 5-in., U. S. Post Cards. The cards are mailed to the District Office by the observers at the end of each week. Cards of this size may be filed in standard card files and are thus readily available for reference. All observers at rainfall stations are instructed to telephone the Office whenever a rainfall of 1 in. or more occurs in 24 hours.

FIG. 16.—FORM FOR WEEKLY PRECIPITATION REPORTS.

Studies are made of every major storm that occurs. To facilitate the collection and use of data for these studies forms such as Figs. 18 and 19 were devised. Fig. 18 is used by the observers at the dams. From the time that the outlet conduits are half full until the stage falls again to that elevation, readings are made every 2 hours at the gauges above and below the dam. A series of staff gauges have been placed on or near the up-stream slope of each dam at convenient locations, the range of these gauges extending from the elevation of the mid-point in the conduit to spillway crest elevation. Below the dams are automatic recording gauges, near which staff gauges are located in the stream. The latter are read by the observers during times of high water, such readings serving as a check on the automatic recorder. From these it is possible to construct inflow and outflow curves for the storms to be studied.

FIG. 19.—FORM FOR RECORDING STORM DATA.

On the form, Fig. 19, are recorded the essential data for each storm. In connection with this a rainfall map is prepared. The observed rainfall at each station is noted on the map and rainfall contours or isohyetals are drawn in. The average rainfall and run-off are computed usually only for the Dayton Station. Average rainfall may be obtained by planimeter from the contour map or by using the mean of the recorded values above Dayton.

FIG. 20.—FORM FOR RECORDING DATA ON SILT DEPOSITS.

It has been found that the latter method is fairly accurate. The run-off is obtained by measuring, with planimeter, the area under a curve constructed from the river-stage record at Dayton for the period of the storm. Maximum run-off in 24 hours may be obtained also from this curve. Maximum discharges at the various river stations are obtained from the rating curves for those stations. Maximum inflow and outflow at the dams are obtained from curves prepared from data contained on the observers' record (Fig. 18) and from the rating curves at stations just below the dam.

A number of silt-catching boxes have been installed in two of the basins near the dams.* Soon after the subsidence of stored water after each major storm, measurements are made of the silt content within the boxes and on the projecting bases. The data thus obtained are recorded on the form similar to Fig. 20 and these are filed for future use. A number of cross-sections have been taken across the valleys near the silt boxes. At intervals of a year or more, these sections will be repeated and platted to a fairly large scale so that the quantity of silt remaining as a permanent deposit may be measured.

Discharge measurement notes, rating tables, records of daily discharge, and other data secured in connection with stream-flow records are arranged on standard forms of the U. S. Geological Survey, because such information is used jointly by the Geological Survey and the District.

MORRIS KNOWLES,† M. AM. SOC. C. E. (by letter).—This paper is an interesting contribution to the already voluminous literature on flood protection works. Its value, however, lies in the fact that it presents actual data on results of works already constructed. There has been a paucity of these data and they are the kind of which the profession should have more, as a guide to the design of future plans of controlling devastating floods.

As the author states, the period of six years since the completion of the Miami System is not long enough to warrant final conclusion, but the observations so far obtained are of value in two respects: They demonstrate that the basic formulas involved in the original studies and the method of attacking the problem have been sound. Of additional interest are the observations which have been made with great care to determine values of the roughness factor, n. Even with the data already at hand, additional values for this factor are always desirable, particularly for improved channels, as in this case.

It is to be noted that observed values of n for the improved channels ranged from 0.015 to 0.0285, but most of them were of the higher values. The low value of 0.015 has been readily explained. The originally adopted values were from 0.0225 to 0.025. The higher figures obtained from observation more nearly approach the value of 0.030 which has often been used as a general criterion for natural river channels of large sizes. Studies recently made along the Ohio River show values for this coefficient ranging from 0.035 to 0.047 in the main channel. These are, of course, in an unimproved reach of the Ohio.

* See discussion by C. H. Elfert, M. Am. Soc. C. E., on the paper entitled "Silting of the Lake at Austin, Texas," by T. U. Taylor, M. Am. Soc. C. E., in this volume of *Transactions*.

† Pres. and Chf. Engr., Morris Knowles, Inc., Pittsburgh, Pa.

The retarding basins, which formed the major parts of the Miami project, have demonstrated their effectiveness. While they are a departure from the generally accepted idea of storage basins, they have shown their value in cutting down peak flows, in distributing the flow over a longer period, and in demonstrating the fact that their operation is entirely automatic. The design of the conduits through the dams has been found to be sound and here, again, some interesting observations upon the value of n have been obtained, which check very closely those used in the design.

The engineers of the District are to be commended for thoroughness in obtaining rainfall and run-off data, and for the provisions being made for securing more of this information by additional stations. It is wisely pointed out that it is impossible to determine run-off from rainfall by any fixed rule or formula. The careful observations of all the factors entering into the determination of run-off will be of great value to those who do not have the facilities, either in time or money, to obtain the detailed field data for similar studies in other localities.

One of the most interesting features of the entire paper is that part which compares the actual run-off at Dayton, which occurred in March, 1927, with the probable run-off without the improvements. A reduction of 27% in the peak flow, which might have taken place, represents considerable less possible flood damage. The retarding basins and channel improvements along the Miami River have already proved beneficial to the District and from observed data it is apparent that the 1913 disaster can never be repeated.

Walter M. Smith,* M. Am. Soc. C. E. (by letter).—The writer has read this paper with a great deal of interest, because the dams, conduits, and spillways on that work were all designed under his direction. It is very gratifying to know that the six years of operation have justified the design and construction of the project as a whole as well as the individual units.

The writer has always had the idea that the value, $n = 0.013$, for the conduits would prove too high and that, therefore, more water would be discharged and less held in storage than the computed quantity. The concrete of the conduits was made very rich in cement—about 2 bbl. per cu. yd. of concrete—in order to secure a very dense and hard concrete that would resist abrasion and a growth of any kind of moss or other material. The material carried through the conduits during floods will naturally scour the floor somewhat, but should not affect the other parts of the surface. Therefore, the roughness factor, n, should not change very much over a long period. It is customary, in water supply or sewer computations, to assign to n a value a little higher than is ever expected in order to provide a factor of safety. In the case of the Miami Conservancy work, however, assigning too large a value to n does not give a factor of safety, but just the reverse. For example, the actual flow through the Englewood conduit, as given in the paper, is 14½% greater than as computed. Should this same ratio hold good at the Taylorsville and Huffman Dams, the total flow for the maximum flood through Dayton would be about 114 000 sec-ft. plus the accumulated flow below the dams, instead of

* Asst. Chf. Designing Engr., Div. of Waterways, State of Illinois, Chicago, Ill.

about 100 000 sec-ft. plus this flow. As the channels through the towns were designed and built to accommodate the computed flow, this additional flow might cause damage.

It is regrettable that the author does not give results of observations at the Taylorsville and Huffman sites if they have been made, because the flow from these two sites combined is 7½ times as great as that at Englewood. If none has been made, it would seem that in view of results at Englewood, observations at these two sites should be taken at as early a date as possible.

With regard to entry loss of head the conduits in all cases were built with a carefully designed bellmouth to prevent, not only loss of head at entrance, but to prevent vibration and booming caused by entrapping air just inside the entrance as would happen if the entrance had been built with a sharp edge. The vertical section through the Germantown conduit (see Fig. 6) shows this entrance with a very slight rounding, much less than it really has. As the author has not mentioned any trouble from vibration or booming at the entrances it is assumed by the writer that the bellmouth entrance is properly designed. This was one of the most serious features of the design and one of those most carefully studied.

B. F. JAKOBSEN,* M. AM. SOC. C. E. (by letter).—Table 1 shows that the roughness coefficient, n, in Kutter's formula is about 10% greater for the Germantown conduit than for the Englewood conduit and that the Chezy coefficient, C, is about 10% greater for the Englewood conduit. Kutter's formula has been derived largely from tests on open channels and the Chezy formula has been superseded by others which do not show a linear relation between r, the hydraulic radius, and h_f, the friction head.

The carefully made measurements afford an opportunity to check the formula for friction head, for water flowing with high velocity in a large conduit. On the assumption, made by the author, that the entrance loss is negligible, the total head is consumed, partly as velocity head and partly as friction, or,

$$h = \frac{v_a^2}{2g} + h_f \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which,

h = total head, in feet;
v_a = actual velocity, in feet per second;
$2g = 64.36$; $\sqrt{2g} = 8.023$; and
h_f = friction head, in feet.

The theoretical velocity head is $\frac{v_a^2}{2g}$ on the assumption that v_a is constant for the entire section. The friction head is,

$$h_f = \frac{m}{2g} \frac{v_a^n}{(4r)^x} L \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which, L = length of conduit, in feet; r = hydraulic radius, in feet; and m, n, and x are constants. For new cast-iron pipe, Unwin gives,† $m = 0.0215$;

* Cons. Engr. (La Rue & Jakobsen), Los Angeles, Calif.
† "A Treatise on Hydraulics," 1912, p. 217.

$x = 1.168$; and $n = 1.95$. Assuming, however, that $n = 2$ (since that checks closely with the results found) and combining Equations (1) and (2):

$$h = \frac{v_a^2}{2g}\left(1 + \frac{m\,L}{(4\,r)^x}\right) \quad \ldots\ldots (3)$$

Let,

$$k = \frac{m\,L}{(4\,r)^x} \quad \ldots\ldots (4)$$

so that,

$$h = \frac{v_a^2}{2g}(1 + k) \quad \ldots\ldots (5)$$

or,

$$v_a = c\sqrt{2\,g\,h} \quad \ldots\ldots (6)$$

in which, c is the author's constant in Table 1. From Equations (5) and (6) it follows that,

$$c = \frac{1}{\sqrt{1+k}}, \text{ or } k = \frac{1}{c^2} - 1 \quad \ldots\ldots (7)$$

If Equation (6) is written,

$$c = \frac{v_a}{\sqrt{2\,g\,h}}$$

and it is assumed that every value of c thus determined from corresponding measurements of v_a and h_1 is equally probable, then the principle of least squares demands, that,

$$\sum\left(\frac{v_a}{\sqrt{2\,g\,h}} - c_m\right)^2 = \text{minimum} \quad \ldots\ldots (8)$$

in which, c_m is the most probable value of the constant, c. If N is the number of tests, then,

$$c_m = \frac{1}{N}\sum\frac{v_a}{\sqrt{2\,g\,h}} = \frac{1}{N}\sum c \quad \ldots\ldots (9)$$

or c_m is the arithmetic mean of all values of c. It would probably be more correct to derive c_m from Equation (5). This requires more work and the value thus found differs only by about 0.1% from the arithmetic mean used by the author. The probable error of c_m is given by,

$$e = \frac{2}{3}\sqrt{\frac{\Sigma\,(c - c_m)^2}{N\,(N-1)}} \quad \ldots\ldots (10)$$

and the probable error of one measurement is,

$$e_1 = \frac{2}{3}\sqrt{\frac{\Sigma\,(c - c_m)^2}{(N-1)}} \quad \ldots\ldots (11)$$

The values of L and r for the two conduits are given in Table 1. From these are obtained for the Germantown conduit, $c_m = 0.79708$; $e = 0.0027$; and $k = 0.5740$, whereas for the Englewood conduit, the values are $c_m = 0.8043$; $e = 0.0026$; and $k = 0.5458$.

For the Germantown conduit the probable error of the mean is $\frac{0.27}{0.797}$ = 0.34% and if the average velocity measured is about 7 ft. (since, presumably, the high velocities in the conduits were not actually measured), the error of the average is $7 \times 0.0034 = 0.0238$ ft. per sec. and the probable error of a single measurement is $\sqrt{12}$ times that, or 0.0825 ft. per sec. For the Englewood conduit about the same results are obtained. This indicates that the measurements were carefully made and that the friction head varies nearly as the square of the velocity.

The constant, m, can now be determined from Equation (4). That gives for the Germantown conduit,

$$m = 0.5740 \times \frac{14.24}{546} = 0.01497$$

and, for the Englewood conduit,

$$m = 0.5458 \times \frac{16.14}{712} = 0.01222$$

Both values are much smaller than the value given by Unwin for cast-iron pipe, and the value for the Germantown conduit is about 20% greater than that for the Englewood conduit. If this is to be accounted for by entrance loss, as the author suggests, assuming that there is no such loss in connection with the Englewood conduit and that $m = 0.01222$ for the Germantown conduit, then,

$$h = \frac{v_a^2}{2g}\left(1 + 0.1222\,\frac{546}{14.24} + C\right)$$

Taking an average test, as, for example, $h = 18.55$ and $v_a = 27.2$, then, $1.614 = 1 + 0.468 + C$, or $C = 0.145$; that is, 14.5% of the velocity head is absorbed as entrance loss, or the entrance loss of the Germantown conduit is $\frac{0.145}{0.468}$, or 31.0% of the friction head, or the entrance head gives a loss equal to about 169 ft. of conduit.

The two conduits are built alike; the area of the Germantown conduit is 2 by 91 sq. ft. and that of the Englewood is 2 by 108.5 sq. ft. It seems unlikely that the constant, m, should vary 20% when determined from measurements on conduits that are so nearly similar. The entrance head of 14.5% seems also excessive, especially in view of the author's opinion that the entrance loss at both conduits should be very small. The writer hopes the author will be able to throw some light on this matter. He may possibly have tests from other reservoirs that may be of assistance.

When the Chezy formula, $v = C\sqrt{r\,\frac{h_f}{L}}$, is used instead of Equation (2), Equation (3) takes the form:

$$h = \frac{v_a^2}{2g}\left(1 + \frac{2g}{C^2}\,\frac{L}{r}\right) \qquad (12)$$

Comparing Equation (3) with Equation (12), it will be seen that the only difference between them is the exponent of r. The coefficient, C, varies about

10% between the two conduits, while m, in Equation (3), varies about 20 per cent. One is hardly justified in concluding from tests on these two conduits of nearly equal dimensions and characteristics that the Chezy formula is the more nearly correct and, therefore, the more reliable, even if in this particular case it obviously fits the two sets of tests better than Equation (3). It would be a simple matter, of course, to determine the exponent, x, of r in Equation (3) in such manner that the coefficient, m, would be the same for the two conduits. This would give x equal to about 0.9, but it is equivalent to thrusting aside all other experimental evidence, which places x at about 1.168, as given by Unwin and referred to previously in this discussion.

As far as the writer knows, there is little information available concerning friction losses in large conduits for high velocities, and it seems, therefore, highly desirable that the meager data shall agree as closely as possible.

K. L. De Blois,* Jun. Am. Soc. C. E. (by letter).—This paper, with actual measurements made during recent high waters, should form an important addition to the Technical Reports of the Miami Conservancy District.

The author mentions that there was a question as to what point between the middle and the top of the conduit the head should be taken in computing the flows. This point cannot be determined theoretically since the outlet is neither an orifice nor an open channel. The conditions below the outlet, therefore, must govern the point to which the head should be taken, and this can be determined only experimentally. A wide variety of conditions may exist below the outlet, namely, the channel sides may be parallel or diverging and the bottom of the channel may slope down from the outlet at varying angles, or may drop off sharply at varying points below the outlet.

This question was made the subject of a thesis† at the Rose Polytechnic Institute, in June, 1922. The object of the experimental work was to find the law by which water flows through conduits, subsequently discharging into the air after passing through an open channel which is variable in length.

In the case of an orifice the flow is computed from the formula, $Q = c\,A\,\sqrt{2\,g\,h}$, in which, h is measured to the center of the section, or a trifle below the center if the head is relatively low compared to the height of the conduit. Fig. 21 (*a*) shows this condition. In the case of an open channel the head in the ordinary channel formulas is measured to the surface of the water. This condition is shown in Fig. 21 (*b*).

The object of these experiments was to show where the h in the formula, $Q = c\,A\,\sqrt{2\,g\,h}$, should be taken for different lengths of channel beyond the outlet, using a relatively low head. Lack of time permitted only the testing of a 3 by 3-in. square conduit with parallel channel sides and horizontal channel bottom. The drop-off lengths beyond the outlet were 1½, 3, 6, 12, 18, 24, and 30 in., respectively (see Fig. 21 (*c*) and Fig. 21 (*d*)).

* Asst. Engr., C. C. C. & St. L. Ry., Cincinnati, Ohio.

† "Experimental Study of the Flow of Water Through Orifices as Determined by Conditions Below the Outlet," by K. L. DeBlois and D. R. Spencer.

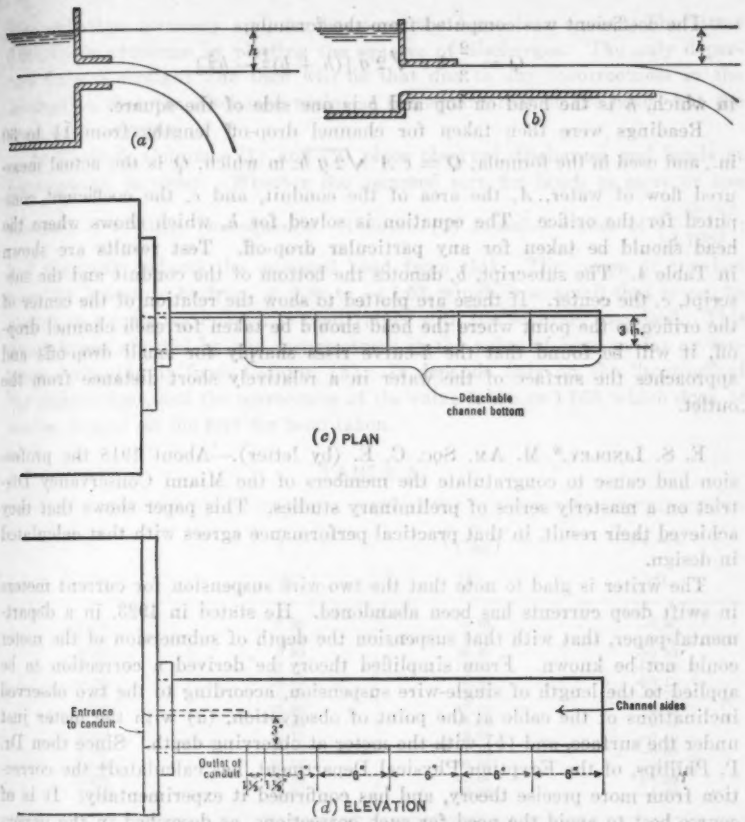

FIG. 21.—ARRANGEMENT OF TEST APPARATUS.

The tests were made to determine the relation between, Q, h, and the channel drop-off. Several readings were taken to determine the coefficient of the orifice which is the condition where the drop-off equals 0.

TABLE 4.—TEST RESULTS, 3 BY 3-INCH CONDUIT, HORIZONTAL CHANNEL.

Test No.	Drop-off, in inches.	Q, in cubic feet per second.	H_b, in inches.	H_c, in inches	h, in inches.	c, in inches $= H_c - h$.
1	0	0.259	5.23	3.73	$c =$	0.935
2	1½	0.258	5.67	4.17	3.63	0.54
3	3	0.247	5.80	4.30	3.33	0.97
4	6	0.232	5.60	4.10	2.94	1.16
5	12	0.250	6.18	4.68	3.40	1.28
6	18	0.236	5.79	4.29	3.04	1.25
7	24	0.244	5.97	4.47	3.25	1.22
8	30	0.242	6.16	4.66	3.20	1.46

The coefficient was computed from the formula,

$$Q = \frac{2}{3} b c \sqrt{2 g} [(h + b)^{\frac{3}{2}} - h^{\frac{3}{2}}]$$

in which, h is the head on top and b is one side of the square.

Readings were then taken for channel drop-off lengths from 1½ to 30 in., and used in the formula, $Q = c A \sqrt{2 g h}$, in which, Q is the actual measured flow of water, A, the area of the conduit, and c, the coefficient computed for the orifice. The equation is solved for h, which shows where the head should be taken for any particular drop-off. Test results are shown in Table 4. The subscript, b, denotes the bottom of the conduit and the subscript, c, the center. If these are plotted to show the relation of the center of the orifice to the point where the head should be taken for each channel drop-off, it will be found that the h-curve rises sharply for small drop-offs and approaches the surface of the water in a relatively short distance from the outlet.

E. S. LINDLEY,* M. AM. SOC. C. E. (by letter).—About 1918 the profession had cause to congratulate the members of the Miami Conservancy District on a masterly series of preliminary studies. This paper shows that they achieved their result, in that practical performance agrees with that calculated in design.

The writer is glad to note that the two-wire suspension for current meters in swift deep currents has been abandoned. He stated in 1923, in a departmental paper, that with that suspension the depth of submersion of the meter could not be known. From simplified theory he derived a correction to be applied to the length of single-wire suspension, according to the two observed inclinations of the cable at the point of observation, (*a*) with the meter just under the surface, and (*b*) with the meter at observing depth. Since then Dr. P. Phillips, of the Egyptian Physical Department, has calculated† the correction from more precise theory, and has confirmed it experimentally. It is of course best to avoid the need for such corrections, as described in the paper; but it is uncertain if that would be possible in an extremely swift deep current, such as that of the Indus in the Attock Gorge.

The writer is also glad to learn that the head for calculating the discharge of outlets has not been measured down to the centers of the orifices. Observations can be used to test the correctness of the assumed position of zero head. Unfortunately, the unavoidable error of observations of the kind made render a certain determination impossible without more readings than are published; but the writer wishes to demonstrate a method that he uses, which seems not to be generally known.

If discharges and water levels are plotted as in Fig. 5, the scale for levels must be small enough to accommodate a range of 35 ft. for Germantown and 45 ft. for Englewood. It is then too small for reading the quantity required

* Superintending Engr., Indian Public Works Dept., Panjab Irrig. Branch, Wotton-under-Edge, Gloucester, England.

† "An Experiment to Determine Corrections to Soundings," by P. Phillips, Egyptian Physical Dept., *Paper 18*, 1925.

with sufficient accuracy and, furthermore, the locus is a curve. The latter difficulty is overcome by plotting the squares of discharges. The only departure from a straight line then will be that due to any incorrectness in the assumption that the discharge varies as the square root of the head; but the small scale remains.

In Table 5, Columns (1) and (2) place observed discharges and heads at Germantown in order. Whether the assumed zero for heads is more or less incorrect is of little consequence. Column (3) includes values of $\left(\frac{Q}{1\,168}\right)^2$; and the next deducts the assumed head from this. The range of the last quantity is seen to be from + 0.80 to — 1.53, which is so small that it can be plotted to a scale big enough to read values with the accuracy required. This range is not affected by any incorrectness in the value of head as far as concerns deducting it from Column (3). It depends only on the "scatter" of the observations, and the correctness of the value taken as 1 168, which does, of course, depend on the zero for head taken.

TABLE 5.

Q. (1)	h. (2)	$\left(\frac{Q}{1\,168}\right)^2$ (3)	$d\sigma - h$ (4)
3 470	9.80	8.83	−0.97
3 653	10.15	9.78	−0.37
3 747	9.90	10.29	+0.39
4 196	12.15	12.91	+0.76
4 253	13.15	13.26	+0.11
4 617	16.40	15.62	−0.78
4 936	18.55	17.86	−0.69
5 038	19.45	18.61	−0.84
5 098	19.15	19.05	−0.10
5 365	21.65	21.10	−0.55
6 019	25.75	26.55	+0.80
6 294	28.65	29.04	+0.39
6 640	33.85	32.32	−1.53

The data of Columns (3) and (4) are plotted in Fig. 22. Because of the "scatter", each point is supplemented by a line measuring the effect of an error of 1% in the observed discharge. The data are so few that rejection of any one makes an appreciable difference to the result.

The "scatter" is such that there is considerable range of choice for the mean locus, with comparatively little difference of "probability". Two extreme alternatives are:

$$y = -0.27 \quad \ldots\ldots (13)$$

$$y = 0.08 - 0.0188\,x \quad \ldots\ldots (14)$$

The similar alternatives for Englewood are:

$$y = -0.31 \quad \ldots\ldots (15)$$

$$y = 0.35 - 0.038\,x \quad \ldots\ldots (16)$$

Equations (13) and (15) entail a change of the zero point for heads, without change of the multiplication factors. Equations (14) and (16) involve a

change of multiplication factor as well, calculated by substituting $\left(\frac{Q}{1\ 168}\right)^2$ for x, and $\left(\frac{Q}{1\ 168}\right)^2 - h$ for y.

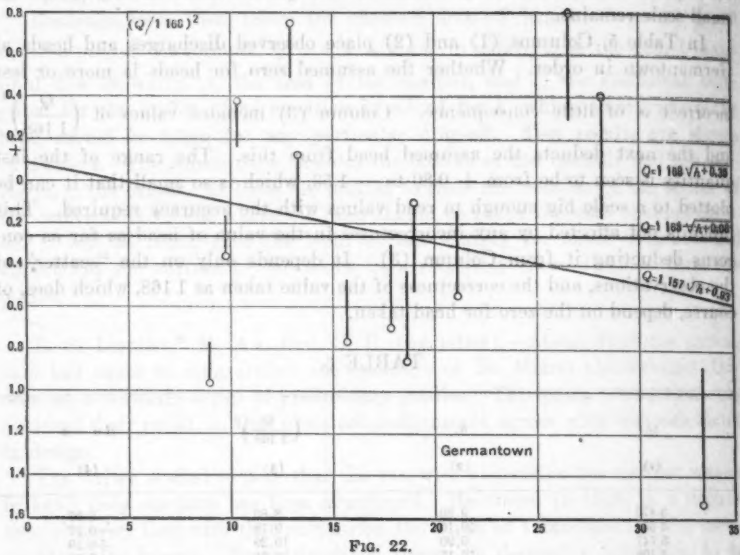

FIG. 22.

If, now, h is written for the head measured down to the crown of the outlet, the author's formulas and the writer's two alternatives become (Table 6):

TABLE 6.

	Germantown.	Englewood.
Author (Table 1).....	$Q = 1\ 168\ \sqrt{h + 0.35}$	$Q = 1\ 404\ \sqrt{h + 0.35}$
Equations (13) and (15).	$Q = 1\ 168\ \sqrt{h + 0.08}$	$Q = 1\ 404\ \sqrt{h + 0.04}$
Equations (14) and (16).....	$Q = 1\ 157\ \sqrt{h + 0.43}$	$Q = 1\ 378\ \sqrt{h + 0.70}$

Equations (14) and (16) have the advantage that they bring the values of Chezy's C down to 156 and 168, making them more nearly equal, and Kutter's n to perhaps more probable values; but they have the disadvantage that the zero points for head show more difference than seems likely from the similarity of form of the outlets. This only emphasizes the fact that the data are insufficient to determine the factors correctly.

C. S. JARVIS,* M. AM. SOC. C. E. (by letter).—Among the benefits that have accrued from the Miami Conservancy Project is the renewed or strengthened confidence in the correctness of conclusions based on comprehensive research, broadened views, and experimental methods, even when they are

* Highway Engr.; Chf. of Hydrographic Section, U. S. Bureau of Public Roads, Washington, D. C.

applied to such elusive subjects as probable rainfall and run-off, routing of floods, and advisable protective measures. The world-wide search for scientific data, the analytical and graphical rendering of that information, the well-conceived hydraulic laboratory experiments, and the concurrent opinion of experts in their respective fields, all led to the adoption of designs which have withstood the six-year test in full accordance with expectations. So effectively have these reservoirs and channels operated that their actual service in flood protection has frequently if not generally been under-estimated. Without regulative measures or channel improvements one or more of the recent floods would undoubtedly have caused serious damage to property in some localities adjoining the Miami River; the new growth and prosperity of the entire valley would have been retarded; and property values in the district would have declined, according to careful estimates, in an amount exceeding the total cost of the protective system.

It is reassuring to learn that the discharge through the conduits exceeds the estimated values by 14%, and that the open channels have some excess capacity. These results were to be anticipated when the errors or uncertainties were thrown to the side of safety. No fear need be entertained on account of this surplus capacity. If the storms and run-off should ever actually equal those assumed for purposes of design (which are regarded as beyond the probable limit of severity attainable in the Miami Valley), the influence of the increased outflow from the reservoirs would be reflected in decreased depth of storage at the peak of the flood. However, there is the remote probability of temporary obstructions, as from poles or uprooted trees that may lodge across a conduit intake after the most violent storms, in spite of the precautionary measures now in vogue for removing fallen timber or cutting it into short lengths. A moderate excess in discharge capacity should be regarded as an advantage on this project.

Any one who views the administrative work in progress in the Miami Valley must be impressed with the orderly methods used to obtain new observations and measurements, as well as to portray and interpret the information. Outstanding among the impressions received by the writer during an inspection trip over the principal structures was the idea of security where the situation had long been precarious, and of confidence, enterprise, and prosperity which had followed in the wake of positive flood protection. While the main problems seem to have been solved satisfactorily, there are details of administration, maintenance, operation, construction, and minor improvements which receive constant attention. In due time, these should form the basis for additional descriptive and analytical contributions to the fund of practical engineering knowledge.

E. W. Lane,* M. Am. Soc. C. E. (by letter).—This paper is especially interesting to the writer since he had the pleasure of working on the project during most of the design period. Although the measurements at the Englewood and Germantown conduits indicate a combined discharge of about 24 500 sec-ft., instead of the 22 000 assumed in the design, it

* Engr., U. S. Bureau of Reclamation, Denver, Colo.

would be a mistake to conclude that the same percentage of error would result in the discharges of the conduits at the other three dams. At the latter, the "conduits" are simply openings through the bottom of the ogee spillway section and are, therefore, of short length. One of the advantages of this type of outlet is that the discharge is nearly independent of the roughness of the concrete. The friction term, $\frac{2\,g\,L}{C^2\,r}$, in the formula, $Q = c\,A\,\sqrt{2\,g\,h}$, in which, $c = \sqrt{\frac{1}{1 + \frac{2\,g\,L}{C^2\,r}}}$, is small for small values of L, especially when the conduits are large, since both C and r are relatively large.

An error in estimating the roughness of the concrete in such conduits, therefore, has little effect. If the roughness at these dams was $n = 0.0101$ instead of $n = 0.0130$ as designed, the discharge would be increased only about 1% at Lockington and about 0.5% at Taylorsville and Huffman. With this assumption for the flow from the Lockington, Taylorsville, and Huffman Basins and the outflows indicated by the measurements from the Germantown and Englewood Basins, the flow at Dayton and Hamilton would exceed the design values by about 2% only, and, therefore, need raise no doubts of the ability of the system to take care of the flood for which it was designed.

The location shown in Fig. 10 is especially favorable for checking the formulas for determining the difference of elevation of the water surface around bends.* The mean difference of elevation at the two sides on March 21, 1927, as shown by data furnished to the writer, was 0.091 ft. Let d = the difference in water surface elevation at the two sides of the stream; V = the mean velocity = 4.06 ft. per sec.; b = breadth of stream = 6.37 ft.; g = acceleration due to gravity = 32.2 ft. per sec. per sec.; and R = the radius of curvature of the center of the stream = 4 093. Then, approximately, $d = \frac{V^2\,b}{g\,R} = 0.080$ ft.

Assuming a parabolic distribution of velocities with zero velocity at the edges, by dividing the channel into six equal strips and computing the difference for each strip and totaling them, a result of 0.096 is obtained. Considering the difficulties of accurate measurement of the water-surface elevations in the field, these seem to be satisfactory checks. The computed difference for the flow for which the channel was designed, is about 1.3 ft.

Charles H. Paul,† M. Am. Soc. C. E. (by letter).—Full-scale results, under actual operating conditions, are most valuable to the engineer who is faced with a problem of design. Had information of this kind been available at the time the Miami flood-control project was designed, much time, labor, and expense would have been saved to the District.

There is much of value in this paper which unfortunately cannot be indicated by the title. Some items, especially, should be mentioned, as fol-

* "Hydraulics of the Miami Flood Control Projects," by S. M. Woodward, M. Am. Soc. C. E., p. 272.

† Managing Director, Dayton Industrial Assoc.; Cons. Engr., Dayton, Ohio.

lows: (1) Actual capacities of large conduits under heads up to 40 ft. or more; (2) actual values of n for improved river channels under various conditions; (3) practical demonstrations of the economical methods of securing the enlargement of cut-off channels by scouring; (4) methods of reducing maintenance costs by gravel plants and low barrier dams; (5) methods of measuring stream flow under high velocities; (6) effect of the hydraulic jump in reducing destructively high velocities; and (7) a most emphatic demonstration of the effect of soil conditions on run-off.

There is a slight difference in the discharge factors of the Englewood and Germantown conduits which, apparently, is difficult to explain. The writer believes, however, that when more measurements are available and a more detailed study has been made, this difference will be reduced or explained. As a matter of fact, it is not of great importance, except that a logical reason for it is not apparent. Both conduits show a larger actual discharge than was indicated by preliminary estimates. This is not surprising: First, because of the inclination to throw factors of safety entirely on the one side; and, second, because conditions of roughness after many years of use were in mind, rather than present conditions, when the conduits are practically new. Fortunately, and perhaps for the same reasons, the river channel sections appear also to have capacities larger than were determined by preliminary estimates. If these comparisons hold for the higher discharges, that is, if both the conduits and the improved river channels have larger discharges than were estimated, that in itself will tend to maintain the balance of the system as a whole. If for any reason it is desired to reduce the capacities of the conduits either temporarily or permanently, this can be done easily and at small expense by simply raising the floors at the inlet ends as much as may be desired.

The writer is especially interested in the comparison of run-offs from the storms of September, 1925, and March, 1927. Both storms were heavy enough to be classed as important. From a study of the rainfall records alone, the September, 1925, storm would be expected to cause the heavier run-off. Due to the conditions of the soil over the drainage area, however, the run-off from this rainfall of 3.2 in. in 2.5 days was hardly noticeable. The same amount of rainfall in March, 1927, spread out over 40% more time, caused a peak discharge twenty-two times as large as the other. This is a remarkable demonstration of the difficulty of applying a formula for run-off based on rainfall data.

C. H. EIFFERT,* M. AM. SOC. C. E. (by letter).—Several of the discussors have deplored the fact that so few observations have been made. It should be remembered that the dams on the Miami Conservancy Project are for flood control only and that observations cannot be made at will as on water-works or irrigation projects; they can be made only when floods occur. To date (1929) it has not been possible to make any satisfactory observations at the Taylorsville and Huffman Dams, where the largest discharges occur. The conduits at these dams have been full only twice, and one of these occurrences was at night, so that sufficient data are not available.

FIG. 23.—DETAILS OF BELLMOUTH ENTRANCES TO CONDUITS.

FIG. 24.—DISCHARGE AT GERMANTOWN, LOOKING UP STREAM TOWARD DAM, FLOOD OF FEBRUARY 25–26, 1929.

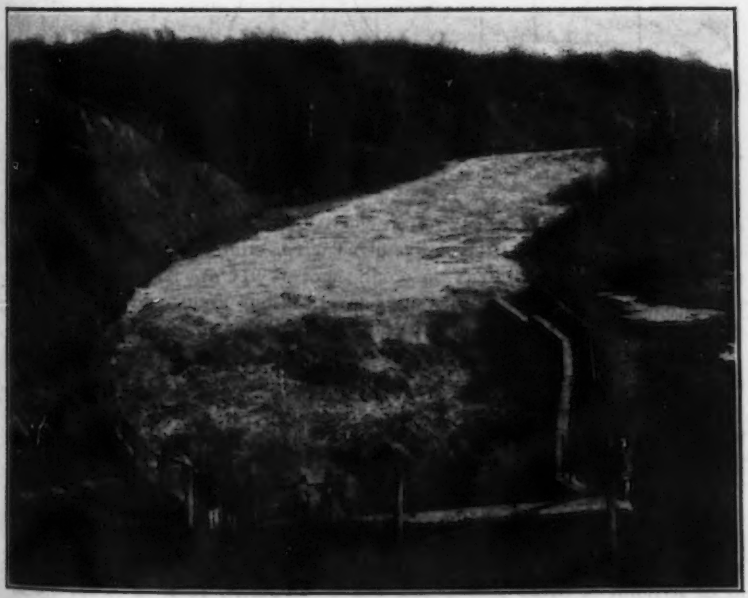

FIG. 25.—DISCHARGE AT GERMANTOWN, LOOKING DOWN STREAM, FLOOD OF FEBRUARY 25–26, 1929.

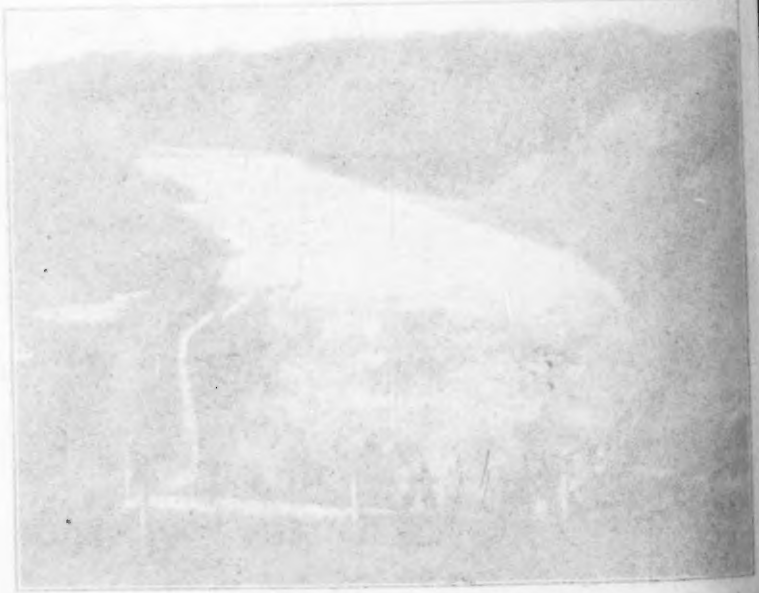

Mr. Smith states that the use of a value of n for the conduit design which is greater than that observed in the completed structures is in this case quite the opposite of a factor of safety. When the conduits were designed it was known that 0.13 was too great for smooth new concrete. It was not known, however, what amount of deterioration might take place in time, thus increasing the actual value of n. It was also recognized that if the conduits proved too large, that is, if the maximum discharges were greater than could be handled safely by the channels in the cities, the conduits could easily be reduced in size; whereas, if they had proved too small, to increase them in size would have been very difficult if not impossible. Discharges from these conduits of less than the design calls for would cause higher water levels in the reservoirs than were anticipated and so would reduce the factor of safety of the dams.

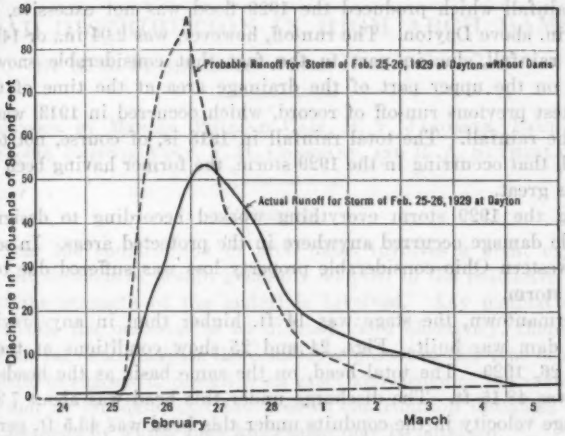

FIG. 26.—REDUCTION OF PEAK RUN-OFF FOR STORM OF FEBRUARY 25 AND 26, 1929, AT DAYTON, OHIO.

Mr. Smith also applies the difference in the designed and actual discharges at Englewood to the conduits at the Taylorsville and Huffman Dams. The conduits at Englewood are 712 ft. long; those at Taylorsville and Huffman are less than 50 ft. in length and are much larger in diameter. A calculation for these dams will show that the effect of the roughness factor is practically negligible. This was shown by Mr. Lane in his discussion.

The conduits are provided with a carefully designed bellmouth entrance as stated by Mr. Smith. The scale of the drawing in Fig. 6 is too small to show this feature. A larger illustration is provided in Fig. 23. While the entrance loss may be greatly reduced or practically eliminated by this design, the writer does not believe that it has been reduced to zero. If there is some entrance loss, it has not been considered in the calculation. The determined values of n would be still further reduced if the entrance losses could be calculated.

The writer is unable at present to explain the reason for the difference in the values of n at Germantown and Englewood, which is referred to in Mr. Jakobsen's discussion. About the same number of measurements were

taken at each location and exactly the same methods were used at both places. As stated in the paper the writer believes that there is a possibility of these values being affected by the entrances to the conduits. By this is meant the concrete entrance channels and not the bellmouth entrances to the conduits themselves.

Since the paper was written a larger flood has occurred (February 25 and 26, 1929) than any on which data were previously given. It would have been nearly as large as that of 1898 (the next to the largest of which there is an accurate record), at Dayton, without the retarding basins and it would have exceeded the 1898 flood at Hamilton in the lower part of the valley. There was storage at all the dams, that at Germantown, Taylorsville, and Huffman being greater than in any previous flood. The total storage, in all five basins, however, was only about 10% of the combined capacities of the basins.

The rainfall which produced the 1929 flood was not excessive, averaging only 1.80 in. above Dayton. The run-off, however, was 2.04 in., or 14% greater than the rainfall, due in part to the fact that considerable snow and ice remained on the upper part of the drainage area at the time of the storm. The greatest previous run-off of record, which occurred in 1913, was equal to 91% of the rainfall. The total rainfall in 1913 is, of course, not to be compared with that occurring in the 1929 storm, the former having been five times or more as great.

During the 1929 storm everything worked according to design and no appreciable damage occurred anywhere in the protected areas. In some cities in Southwestern Ohio considerable property loss was suffered due to flooding from this storm.

At Germantown, the stage was 14 ft. higher than in any previous flood since the dam was built. Figs. 24 and 25 show conditions at the dam on February 26, 1929. The total head, on the same basis as the heads given in Table 2, was 48.15 ft. The discharge under this head was about 7 900 sec-ft. The average velocity in the conduits under this head was 43.5 ft. per sec. and, where the water enters the natural channel below the outlet works, the average velocity was 8.6 ft. per sec. Fig. 26 shows the reduction of the peak flood run-off at Dayton for the storm of February, 1929. It is similar to Fig. 14 except that the reduction is greater.

Paper No. 1719

LOAD DISTRIBUTION IN HIGH ARCH DAMS*

By R. A. Sutherland,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. William Cain, B. F. Jakobsen, Paul Bauman, A. Floris, Fredrik Vogt, F. H. Constant, and R. A. Sutherland.

Synopsis

Every year the construction of arch dams involves a great expenditure of money, but methods of design generally adopted in the past have not made full use of the strength of the materials involved. Any method of design that will enable the material to be utilized more effectively, therefore, will effect large savings and increase the confidence placed in this type of structure. A prerequisite to successful design is an exact knowledge of the various forces acting on and in the dam, and the present contribution discusses the principles and methods by which such knowledge may be obtained.

On account of the complexity of the factors involved, previous methods of load analysis were based on many assumptions which aimed at reducing these factors to a form susceptible to mathematical treatment. The principal assumptions are herein reviewed, particularly those relating to the so-called cantilever action. The assumption most strongly attacked is that which regards the arch as being uniformly loaded, and a powerful method of correctly determining the actual non-uniform beam and arch loading is explained.

The methods proposed are based primarily on beam and arch deflections and by means of charts and simplified procedure the application of these methods is made comparatively simple and accurate, and dependent on the minimum number of arbitrary assumptions. When the actual loading on beams and arches under any given set of conditions is known, the resultant stresses may readily be determined, and such modifications in design may be made as are required to enable the dam to carry the load most effectively.

* Published in April, 1928, *Proceedings*.

† Chf. Engr. and Asst. Mgr., Christmas Island Phosphate Co., Christmas Island.

The lines along which improvements in design may be made, are then suggested.

A satisfactory method of arch dam design requires a more complete knowledge of actual temperature variations in concrete, of its elastic properties, and of the effect on the dam of the elastic properties of the foundation rock. Such knowledge will be obtained mainly from measurements and observations on existing dams. Apart from the incompletely known effect of these factors, arbitrary assumptions in the past have led to errors and should be avoided.

Load Distribution

A number of published investigations on this subject have appeared during the last few years (see Bibliography). Of these, some are so highly mathematical as to be beyond the scope of many engineers, whereas others, in order to obtain simplicity, have introduced assumptions which militate against their accuracy. It is the writer's hope that his method may indicate, perhaps, the lines on which a convenient and accurate analysis may be evolved. To avoid covering elementary ground, a general acquaintance with recently published investigations is assumed, in particular with that* of Fred A. Noetzli, M. Am. Soc. C. E. The latter is a very clear statement of the whole problem, and includes comparatively simple methods for the analysis of load distribution which are extremely useful in the preliminary design of an arch dam. To promote uniformity Mr. Noetzli's symbols have been used as much as possible. It may be mentioned that the work of Professor Camillo Guidi, of Turin, Italy, is of great value to any engineer interested in arch analysis, and should be better known in other countries. Guidi's analysis, although developed primarily from an academic standpoint, are direct and may readily be adapted for practical use, as is shown by their extensive adoption in his own country. For instance, his methods were used in the design of such important multiple-arch dams as that at Tirso, which is probably the largest of its kind in the world.

The arch dam may be regarded as a curved plate of varying thickness and generally of irregular outline, restrained only along a part of its periphery, and subjected to non-uniform loads due to water pressure, temperature, and concrete shrinkage. The single feature favorable to a stress analysis, as against the case of structures, such as bridges or buildings, is that the total water load is known with absolute accuracy. This load, however, is not always the most important one in producing stresses, and certain assumptions have to be made in regard to temperature and shrinkage loads.

Most arch dams have been designed on the basis of the "cylinder formula", in which it is assumed that the dam is composed of a number of horizontal arch slices, each consisting of a part of the wall of a complete thin cylinder. It has always been recognized that this assumption is far from representing actual conditions, and to compensate for it, the stresses allowed in design are generally lower than in other types of structures using the same materials. In time, this tacit confession of ignorance must be replaced by more complete and more exact knowledge of the distribution of load in an arch dam, and it seems reasonable to expect that such knowledge will permit the use of

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

higher stresses and enable modifications in dimensions to be made, which will result in economy of material and, at the same time, in a greater degree of confidence in the safety of such structures.

Before proceeding to the examination of actual stress distribution in an arch dam, it will be well to examine how far the cylinder theory may be assumed to hold good, even considering that the dam may be divided legitimately into a number of independent arch slices. The equation:

$$t = \frac{P_c r_u}{f} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

is based on the assumption of a perfect and complete cylinder subjected to uniform pressure, the thickness of which is negligible in comparison with the radius. Errors are obviously introduced in the following respects:

(1) The cylinder may not be perfectly circular. A flattened cylinder will obviously endure greater stresses because of bending moments in the planes of the major and minor axes. Arched dams are bound to vary slightly from a true circular shape, but errors due to this cause are probably not great, and of course will be introduced by any method of design.

(2) The ratio of thickness to mean radius in an arch may be as much as 0.72 (Shoshone). It is small only in the upper portion of a dam where direct arch load is small. A high ratio does not, of course, effect the average stress on any section, but causes an inequality between the stresses on the intrados and the extrados.

(3) Probably the greatest error is introduced by the fact that, on account of restraint at the sides of the gorge, all parts of the arch ring are not equally free to deflect radially, as they would be in a complete circular ring. This restraint at once introduces bending moments which have the effect, not only of altering the distribution of stress at any given section, but also of producing a variation between the average stresses at different sections. The analysis of a fixed ended arch under uniform load is given in Appendix I, and, by means of Figs. 11 to 13, the actual stresses at four points in the arch may be found at once for any given conditions. These points are the extradosal and intradosal points of the crown and abutment sections, respectively. It should be mentioned that in this discussion the arch is assumed to be fixed at the abutments. This fixation, although perhaps not absolutely in accord with actual conditions, is considered to be more correct than Mr. Noetzli's assumption of a two-hinged arch, for example, which is inconsistent with the assumption of a fixed ended cantilever.

It will be evident from the foregoing that the cylinder formula, except for small thin arch dams, is unworthy of the confidence frequently placed in it. Most attempts to evolve an alternative basis of design have been along the lines of complicated mathematical theory in which, in many cases, the dam was assumed to be confined between vertical abutments and to have a horizontal base. William P. Creager, M. Am. Soc. C. E., expresses this opinion clearly,* stating further that various compensating and cumulative effects, such as stresses due to temperature changes, moisture content, etc.,

* "Masonry Dams," N. Y., John Wiley & Sons, 1917, p. 154.

"are sufficient to nullify practically the basic assumptions of such investigations." To the writer, however, the fact that certain assumptions must be made with regard to temperature, shrinkage, etc., appears to be no warrant for evading the investigation of the loads caused in a dam in the fulfillment of its primary purpose, namely, that of retaining water. The load due to the water is known with absolute accuracy.

The object of the present paper is to make some small contribution toward:

(*a*) The determination of the distribution of the primary or water load, and of the resultant stresses.

(*b*) The determination, with suitable assumptions, of the effect caused by secondary loads due to temperature, shrinkage, etc.

(*c*) The indication of possible variations in design and construction with a view to a better utilization of material and consequent economy.

The fundamental distribution of load in an arch dam has been stated with great clearness in most of the papers mentioned in the Bibliography, and will be clear from the following considerations. An arch can take its full load only if it is perfectly free to deflect. The crest sections of an arch dam approximate this condition of freedom, but at points nearer the base a greater restraint comes into play, until at the base itself no deflection is possible, and this has led to the conception of the "vertical cantilever"; that is, the dam is assumed to be composed of a series of imaginary vertical strips,* each resting on a series of imaginary horizontal arch strips, constituted of the same material. Among the arch strips, the degree of freedom is a maximum at the crest and decreases to zero at the base. The result is, obviously, that the lower arches take less and less of the total load, which is progressively transferred to, and taken by, the cantilever strips. Assuming the cantilevers to be fixed at the base, a considerable bending moment will be developed there. If on the other hand the cantilevers (which now become beams) are assumed to be hinged or freely supported at the base, no bending moment can be developed there, and the effect of the beams is then merely to transfer load from the more heavily loaded arch strips to those less heavily loaded. Bending moments will occur in the beam itself, but not at the base. Both these cases are dealt† with very clearly by the late R. Shirreffs, M. Am. Soc. C. E., on the basis, however, of assumptions "some of which", Creager states,‡ "are impossible, and others of which are unusual."

It will be well at the outset to examine the legitimacy of the various assumptions made by previous writers. The principal of these are:

1.—The site section is of a rectangular or other regular shape.
2.—The up-stream and the down-stream faces in a vertical section are rectilinear.
3.—The geometrical shape of every vertical section is similar.
4.—The horizontal cross-section of the vertical cantilever is rectangular.
5.—The load distribution on any horizontal arch slice is uniform.
6.—Shear deflection may be neglected.
7.—Young's modulus is constant.

---

* See p. 1192, Fig. 1.

† *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 155.

‡ "Masonry Dams," p. 154.

Assumption 1.—Practically all authorities assume vertical gorge sides and horizontal floor, which typifies the average dam site very remotely. For example, Noetzli dismisses variations from this assumed site section by stating* that: "In general it will be desirable to investigate also the sections at about the quarter-points of the highest arches." The writer wishes to emphasize, not only the desirability of investigating the sections at about the quarter-points of the highest arches, but the absolute necessity of doing so if a correct load distribution is to be obtained.

Cross-sections of the sites of several of the largest dams in the world are shown in Fig. 1. The approximate dimensions are also given. The Shoshone and the Pathfinder Dams are the only ones which approach a rectangular shape. The error of the assumption in the majority of cases is very evident.

However, the dimensions of most masonry dam sites can be reduced to a mathematical formula of the type, $x = Ay^m$. This fact makes it possible to obtain simple expressions for the quantity of masonry in any type of dam built in such a site.†

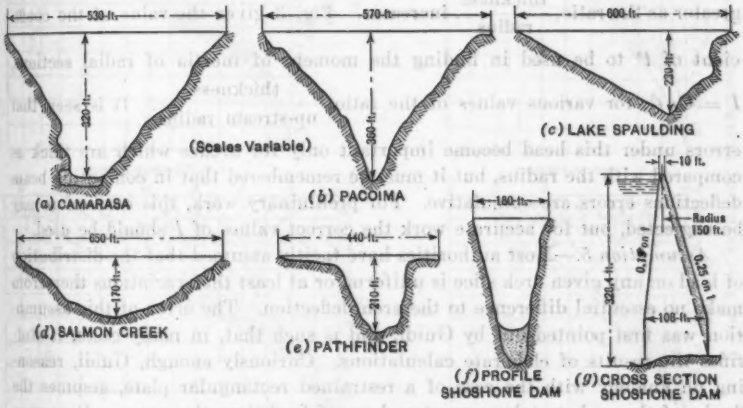

FIG. 1.—SITE SECTIONS OF VARIOUS DAMS.

Assumption 2.—Most writers consider the dam to be of triangular section, which is the theoretical shape for both gravity and arched dams. Many small dams, such as the Barren Jack Creek Dam, in New South Wales, and Las Vegas, in New Mexico, are practically triangular in section, with a slight thickening at the crest. In most cases, however, the section is trapezoidal, as shown in Fig. 1 (*g*). The extra material more than the theoretical amount is shown stippled, and although this may appear to be an inconsiderable addition it represents, toward the crest, a relatively large increase on the theoretical thickness, and causes a considerable divergence from the results evolved on the triangular profile. Noetzli finds the deflection for a trapezoidal cantilever by first computing it for a triangular and for a parallel-sided section, and taking a pro-

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 25.
† *Commonwealth Engineer* (Australia), June, 1928.

portionate figure between the two. This also introduces errors. Fig. 2 shows the deflection at any point of a trapezoidal cantilever, supporting a water load, for various values of the ratio, $\frac{\text{crest thickness}}{\text{base thickness}}$. The error of assuming a linear relationship between this ratio and crest deflection is evident.

In the case of the constant-angle dam, the section is not even trapezoidal. Shirreffs* has indicated how allowance can be made for this variation from the assumed section, but his complicated equations are of little use in any practical case. The arithmetical method explained by the writer covers any actual case that may arise in practice.

Assumption 3.—In the case of dams of homocentric curvature, any cross-section is, of course, similar in shape. In constant angle dams, however, the section varies according to its position. The method of analysis, to be correct, should take cognizance of this fact.

Assumption 4.—The magnitude of errors introduced by the assumption that horizontal cross-sections of the cantilever are rectangular, becomes greater as the ratio, $\frac{\text{thickness}}{\text{radius}}$, increases. Fig. 3 gives the value of the coefficient of t^3 to be used in finding the moment of inertia of radial sections, $I = C_I\, t^3$, for various values of the ratio, $\frac{\text{thickness}}{\text{up-stream radius}}$. It is seen that errors under this head become important only for arches which are thick as compared with the radius, but it must be remembered that in computing beam deflections errors are cumulative. For preliminary work, this correction may be neglected, but for accurate work the correct values of I should be used.

Assumption 5.—Most authorities have tacitly assumed that the distribution of load on any given arch slice is uniform, or at least that variations therefrom make no essential difference to the arch deflection. The error of this assumption was first pointed out by Guidi, and is such that, in many cases, it stultifies the results of elaborate calculations. Curiously enough, Guidi, reasoning on analogy with the case of a restrained rectangular plate, assumes the flanks of the arch to take a greater share of load than the crown. It appears probable that the reverse is the case.

A small variation from uniform distribution of load on an arch will cause a difference in crown deflection that is out of all proportion to the magnitude of such variation. Non-uniform arch load may best be taken account of by the use of influence curves. (See Appendix II.)

Assumption 6.—The assumption has generally been made that shear deflection is negligible. As every engineering student knows, shear deflection is important only in beams or arches the thickness of which is great compared with their length. It may sometimes be safely neglected for the central cantilever sections of an arch dam, or for the highest arch slices, but considering the ease with which it may be computed, it is believed to be desirable in all cases to allow for it. The neglect of shear deflection will generally cause an error of from 5 to 15 per cent.

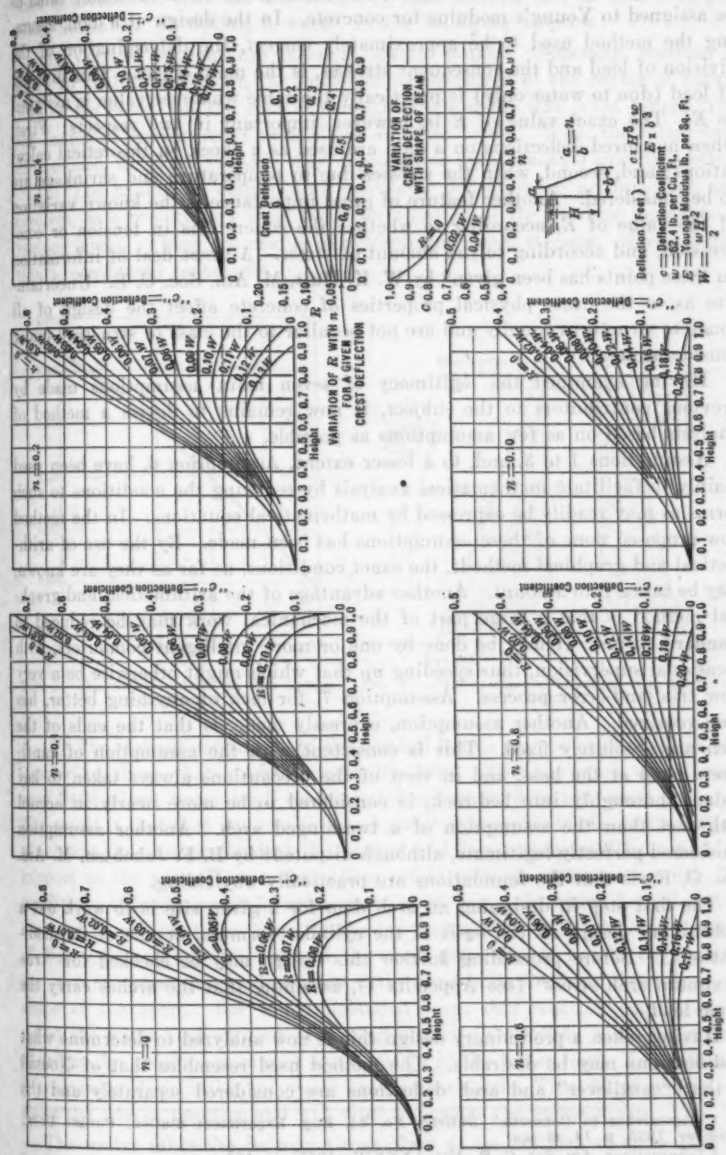

FIG. 2.—CANTILEVER DEFLECTION CURVES.

Assumption 7.—Much discussion has taken place as to the exact value to be assigned to Young's modulus for concrete. In the design of a dam, assuming the method used to be approximately correct, the determination of the division of load and the consequent stresses, is the main object. This division of load (due to water only) is practically the same whatever value is assigned to E. The exact value of E is, however, important in two respects: First, when measured deflections on a dam are used as a check on theoretical calculations; and, second, when the stresses due to temperature and shrinkage are to be considered. Another feature of great importance is the known variation of the value of E, according to whether the concrete is in tension or compression, and according to the amount of stress. A great deal of information on these points has been given* by W. K. Hatt, M. Am. Soc. C. E. Uncertainties as to the exact physical properties of concrete affect the design of all concrete structures equally and are not peculiar to the class of structure under consideration.

Having examined the legitimacy of seven main assumptions made by previous contributors to the subject, it now remains to devise a method of analysis based on as few assumptions as possible.

Assumptions 1 to 5, and, to a lesser extent, Assumption 6, have been used mainly to facilitate mathematical analysis by reducing the conditions to such forms as may readily be expressed by mathematical equations. In the method now proposed none of these assumptions has been made. By the use of arithmetical and graphical methods, the exact conditions, as far as they are known, may be taken into account. Another advantage of the arithmetical and graphical method is that a large part of the mechanical work may be reduced to standard forms. It may be done by one or more intelligent computers, with occasional supervision, thus speeding up that which might otherwise be a very slow trial-and-error process. Assumption 7, for lack of anything better, has been retained. Another assumption, expressly made, is that the ends of the arch are absolutely fixed. This is consistent with the assumption of cantilevers fixed at the base, and in view of the precautions always taken to key a dam thoroughly into bed-rock, is considered to be more nearly in accord with fact than the assumption of a two-hinged arch. Another assumption considered perfectly legitimate, although disputed† by B. F. Jakobsen, M. Am. Soc. C. E., is that the foundations are practically unyielding.

The first step in designing an arch dam for a given site is to work out a preliminary design on the basis of the cylinder formula, or one of its modifications.‡ Before proceeding further this design may be checked for "true maximum arch stress" (see Appendix I), assuming that the arches carry the whole load.

Having taken a preliminary design this is now analyzed to determine what modifications may be desirable. The method used resembles that of Noetzli in that "cantilever" and arch deflections are considered separately and the

* "Researches in Concrete," *Bulletin No. 24*, Eng. Experiment Station, Purdue Univ., November, 1925, p. 14, *et seq.*

† *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 102.

‡ See "The Control of Water," by the late Philip A Morley Parker, M. Am. Soc. C. E., p. 403.

load is divided so that the deflections by each method are, as nearly as possible, the same. It differs, however, in the following respects:

(1) Vertical sections are taken at several points. Generally, sections at every 10° will be sufficient, the angles being measured at the center of curvature of the crest. In the case of constant-angle dams this point differs from the center of curvature of arch slices at other levels. With the latter type of dam also, the flank sections may approach or even exceed a gravity section.

(2) The method of determining cantilever deflections is arithmetical, and involves, as a preliminary step, the determination of the bending moments at various levels. These are useful in determining beam stresses. Shear deflection is considered separately.

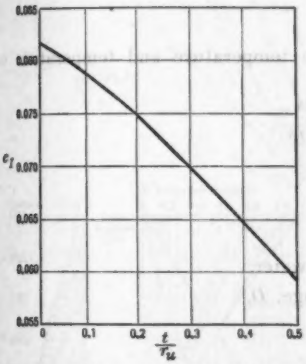

FIG. 3.—MOMENTS OF INERTIA FOR RADIAL SECTIONS.

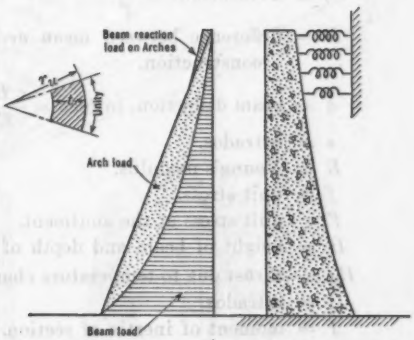

FIG. 4.—DIAGRAMMATIC LOADING FOR VERTICAL BEAM.

(3) The statical conditions of the vertical beams may be considered as very similar to those that probably actually exist. The top arch slices carry very little direct water load, especially if the water does not reach the crest. The result is that they act as a series of yielding supports to the vertical slices, which are thus beams fixed at the bottom and freely supported by a yielding support at the top. Hence, the writer refers to these strips as beams. The conditions of loading may be represented as in Fig. 4, in which helical springs are used to represent the thrust of the top arches. From the deflection curves of Fig. 2, it will be seen that, if the crest deflection is not to be negative, the amount of reaction load possible at the crest is limited, and depends on the shape of the beam. For a parallel-sided beam this reaction cannot exceed 0.2 of the water load without producing negative deflection, while for a beam of triangular section, it cannot exceed 0.075 of the water load. In both cases a triangular distribution of water load is assumed. This is, of course, not quite the case in practice and will alter somewhat the values given.

The writer takes the Salmon Creek Dam as an example to show that the method herein proposed is quite general. The example given merely illustrates the general method and is not a complete analysis. In order to produce

exact agreement between arch and cantilever deflections possibly a half dozen separate trials would be required.

Notation

The following notation is used in the paper:

a = top thickness of beam (Fig. 2).

A = a constant $= \frac{x}{y^m}$.

α = coefficient of linear expansion applied to arch material.

b = base thickness of beam.

c = beam deflection coefficient $= \frac{\delta E b^3}{H^5 w}$.

C_I = a coefficient $= \frac{I}{t^3}$.

D = difference between mean arch temperature and temperature of construction.

δ = beam deflection, in feet $= \frac{c H^5 w}{E b^3}$.

e = extrados.

E = Young's modulus.

f = unit stress.

f' = unit stress at the abutment.

H = height of beam and depth of water.

H_D = thrust due to temperature change, D.

i = intrados.

I = moment of inertia of section.

m = a constant.

$n = \frac{a}{b}$.

p_e = external pressure due to water load = 6.24 H lb. per sq. ft.

r = mean radius of arch.

r_u = radius of up-stream face.

R = "crest-reaction" load on beam.

t = thickness of arch (Fig. 7).

w = weight of a unit cube of water.

W = total water load on beam.

x = width of canyon at a height, y, above bed-rock.

y = height above bed-rock to the point where x is measured.

Distribution of Water Load

Sections of the proposed dam, all taken radially through the center of curvature of the crest, are set out, and the water-load diagram is drawn against each one. The water load on the central section is now divided into that part which is to be taken by beam action, and that which is to fall on the arches (Fig. 5(*c*)). This may be done merely by judgment or by Noetzli's preliminary trial method, using the curves of Fig. 2 for beam deflections, and the arch deflection coefficients of Fig. 13 (Appendix I). In using Fig. 2, the non-

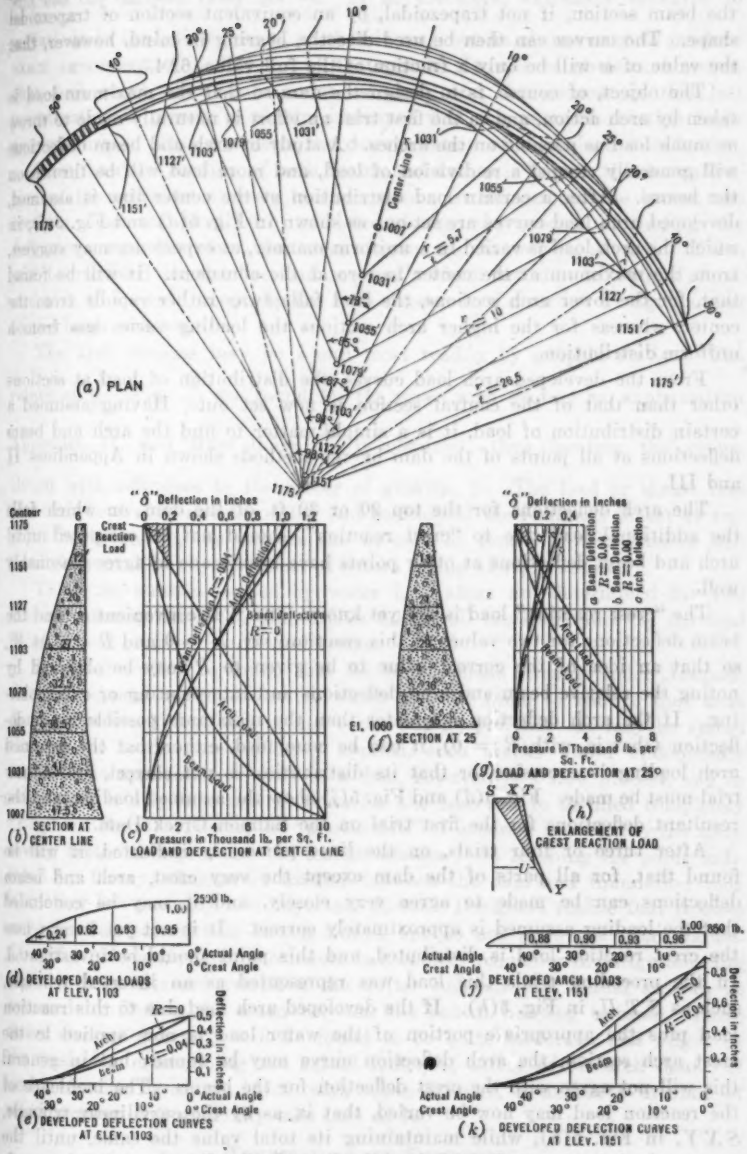

FIG. 5.—DESIGN OF SALMON CREEK DAM.

triangular water load should be replaced by an equivalent triangular load, and the beam section, if not trapezoidal, by an equivalent section of trapezoidal shape. The curves can then be used directly, bearing in mind, however, that the value of w will be only a fraction of the full value, 62.4.

The object, of course, is to design the dam so that the maximum load is taken by arch action, and in the first trial an effort is naturally made to throw as much load as possible on the arches. A study of arch and beam deflections will generally compel a re-division of load, and more load will be thrown on the beams. After a certain load distribution at the center line is assumed, developed arch load curves are set out as shown in Fig. 5(d) and Fig. 5(j), in which the arch load is varied in a uniform manner, as experience may suggest, from the maximum at the center to zero at the abutment. It will be found that, for the lower arch sections, the load falls away rather rapidly from the center, whereas for the higher arch sections the loading varies less from a uniform distribution.

From the developed arch load curves, the distribution of load at sections other than that of the central section is now set out. Having assumed a certain distribution of load, it is a simple matter to find the arch and beam deflections at all points of the dam by the methods shown in Appendices II and III.

The arch deflections for the top 20 or 30 ft. of the dam, on which falls the additional load due to "crest reaction", should not be computed until arch and beam deflections at other points have been made to agree reasonably well.

The "crest reaction" load is not yet known, and it is convenient to find the beam deflections for two values of this reaction, say, $R = 0$ and $R = 0.04\ W$, so that an idea of the correct value to be given to R may be obtained by noting the relative beam and arch deflections and interpolating or extrapolating. If the arch deflection is greater than the maximum possible beam deflection (that is, with $R = 0$), it can be concluded, either that the assumed arch loading is excessive, or that its distribution is not correct, and a new trial must be made. Fig. 5(d) and Fig. 5(j) show the assumed loading, and the resultant deflections for the first trial on the Salmon Creek Dam.

After three or four trials, on the lines previously indicated, it will be found that, for all parts of the dam except the very crest, arch and beam deflections can be made to agree very closely, and it may be concluded that the loading assumed is approximately correct. It is not yet known how the crest reaction load is distributed, and this point should be investigated. In the preceding trials this load was represented as an inverted triangle, such as $S\ T\ U$, in Fig. 5(h). If the developed arch load due to this reaction load plus the appropriate portion of the water load is now applied to the crest arch section, the arch deflection curve may be found; but in general this will not agree with the crest deflection for the beams. The incidence of the reaction load may now be varied, that is, as by the curvilinear triangle, $S\ X\ Y$, in Fig. 5(h), while maintaining its total value the same, until the crest arch deflections are brought into line with the beam deflections. It must be remembered that the crest arch section subtends the greatest angle

and has the highest value for $\frac{r}{t}$. It is, therefore, extremely sensitive to variations in load distribution, so that it may not be always easy to produce exact agreement of deflections at that point. It will be obvious, however, that such exact agreement is not essential, and the purpose of this last investigation is merely to obtain assurance that the assumed reaction loads are reasonable. This completes the determination of water-load distribution.

Once the exact loading of both beams and arches is known, the determination of the resultant stresses becomes easy. In the case of the beams, the bending moments have been tabulated during the process of finding the deflections, and, therefore, the beam stresses can be written at once. These will be modified by the "no-load stresses", which are due to weight alone, and also, to a small extent, by the arch stresses in a direction at right angles to the beam stresses.

The arch stresses may be found most readily by graphic statics. The values of $\frac{M}{P\,r}$ and $\frac{H}{P}$ are found for the given arch loading as explained in Appendix II, and from these $\frac{M}{H\,r}$ is obtained, thus locating the crown thrust with reference to the center of gravity, G. The load or thrust line can then be drawn, and the value and position of the resultant thrust at any point being known, the stresses can at once be found. These stresses will be slightly modified by the effect of others acting at right angles.

Thus, the stresses caused by water load alone are determined for two extreme assumptions: (1) The arches taking all the load; and (2) the load being shared between beams and arches.

It will generally be found that the beam tensile stresses under Assumption (2) appear to be excessive, which has led some to believe that arch dams must crack, but this is not borne out by practice. It may be stated that if the loads were suddenly applied, such cracks would undoubtedly occur. The application of load in a dam, however, is a slow process, and in some cases it may take several years for the reservoir to be filled completely (Elephant Butte). Hence, the "plastic flow" of concrete is evidently the main saving factor that prevents the tensile stresses from reaching the point indicated by theory. Imperfect fixation between the dam and foundation rock is another but probably less important factor. Designers realize that stresses must lie between certain known limits, but do not know the exact values. The effect of plastic flow of concrete is a subject requiring investigation, and until such results are available, the writer suggests that actual stresses be assumed by finding the mean between the known limiting stresses. These mean stresses generally will be found to be quite moderate, and might be the basis for determining the actual factor of safety of an arch dam. If undue tension is shown, even with mean stresses, a moderate amount of reinforcement will generally take care of it.

Temperature and Shrinkage

Temperature and shrinkage can be classed together since the effect of shrinkage is identical with that produced by a drop of temperature. For in-

stance, in the latest Italian Government regulations for dams, shrinkage is to be allowed for as a fall of temperature of 18° Fahr. For any given combined temperature and shrinkage effect (Fig. 12, Appendix I) the values of the stresses at the four critical points of the arch can be found if it is assumed that beam action does not restrain the arches. With the same assumption, the arch deflection curve may be traced, either from Fig. 13 which applies to the crown deflection only, or by the use of the deflection influence curves, Fig. 15, by regarding the temperature change (for the purposes of arch deflection only) as equivalent to a uniform water load such as would produce a cylinder stress equal to $E \alpha D$.

This conception of the "equivalent water load" may be misleading as a means of finding arch stresses. In considering deflection and stresses the arch was assumed to deflect to its final position in two steps. First, the ends being assumed free to slide, the whole arch was allowed to shrink. In this position, a certain deflection has occurred, due to temperature, which is completely analogous to that due to water load. This is the "Hauptsystem" of the German writers.* In the case of temperature shrinkage, however, the arch is unstressed, while under water load it is subjected to uniform cylinder stress. The second step, that of moving the abutment back to its original position by the application of a horizontal thrust, is identical in regard to its effect on both deflection and stress. The result is that for each step the two cases are analogous as regards deflection, but not as regards stress.

In the particular case considered, the center line section of Salmon Creek Dam, a temperature change varying uniformly from 10° Fahr. at the base to 20° Fahr. at the crest, has been assumed. The unrestrained arch deflection curve is shown in Fig. 6(*a*). The "equivalent water load" is also shown. It is obvious that beam action will restrain the arch deflection just as it did in the case of water load, and it might be thought that it would be sufficient to analyze the distribution of this hypothetical water load by the same procedure as was applied in the case of the actual water load which, however, is not correct. In the case of water load, arches and beams deflect until at a certain point each is in equilibrium under the influence of its own share of load and the resisting forces called into play thereby. At a few points in the dam the load on the arch and that on the beam may happen to be equal, but, in general, this is not so. In the case of temperature, however, the deflecting loads on the beams are produced directly by the deflection of the arches, and since action and reaction are equal and opposite, the actual loading on beam and arch is at all points equal.

What actually happens may be analyzed with the help of Fig. 6. Assume that the arch and beam strips are perfectly independent, and allow the temperature variation to occur. The beams will remain unmoved, but the arches will move to a position, such as $L\ M\ N$. The "equivalent water load" producing this deflection is purely imaginary. Both beams and arches are now in a position of rest, which may be taken as a vertical, $L\ Q$, for the beams, and $L\ M\ N$ for the arches. Now, allow the interaction between beams and

* "Die Staumauern," by Kelen, 1926.

arches to come into play. These will now come together until they coincide at some position, such as $L\ P\ O$. The beam deflection produced is represented by the difference between the vertical, $L\ Q$, and the line, $L\ P\ O$, while the arch deflection produced is represented by the difference between $L\ M\ N$ and $L\ P\ O$. Both deflections have been produced by equal but opposite loads, and these loads are real, being the system of forces generated by the interaction of arches and beams.

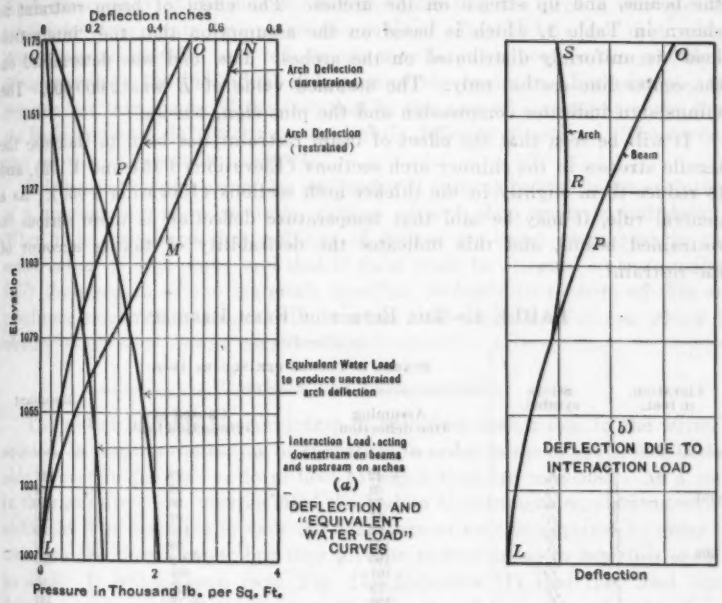

FIG. 6.—TEMPERATURE DEFLECTION CURVES.

Representing arch and beam deflections in the usual way, as in Fig. 6(*b*), it is required to find the real load, which, if applied equally to beams and arches, would cause the former to deflect to the position, $L\ P\ O$, and the latter to the position, $L\ R\ S$. The load which would produce this arch deflection can be determined without trouble, and it then simply remains to check whether or not this same load would produce the required beam deflection. If not, a new trial deflection line, $L\ P'\ O'$, must be taken and the process repeated. After two or three trials the required load can be found.

To determine the stresses is then not difficult. In the case of the beams the only load acting is the real load just found, and the bending moments have already been recorded in the course of the deflection calculation, so that the stresses can be found immediately. In the case of the arches it is necessary to find first the stresses caused by the free deflection (to $L\ M\ N$), and these can be determined at once for the four critical points of the arch from Fig. 12, or for any other point by considering the effect of the thrust, H_D,

which can be readily evaluated. These arch stresses must then be corrected for the effect of the stresses caused by the real "interaction load" which has just been found, and which may be regarded as a water load (although its variation with depth will not, in general, be linear). These second stresses are such as sometimes to ameliorate, and sometimes to aggravate, the effect of the first stresses. In the case considered (drop of temperature), the interaction load shown is to be regarded as a water load acting down stream on the beams, and up stream on the arches. The effect of beam restraint is shown in Table 1, which is based on the assumption that the "interaction load" is uniformly distributed on the arches. The load was determined on the center line section only. The assumed value of E was 2 000 000. The minus sign indicates compression and the plus sign, tension.

It will be seen that the effect of beam restraint has been to increase the tensile stresses in the thinner arch sections (Elevations 1 151 and 1 103), and to reduce them slightly in the thicker arch sections (Elevation 1 055). As a general rule, it may be said that temperature deflection is more serious in restrained beams, and this indicates the desirability of taking account of the restraint.

COMBINED EFFECT OF WATER LOAD AND UNIFORM TEMPERATURE VARIATION

The simplest way to investigate the combined effect of water load and uniform temperature variation is to consider each one separately and combine the resultant stresses. In this manner it is possible to find, for each part of the dam, the maximum stress occurring under any possible set of conditions, and provision should be made either to sustain this stress, or to reduce it by appropriate alterations in the design.

The most important cases are: (1) Full water load and temperature drop; and (2) no water load and temperature rise. It has been shown that temperature drop, combined with the effect of beam restraint, will cause a fairly general state of arch tension. Hence, under water load, part of the arch compression will be cancelled by this initial tension, and the arch will be more lightly stressed than at the normal temperature. At the same time the

beams will be more heavily loaded. It should be noted that the effect of temperature drop is not merely to throw more of the water load on the beams, since the load diagram now contains extraneous loads not comprised within the water load diagram.

General Discussion

The writer has intentionally confined himself to discussing general principles, since many of the details of their application are already very clearly treated in other contributions to the subject. It will be clear that many details may be modified and refinements may be introduced in the procedure as suggested by the individual judgment of the engineer. For example, no mention has been made of the fact that in the case of a constant angle dam the beam and arch deflections are in slightly different directions. The correction for this is generally negligible.

It is hoped that the principles outlined will eventually lead to the evolution of a quicker, but more accurate, method of arch dam analysis and design. When it is considered that millions of dollars are spent every year in the construction of arch dams, and that if these could be designed so as to utilize fully the strength of the materials specified, probably 20 to 40% of this expenditure might be saved, it will be clear that the subject is one which is worthy of the very closest consideration.

Proposals for Improvements

The widest field for improvements in arch dam design lies, in the writer's opinion, in varying the radius of curvature in order to make the arches better able to sustain the non-uniform load to which they are subjected. As a step in the right direction, may be cited the Italian Government regulations which state that it is desirable to vary the curvature as may be required in order to maintain the thrust axial; but they give no indication as to how this should be done. It will be seen from Fig. 17 (Appendix II) that the "load line" departs considerably from the geometrical axis of the arch, and the object of all arch design is to make the two as nearly coincident as possible. This may be done by appropriately varying the curvature of the arch, except that it vitiates at once the relatively simple methods of analysis discussed in this paper. Recourse must then be had to arithmetical and graphical methods of analysis, which in the present case are very laborious. In the case of a dam, the designer is, of course, limited in varying the curvature by the necessity of avoiding overhang. Another proposal investigated by the writer for counteracting the effects of beam action was that of giving the dam a slight overhang in an up-stream direction, at the same time adding a moderate amount of hoop steel to insure stability with reservoir empty. The object was to create sufficient residual compression at the up-stream heel to cancel the beam tension. This is practically equivalent to removing beam action altogether, and thus enabling the dam to act purely as an arch. Such a proposal is not advantageous in the case of a single arch dam, but might, in certain cases, be worthy of investigation. The Coolidge Dam,* of the multiple-dome type,

* *Engineering News-Record*, May 27, 1926, p. 865.

appears to take advantage of this residual compression at the up-stream heel, by reason of the beam section being convex up stream.

It has been seen that the excess arch thickness near the crest has a beneficial effect in reducing beam stresses, and the writer considers that additional concrete placed in the crest is a sound investment.

Acknowledgments

The writer acknowledges his great indebtedness to the work of Professor Guidi, whose method of analysis has been followed very closely in Appendices I and II. He also wishes to thank Mr. R. J. Spowart for the very careful preparation of most of the diagrams and for considerable assistance in the computations, and Mrs. R. A. Sutherland for assistance in preparing the paper for publication.

APPENDIX I

Notation

The following notation is used:

α = coefficient of linear expansion of arch material.
B = coefficient for determining crown deflection under uniform load (see Fig. 13).
c = coefficient for finding true arch stress from cylinder stress.
d = distance from the center line (Fig. 10) of the elastic center of the half arch.
d_x = distance of the antipole, Y, from Axis x-x (with respect to the elastic ellipse of the half arch (see Equation (59)).
D = difference between mean arch temperature and temperature of construction.
δ = crown deflection.
e = extrados.
E = Young's modulus.
f = unit stress.
f' = unit stress at the abutments.
g = elastic weight (in general).
dg = elastic weight of the arch element.
g' = elastic weight of the half arch.
G = coefficient of rigidity.
h = rise of arch.
Δh_p = total crown deflection, due to water load.
Δh_D = total crown deflection, due to a uniform variation of temperature, D, from the temperature of construction.
Δh_H = crown deflection, due to the effect of arch thrust.
Δh_k = crown deflection, or change of arch rise, due to uniform arch shortening (neglecting the effect of arch thrust).
H_D = thrust due to temperature change, D.
H_p = horizontal thrust due to water pressure.

i = intrados.

I = moment of inertia of unit arch slice $\left(=\frac{t^3}{12}\right)$.

I_x = moment of inertia of the elastic arch with respect to x-x axis.

I_X = moment of inertia of the elastic arch with respect to X-X axis.

K = constant depending only on the dimensions of the arch section (see Equation (22)).

l = chord of arch ($A\,B$, Fig. 7) measured from center to center of haunches.

L = length of mean arc.

ΔL = length of arch element.

M = bending moment.

p_e = external pressure due to water load.

ρ = radial semi-axis of the ellipse of elasticity of the arch element.

ρ_1 = tangential semi-axis of the ellipse of elasticity of the arch element (Fig. 8).

r = mean radius of arch.

r_u = radius of up-stream face.

t = thickness of arch (Fig. 7).

T = coefficient for finding stresses due to uniform temperature change.

τ = temperature.

τ_e = difference between extradosal temperature and temperature at which arch was sealed (temperature of construction).

τ_i = difference between intradosal temperature and temperature of construction.

$\Delta\tau$ = difference of temperature between faces.

x = distance from Y-axis of the center of gravity of the arch element.

x-x = axis through the center of gravity of the mean arc and parallel to the chord (see Fig. 7).

X-X = axis parallel to x-x through the center of curvature.

χ = coefficient relating to the distribution of shear over a cross-section, and depending only on the shape of the section.

y = distance from the x-x axis of the center of gravity of the arch element.

y' = distance from the Axis x-x of the antipole of x-x with respect to elastic ellipse of the arch element.

y_X = distance from Axis X-X of the center of gravity of the arch element.

$y_{X'}$ = distance from Axis X-X of the antipole of X-X with respect to the elastic ellipse of the arch element.

Z = section modulus.

ϕ = angle measured at the center, O (Fig. 8), from the crown to the arch element.

$\Delta\phi$ = differential angle, ϕ.

ϕ_0 = one-half the central angle measured at the center, O (Fig. 7).

Stress Analysis of an Arch Subjected to Uniform Water Pressure*

A horizontal circular arch strip is taken, with unit height and uniform thickness, and is loaded on the extradosal face by a uniform water load. In such an arch $\left(\text{assuming the ratio, } \frac{\text{radius}}{\text{thickness}}, \text{ to be great}\right)$ the pressure line would correspond with the geometrical arch axis, if the arch were indeformable, and in this case the load on every radial section would reduce to a normal uniform compression of the value, $p_e\, r_u$, or of the value, $p\, r$, in which, r is the mean radius and (see Fig. 7),

$$p = p_e \frac{r_u}{r} \qquad (2)$$

Actually, the arch is shortened by the load to which it is subjected, and the effect of this is evaluated in the following manner. If the abutment exerted simply a thrust, $p\, r$, normal and central, and did not otherwise restrain the section, A, each arch element, ΔL, would be shortened by the amount,

$$d(\Delta L) = \frac{p\, r}{E\, 1\, t}\, \Delta L \qquad (3)$$

Hence, the chord, l, would be shortened by the amount,

$$\Delta l = \frac{p\, r}{E\, t}\, l \qquad (4)$$

or, this amount of translation to the right, without rotation, would have to be given to the section, A. Since, however, Section A is effectively immovable, it must develop a supplementary reaction capable of annulling the displacement mentioned, which reaction, according to the elastic theory, has for its line of action the axis, x-x, passing through the elastic center of gravity, G,

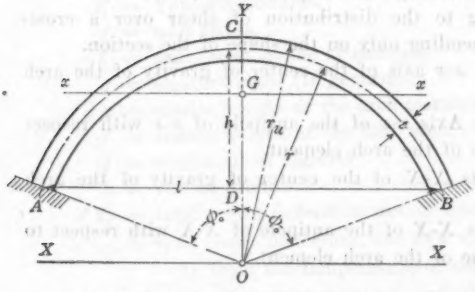

Fig. 7.—Arch Dimensions.

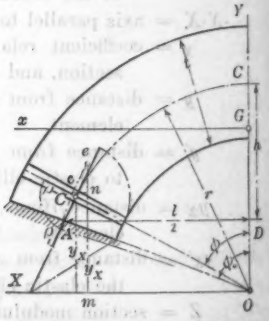

Fig. 8.—Arch Stress Theory.

* Adapted from "Statica delle dighe per laghi artificiali," by Prof. Camillo Guidi, Royal Polytechnic Coll., Turin, Italy, pub. by Vincenzo Bona, Turin, 1921.

of the arch, and parallel to the chord, $A\,B$. This reaction is directed outward (that is, negative) and its value is given by,

$$H_p = \frac{\frac{p\,r}{E\,t}\,l}{\frac{I_z}{}} \quad \ldots\ldots(5)$$

Now, the elastic weight of the arch element is given by,

$$dg = \frac{dL}{E\,I} \quad \ldots\ldots(6)$$

Hence, dg is proportional to dL, and, therefore, the elastic center of gravity, G, of the arch corresponds with the center of gravity of its geometrical axis. Referring to Fig. 7:

$$I_X = \frac{12}{E\,t^3}\int y\,y'\,d\,L \quad \ldots\ldots(7)$$

This is the moment of inertia with respect to the axis, X, passing through the center of curvature. Then, transferring to Axis x:

$$I_x = \frac{12}{E\,t^3}\left(\int y_X\,y_{X'}\,d\,L - (\text{line } O\,G)^2\int d\,L\right) \quad \ldots\ldots(8)$$

Fig. 8 represents the half arch, with an exaggerated ratio of radius to thickness for the sake of clearness.

For the arch element, ΔL (Fig. 8):

$$\rho^2 = \frac{1}{12}\,t^2 \quad \ldots\ldots(9)$$

and,

$$\rho_1{}^2 = \frac{(\Delta L)^2}{12} + \chi\,\frac{E}{G}\,\rho^2 \quad \ldots\ldots(10)$$

Taking $\frac{E}{G} = \frac{5}{2}$, and remembering that, for a rectangular section, $\chi = \frac{6}{5}$:

$$\rho_1{}^2 = \frac{(\Delta L)^2}{12} + 3\cdot\rho^2 \quad \ldots\ldots(11)$$

When ΔL becomes infinitesimal,

$$\rho_1{}^2 = 3\,\rho^2 = \frac{t^2}{4}$$

For any arch element (Fig. 8):

$$y_X = r\cos\phi \quad \ldots\ldots(12)$$

$$y_{X'} = (\text{line } m\,n) + (\text{line } n\,e) = (\text{line } O\,c\cos\phi) + (\text{line } c\,e\sin\phi)$$

$$= \left(r + \frac{\rho^2}{r}\right)\cos\phi + \frac{\rho_1{}^2}{r\cot\phi}\sin\phi = \left(r + \frac{t^2}{12\,r}\right)\cos\phi + \frac{t^2}{4\,r}\,\frac{\sin^2\phi}{\cos\phi} \quad \ldots\ldots(13)$$

Also,

$$d\,L = r\,d\,\phi \quad \ldots\ldots(14)$$

and,

$$(\text{line } O\,G) = \frac{r\cdot\sin\phi_0}{\phi_0} \quad \ldots\ldots(15)$$

Hence,

$$\int y_X\, y_{X'}\, d\,L = 2\,r^3\left[\left(1+\frac{t^2}{12\,r^2}\right)\int_0^{\phi_0}\cos^2\phi\,d\,\phi+\frac{t^2}{4\,r^2}\int_0^{\phi_0}\sin^2\phi\,d\,\phi\right]$$

$$=r^3\left[\left(1+\frac{t^2}{12\,r^2}\right)\left(\phi_0+\frac{\sin 2\,\phi_0}{2}\right)+\frac{t^2}{4\,r^2}\left(\phi_0-\frac{\sin 2\,\phi_0}{2}\right)\right]\ldots.(16)$$

Also,

$$(\text{line } (O\,G)^2)\int d\,L = 2\,r^3\,\frac{\sin^2\phi_0}{\phi_0}\ldots\ldots\ldots\ldots\ldots\ldots(17)$$

Hence,

$$I_x=\frac{12\,r^3}{E\,t^3}\left[\left(1+\frac{t^2}{12\,r^2}\right)\left(\phi_0+\frac{\sin 2\,\phi_0}{2}\right)\right.$$

$$\left.+\frac{t^2}{4\,r^2}\left(\phi_0-\frac{\sin 2\,\phi_0}{2}\right)-\frac{2\sin^2\phi_0}{\phi_0}\right]\ldots\ldots\ldots\ldots\ldots(18)$$

From geometry (Fig. 8):

$$\phi_0=\frac{L}{2\,r}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19)$$

$$\frac{\sin 2\,\phi_0}{2}=\sin\phi_0\cos\phi_0=l\,\frac{r-h}{2\,r^2}\ldots\ldots\ldots\ldots\ldots\ldots(20)$$

$$\frac{2\sin^2\phi_0}{\phi_0}=\frac{l^2}{r\,L}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(21)$$

Hence,

$$I_x=\frac{6\,r^2\,l}{E\,t^3}\left[\frac{L}{l}+\frac{r-h}{r}-\frac{2\,l}{L}+\frac{t^2}{6\,r^2}\left(\frac{2\,L}{l}-\frac{r-h}{r}\right)\right]\ldots\ldots(22)$$

Calling the expression in square brackets, K_0, this reduces to,

$$I_x=\frac{6\,K_0\,r^2\,l}{E\,t^3}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(23)$$

Equation (5) now reduces to,

$$H_p=p\,r\,\frac{t^2}{6\,K_0\,r^2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(24)$$

On account of this outward supplementary reaction, the line of pressure is displaced outward above the axis, x, and inward below this axis. The algebraic sum of the areas between the new pressure line and the geometric axis of the arch is almost exactly zero.

Maximum Stresses Due to Water Load

The sections of the arch most heavily stressed are those at the crown and at the abutment. Assuming the trapezium law to be correct (Fig. 8):

$$f_e=-\frac{p\,r}{t}-\frac{6\,H_p\left[(\text{line } G\,C)-\dfrac{t}{6}\right]}{t^2}\ldots\ldots\ldots\ldots\ldots(25)$$

$$f_i = -\frac{p\,r}{t} + \frac{6\,H_p\left[(\text{line } G\,C) + \frac{t}{6}\right]}{t^2} \quad \ldots\ldots (26)$$

$$[\text{line } G\,C] = r\left(1 - \frac{\sin\phi_0}{\phi_0}\right) = r\,\frac{L-l}{L} \quad \ldots\ldots (27)$$

Substituting the value of H_p from Equation (24):

$$f_e = -p\left[\frac{r}{t} + \frac{1}{K_0}\left(\frac{L-l}{L} - \frac{t}{6\,r}\right)\right] \quad \ldots\ldots (28)$$

$$f_i = -p\left[\frac{r}{t} - \frac{1}{K_0}\left(\frac{L-l}{L} + \frac{t}{6\,r}\right)\right] \quad \ldots\ldots (29)$$

also,

$$f_e' = -\frac{p\,r}{t} + \frac{6\,H_p}{t^2}\left[(\text{line } G\,D) + \frac{t}{6}\cos\phi_0\right] \quad \ldots\ldots (30)$$

$$f_i' = -\frac{p\,r}{t} - \frac{6\,H_p}{t^2}\left[(\text{line } G\,D) - \frac{t}{6}\cos\phi_0\right] \quad \ldots\ldots (31)$$

Since (Fig. 8),

$$(\text{line } G\,D) = (\text{line } G\,O) - (\text{line } D\,O) = \frac{r\sin\phi_0}{\phi_0} - r\cos\phi_0$$

$$= r\left(\frac{l}{L} - \frac{r-h}{r}\right) \quad \ldots\ldots (32)$$

therefore,

$$f_e' = -p\left\{\frac{r}{t} - \frac{1}{K_0}\left[\frac{l}{L} - \frac{r-h}{r}\left(1 - \frac{t}{6\,r}\right)\right]\right\} \quad \ldots\ldots (33)$$

$$f_i' = -p\left\{\frac{r}{t} + \frac{1}{K_0}\left[\frac{l}{L} - \frac{r-h}{r}\left(1 + \frac{t}{6\,r}\right)\right]\right\} \quad \ldots\ldots (34)$$

The value determined from Equation (34) is always the greatest of the four stresses evaluated. Hence, Noetzli's assumption of a two-hinged arch errs not only qualitatively, but quantitatively, in that it assumes the crown stresses to be the deciding factor.

Stresses Due to Temperature Variation

In general, the up-stream and down-stream faces of a dam will not be at the same temperature, nor will they be at the temperature of construction. Hence, stresses are introduced due both to the mean variation from the temperature of construction and to the difference of temperature between the two faces. Calling these τ_e and τ_i for the extrados and intrados, respectively, and assuming a linear variation between the two, it is safe to assume that the values, τ_e and τ_i, have been reached by: (1) A uniform variation of temperature equal to $\frac{\tau_e + \tau_i}{2} = D$ from the temperature of construction; and (2) a local variation of $\frac{\tau_e - \tau_i}{2}$ at the extrados, and $\frac{-\tau_e + \tau_i}{2}$ at the intrados. Assuming a linear variation between τ_e and τ_i may be quite legitimate for thin

arches, such as small dams, or multiple-arch dams, but will not in general be even approximate for large arch dams.

For example, supposing both τ_e and τ_i represent rises in temperature, Fig. 9 shows (to an exaggerated scale) the effect on a small arch element. Assuming first that one abutment of the arch is free, the terminal face of the arch element, EF, would assume the position, $E'F'$, in which, $EE' = \alpha \tau_e \Delta L$ and $FF' = \alpha \tau_i \Delta L$.

This deformation consists of two parts: (1) A translation, $d(\Delta L)$, due to the general rise of temperature, $\frac{\tau_e + \tau_i}{2}$; and (2) a rotation expressed by:

$$d(\Delta \phi) = \frac{\alpha(\tau_e - \tau_i)}{t} \Delta L = \frac{\alpha \Delta \tau \Delta L}{t} \quad \ldots\ldots (35)$$

The first deformation taking place over the whole arch, would produce a translation of the free abutment of the dam by a distance,

$$\alpha \frac{\tau_e + \tau_i}{2} l = \alpha D l$$

Since the abutment is effectively immovable, the thrust exerted along the axis, x, in an inward direction, has the value,

$$H_D = \frac{\alpha D l}{I_x} \quad \ldots\ldots (36)$$

and substituting the value of I_x, Equation (23),

$$H_D = \frac{t^3}{6 K_0 r^2} E \alpha D \quad \ldots\ldots (37)$$

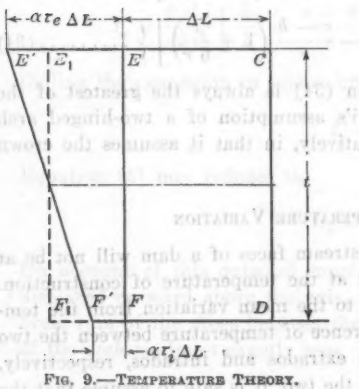

FIG. 9.—TEMPERATURE THEORY.

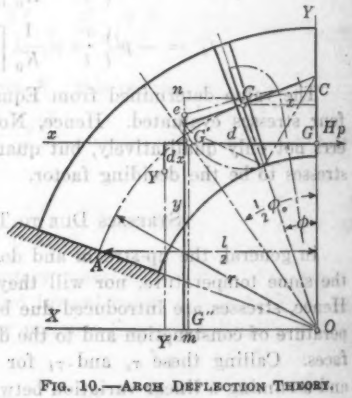

FIG. 10.—ARCH DEFLECTION THEORY.

The second deformation, due to the local temperature variations of the two faces, would cause the end of the arch, if free—and hence the elastic center of gravity, G, which is always considered to be rigidly connected thereto—to undergo a rotation,

$$\Delta \phi = \alpha \Delta \tau \sum \frac{\Delta L}{t} \quad \ldots\ldots (38)$$

Hence, the point, G, would be translated a distance, the co-ordinates of which are,

$$\Delta x = \alpha \Delta \tau \sum \frac{\Delta L}{t} y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

$$\Delta y = \alpha \Delta \tau \sum \frac{\Delta L}{t} x \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

The term, t, being constant, may be taken outside the summation sign, and since G coincides with the center of gravity of the arch axis,

$$\sum y \Delta L = \sum x \Delta L = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (41)$$

hence,

$$\Delta x = \Delta y = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

Therefore, the point, G, does not move, which means that if the end of the arch were free, it would rotate about G. Since the end of the arch is fixed, it must develop a moment, given by Equation (43),

$$M = E \frac{\Sigma d(\Delta \phi)}{\sum \frac{\Delta L}{I}} = \frac{E I \alpha \Delta \tau}{t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

and, since,

$$I = \frac{t^3}{12}$$

$$M = \frac{E \alpha \Delta \tau}{12} t^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

To find the stresses caused by the general and local variations of temperature is now easy. The former will bear, numerically, the same ratio to the stresses due to water load as H_D bears to H_p; that is, as $E \alpha D \tau$ is to $p r$. Algebraically, they will be subtracted from or added to those, according as the general temperature variation is a rise or fall. The stresses due to local temperature variation are equal for all arch sections and are given by,

$$\pm \frac{M}{Z} = \frac{\frac{E \alpha \Delta \tau}{12} t^2}{\frac{t^2}{6}} = \frac{E \alpha \Delta \tau}{2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

The negative sign is given to the stress that occurs at the face where the temperature is the greater, and the positive sign to the stress at the other face.

It is convenient to combine Equations (33) and (34) for stress into one expression giving the stress at the four critical points (see Equation (23)).

For brevity, let,

$$K_c = \frac{1}{K_0} \left[\frac{L - l}{L} - \frac{t}{6 r} \right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

$$K_i = \frac{1}{K_0} \left[\frac{L - l}{L} + \frac{t}{6 r} \right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

$$K_e' = \frac{1}{K_0}\left[\frac{l}{L} - \frac{r-h}{r}\left(1 - \frac{t}{6\,r}\right)\right] \quad \ldots\ldots\ldots\ldots (48)$$

$$K_i' = \frac{1}{K_0}\left[\frac{l}{L} - \frac{r-h}{r}\left(1 + \frac{t}{6\,r}\right)\right] \quad \ldots\ldots\ldots\ldots (49)$$

Then, the crown stresses are:

$$f_e = -\,p\left(\frac{r}{t} + K_e\right) + E\,\alpha\left(D\,\frac{t}{r}\,K_e - \frac{\Delta\,\tau}{2}\right) \ldots\ldots (50)$$

$$f_i = -\,p\left(\frac{r}{t} - K_i\right) - E\,\alpha\left(D\,\frac{t}{r}\,K_i - \frac{\Delta\,\tau}{2}\right) \ldots\ldots (51)$$

and the abutment stresses are:

$$f_e' = -\,p\left(\frac{r}{t} - K_e'\right) - E\,\alpha\left(D\,\frac{t}{r}\,K_e' + \frac{\Delta\,\tau}{2}\right) \ldots\ldots (52)$$

$$f_i' = -\,p\left(\frac{r}{t} + K_i'\right) + E\,\alpha\left(D\,\frac{t}{r}\,K_i' + \frac{\Delta\,\tau}{2}\right) \ldots\ldots (53)$$

The term, $\frac{\Delta\,\tau}{2}$, should be used as it stands only for relatively thin arches.

Table 2 is useful in showing at a glance the direction of the stress due to any given condition.

Crown Deflection Due to Water Load

Crown deflection takes place in the direction of the axis, Y, and may be regarded as the sum of that due to the uniform shortening of the arch under the stress, $\frac{p\,r}{t}$, and that due to the reaction, H_p, given by Equation (24).

The first deflection is obviously equal to,

$$\Delta\,h_k = \frac{p\,r}{E\,t}\,h \quad \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

and the second, $\Delta\,h_H$, must now be determined.

Consider the half arch fixed at one abutment and loaded on the crown section by the reaction, H_p, passing through the elastic center of gravity, G,

of the whole arch (see Fig. 10). According to the theory of the ellipse of elasticity, the deflection, Δh_H, is given by the expression,

$$\Delta h_H = H_p\, g'\, d\, d_x \qquad (55)$$

in which,

$$g' = \frac{1}{2}\,\frac{L}{E\,I} = \frac{6\,L}{E\,t^3} \qquad (56)$$

The elastic center of gravity, G', of the half arch evidently falls on the x-x axis passing through G, and,

$$(\text{line } O\ G') = r\,\frac{r\sin\frac{\phi_0}{2}}{r\,\frac{\phi_0}{2}} = \frac{r\sin\frac{\phi_0}{2}}{\frac{\phi_0}{2}} \qquad (57)$$

Whence,

$$d = (\text{line } G\ G') = (\text{line } O\ G')\sin\frac{\phi_0}{2} = \frac{r\sin^2\frac{\phi_0}{2}}{\frac{\phi_0}{2}} \qquad (58)$$

Also,

$$d_x = (\text{line } G'\ G'') - (\text{line } Y\ Y') \qquad (59)$$

Now,

$$(\text{line } G'\ G'') = (\text{line } O\ G) = r\,\frac{\sin\phi_0}{\phi_0} \qquad (60)$$

and,

$$(\text{line } Y\ Y') = \frac{\int_0^{\phi_0} x\ y\ d\ L}{r\,\phi_0\,r\,\dfrac{\sin^2\frac{\phi_0}{2}}{\frac{\phi_0}{2}}} \qquad (61)$$

The expression to be integrated may be reduced as follows:

$$x\ y\ d\ L = r\ d\ \phi\sin\phi\,[(\text{line } m\ n) - (\text{line } e\ n)]$$

$$= r^3\left(1 - \frac{t^2}{6\,r^2}\right)\sin\phi\cos\phi\ d\ \phi \qquad (62)$$

Hence, from Equations (62) and 61):

$$Y\ Y' = r\left(1 - \frac{t^2}{6\,r^2}\right)\frac{\int_0^{\phi_0}\sin\phi\cos\phi\ d\ \phi}{2\sin^2\frac{\phi_0}{2}}$$

$$= \frac{r}{2}\left(1 - \frac{t^2}{6\,r^2}\right)(1 + \cos\phi_0) \qquad (63)$$

and,

$$d_x = r\,\frac{\sin\phi_0}{\phi_0} - \frac{r}{2}\left(1 - \frac{t^2}{6\,r^2}\right)(1 + \cos\phi_0) \qquad (64)$$

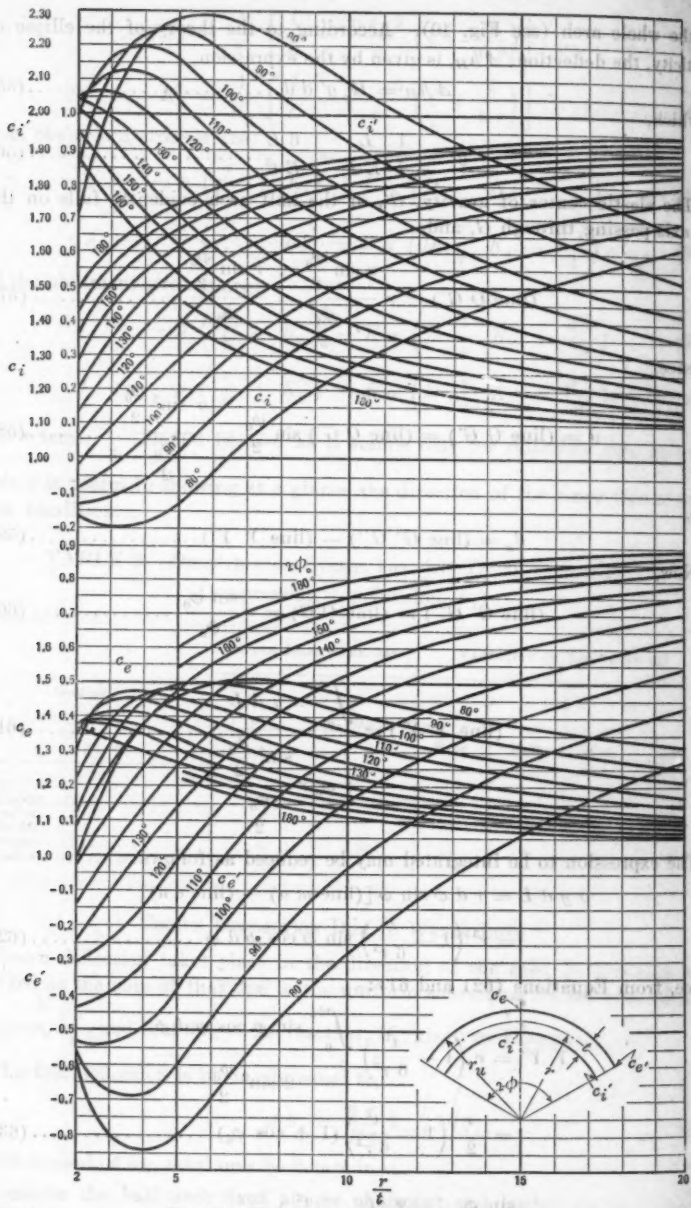

FIG. 11.—WATER LOAD STRESS COEFFICIENTS.

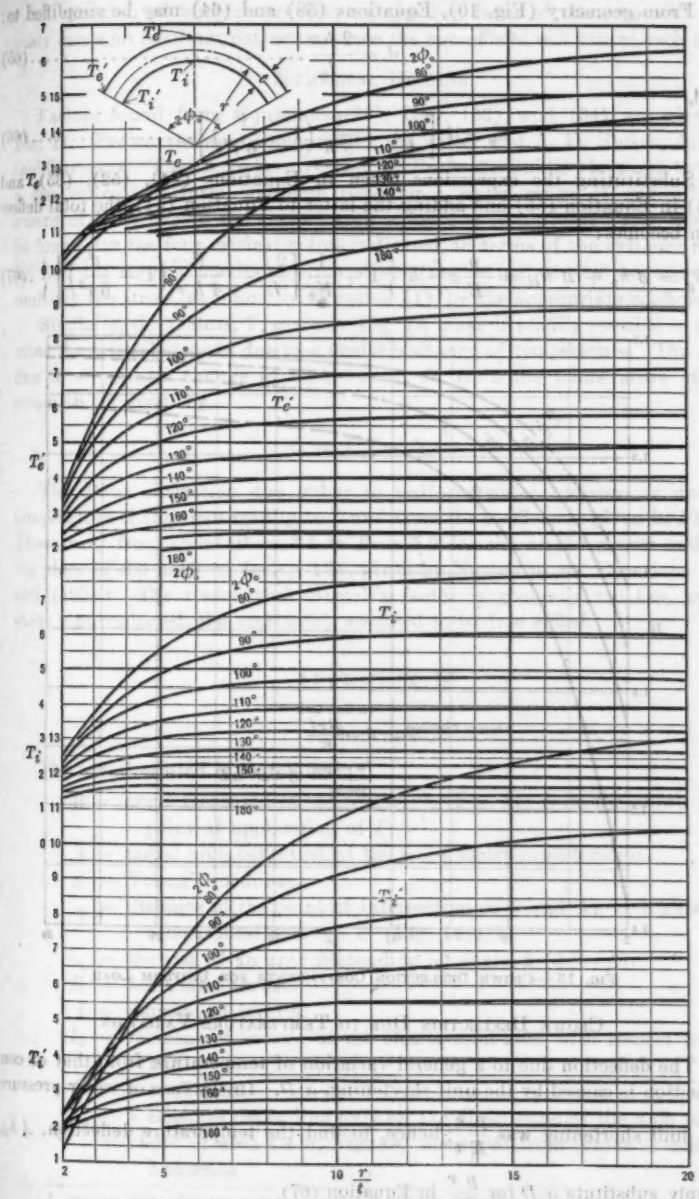

FIG. 12.—TEMPERATURE STRESS COEFFICIENTS.

From geometry (Fig. 10), Equations (58) and (64) may be simplified to:

$$d = \frac{2\,h\,r}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (65)$$

and,

$$d_x = l\left[\frac{r}{L} - \frac{l}{8\,h}\left(1 - \frac{t^2}{6\,r^2}\right)\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

Substituting the expressions given in Equations (24), (52), (65), and (66) in Equation (55) and adding the latter to Equation (54), the total deflection becomes:

$$\Delta h_p = \Delta h_k + \Delta h_H = \frac{p}{E}\,\frac{r}{t}\,h\left\{1 + \frac{1}{K_0}\left[\frac{2\,l}{L} - \frac{l^2}{4\,h\,r}\left(1 - \frac{t^2}{6\,r^2}\right)\right]\right\} \quad \ldots (67)$$

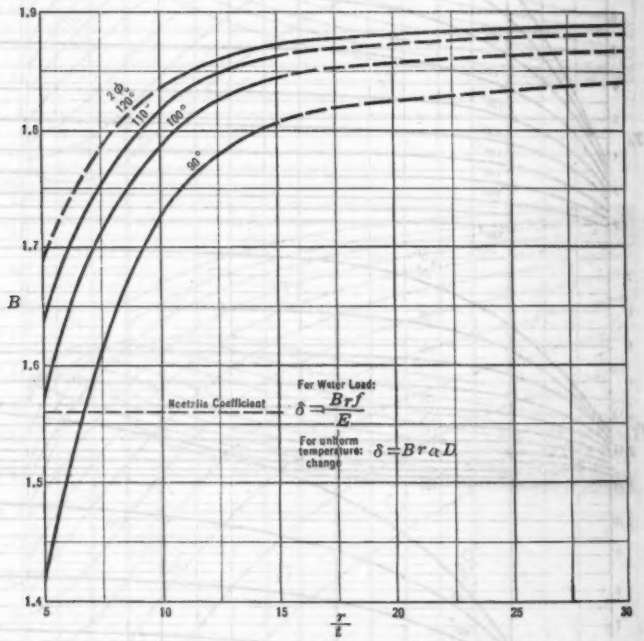

FIG. 13.—CROWN DEFLECTION COEFFICIENTS FOR UNIFORM LOAD.

CROWN DEFLECTION DUE TO TEMPERATURE VARIATION

The deflection due to a general variation of temperature from that of construction is caused by the unit shortening, $\alpha\,D$. In the case of water pressure, the unit shortening was $\frac{p}{E}\,\frac{r}{t}$; hence, to find the temperature deflection, Δh_D, simply substitute $\alpha\,D$ for $\frac{p}{E}\,\frac{r}{t}$ in Equation (67).

A variation of temperature between the two faces of the arch will obviously cause no resultant deflection, since the two effects will cancel each other.

Numerical Results

Factors found from Equations (28), (29), (33), and (34) are given in Fig. 11. The curves were computed by the writer and A. H. Stokes, Authorized Surveyor. They have been verified by Professor Guidi, who gives them in a less convenient form, although covering a wider range of angles.* By means of these curves the correct arch stress due to uniform water load can be found, for the four critical points indicated, in terms of the cylinder stress. To find the correct maximum arch stress (neglecting vertical beam action) multiply the stress, as found by Equation (1), by the appropriate coefficient.

Similarly, the factors, T, given in Fig. 12, make it readily possible to determine the critical stresses due to a uniform change of temperature. The stress due to a uniform change of temperature, D, from the temperature of construction, is given by,

$$f_\tau = T\,E\,\alpha\,D\,\frac{t}{r}\,.$$

The crown deflection due either to uniform water pressure or uniform temperature change can readily be found from the coefficients given in Fig. 13. These vary from about $B = 1.4$ to $B = 1.9$ for the angles shown and take the place of the uniform factor, 1.56, given by Noetzli in his Equations (13a) and (13b).† The reason that Noetzli's factor is generally too low, is that shear was neglected, the arch being assumed to be free ended.

APPENDIX II

Notation

The notation used is as follows:

β = angle measured at the center, O, (Fig. 14) from the crown to the point of application of P.
δ = radial arch deflection at the point under consideration.
E = Young's modulus.
η = distance of the point of intersection of P and the arch axis from a horizontal through C (Fig. 14(a)).
h_1 = the rise of an arch subtending an angle, $2\,(\phi_0 - \beta)$.
H = horizontal thrust.
I = moment of inertia.
I_x = moment of inertia of the elastic semi-arch with respect to Axis x-x.
K = a coefficient.
K_0 = a constant depending only on the dimensions of the arch section.
l = chord of arch ($A\,B$, Fig. 15) measured from center to center of haunches.

* "Statica delle dighe per laghi artificiali," Second Edition, 1926.
† *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 12.

L = length of mean arc.

L_1 = length of arc comprised between two symmetrical forces, P.

M = bending moment added to counteract the translation of the arch thrust, H, from the crown to the axis through the elastic center, G', of the half arch.

N = a coefficient = $\frac{\delta E I}{P r^3}$ (see Fig. 15).

p = pressure due to water load.

p_e = external pressure due to water load.

P = one of a pair of equal radial forces applied to the arch at equal angles, β, from the center line.

ρ = radial semi-axis of the ellipse of elasticity of the arch element.

ρ_1 = tangential semi-axis of the ellipse of elasticity of the arch element (Fig. 8).

q = distance from the line of action of the thrust, H, of the antipole, with respect to the elastic ellipse of the arch element, of the radius through the point under consideration (Line ND, Fig. 14(d)).

r = mean radius of arch.

r_u = radius of up-stream face.

s = Line SD, Fig. 14(d) = distance of antipole defined by q from the line of action of the force, P.

t = thickness of arch.

x-x = axis through the center of gravity of the mean arc and parallel to the chord (see Fig. 14).

X-X = axis parallel to x-x through the center of curvature.

y = distance from the axis, x-x, of the antipole of line of action of P with respect to the ellipse of elasticity of the arch element.

y_X = distance from the axis, X-X, of the antipole of line of action of P, with respect to the ellipse of elasticity of the arch element.

z = distance of the center of the arch element from the line of action of the force, P.

z_1 = distance of the center of the arch element from the radius through the point under consideration.

ζ = distance from the center line, of the point of intersection of P and the mean arc, or arch axis.

ϕ = angle measured at the center, O (Fig. 14), from the crown to the arch element.

ϕ_o = one-half the central angle measured at the center, O (Fig. 14).

ψ = angular distance from the center line of the point the deflection of which is to be found.

Deflection Produced by Non-Uniform Water Pressure

The hypothesis generally accepted in the design of arch dams is that the water pressure is uniform over any given horizontal arch slice, but this does not

correspond with fact. This conclusion, if it holds at all, can do so only for a dam in a site of rectangular section. In the vast majority of cases, with a V- and U-shaped site, the reverse is the case; that is, the pressure on the arch slice is greatest in the center. This is amply borne out by measurements on the Stevenson Experimental Dam.* The arch dam acts as a plate, and the pressure on any given arch slice increases from the abutments to the crown, which is the only place that it has full value due to the head of water.

It is of interest to examine the effect of such unequal load distribution on the stresses and deflections produced. Consider an arch slice of constant section and unit height, as shown in Fig. 14, and determine first the thrust deflection at the crown produced by two equal and symmetrical radial forces, P. The crown section will obviously not rotate nor be displaced in a direction normal to the radius through it. Hence, take the half arch, Fig. 14(a), solidly fixed at A and loaded by the force, P, and by the thrust, H, produced by the other half arch similarly loaded. By reason of symmetry the thrust, H, is normal to the radius, $O\,C$, and may be translated to pass through the elastic center, G', of the half arch by adding the moment, M, at G'.

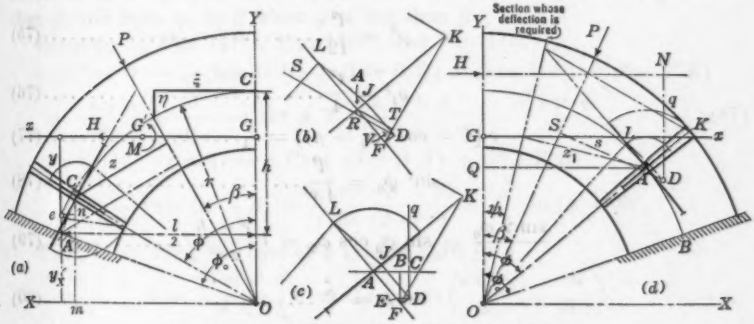

FIG. 14.—ARCH THEORY FOR CONCENTRATED LOADS.

It is then possible to write two equations expressing the fact that the rotation of the crown section is nil, as is also the deflection (in a direction normal to the Y-axis) of the elastic center of gravity, G', which is considered rigidly connected with the crown, C.

The first equation is,

$$-\frac{L}{2}M + P\int_{\beta}^{\phi_0} z\,dL = 0 \qquad (68)$$

Noting that $dL = r\,d\phi$, and integrating, this equation may be written:

$$M = 2\frac{P\,r^2}{L}[1 - \cos(\phi_0 - \beta)] = 2\,P\,r\,\frac{h_1}{L} \qquad (69)$$

The other equation is,

$$-H\,I_x + P\int_{\beta}^{\phi_0} z\,y\,dL = 0 \qquad (70)$$

* As reported in *Engineering News-Record*, November 18, 1926, p. 828.

Representing the elementary elastic weight simply by dL (to which it is proportional), the value of I_x is given by,

$$I_x = \frac{l\, r^2\, K_0}{4} \quad \ldots\ldots (71)$$

Furthermore,

$$z = r \sin (\phi - \beta) \quad \ldots\ldots (72)$$

and,

$$y = (\text{line } O\,G) - [(\text{line } m\,c) - (\text{line } n\,c)] = \frac{r \sin \phi_0}{\phi_0} - \left[\left(r + \frac{\rho^2}{r}\right) \cos \phi - \frac{{\rho_1}^2}{r \tan (\phi - \beta)} \sin \phi\right] \quad \ldots\ldots (73)$$

Hence,

$$\int_\beta^{\phi_0} z\, y\, dL = r^3 \left[\frac{\sin \phi_0}{\phi_0} \int_\beta^{\phi_0} \sin (\phi - \beta)\, d\phi - \left(1 + \frac{\rho^2}{r^2}\right) \int_\beta^{\phi_0} \sin (\phi - \beta) \cos \phi\, d\phi - \frac{{\rho_1}^2}{r^2} \int_\beta^{\phi_0} \sin \phi \cos (\phi - \beta)\, d\phi\right] \quad \ldots\ldots (74)$$

To simplify the integration, the following relationships are convenient:

$$\rho^2 = \frac{t^2}{12} \quad \ldots\ldots (75)$$

$${\rho_1}^2 = \frac{t^2}{4} \quad \ldots\ldots (76)$$

$$r\,[1 - \cos (\phi_0 - \beta)] = h_1 \quad \ldots\ldots (77)$$

$$\sin^2 \phi_0 = \frac{l^2}{4\, r^2} \quad \ldots\ldots (78)$$

$$\frac{\sin 2\,\phi_0}{2} = \sin \phi_0 \cos \phi_0 = l\, \frac{r - h}{2\, r^2} \quad \ldots\ldots (79)$$

$$\sin \beta = \frac{\zeta}{r} \quad \ldots\ldots (80)$$

$$\phi_0 - \beta = \frac{L - L_1}{2\, r} \quad \ldots\ldots (81)$$

and,

$$\cos \beta = \frac{r - \eta}{r} \quad \ldots\ldots (82)$$

Substituting Equations (75) to (82) in Equation (74):

$$\int_\beta^{\phi_0} z\, y\, dL = \frac{r^3}{2} \left[2\, \frac{l}{L}\, \frac{h_1}{r} - \left(1 - \frac{t^2}{6\, r^2}\right) \left(\frac{r - \eta}{r}\, \frac{l^2}{4\, r^2} - \frac{\zeta}{r}\, \frac{l}{2\, r}\, \frac{r - h}{r}\right) + \left(1 + \frac{t^2}{3\, r^2}\right) \frac{\zeta}{r}\, \frac{(L - L_1)}{2\, r}\right]$$

Hence,

$$H = \frac{2\, P}{K_0} \left[\frac{2\, h_1}{L} + \left(1 + \frac{t^2}{3\, r^2}\right) \frac{\zeta}{r}\, \frac{(L - L_1)}{2\, l} - \frac{1}{2} \left(1 - \frac{t^2}{6\, r^2}\right) \left(\frac{l}{2\, r}\, \frac{(r - \eta)}{r} - \frac{\zeta}{r}\, \frac{(r - h)}{r}\right)\right] \quad \ldots\ldots (83)$$

Taking Equations (69) and (83) for M and H, respectively, and substituting therein $p\,r\,d\,\beta$ for P (uniform water load), and integrating with respect to β:

$$M = p\,r\,(\text{line } G\,C) = p\,r^2\,\frac{L-l}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots (84)$$

$$H = p\,r\left(1 - \frac{t^2}{6\,K_0\,r^2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (85)$$

M and H, thus obtained, are identical in effect with the value of H given in Equation (24), thus verifying the case of uniform water pressure as a special case of non-uniform pressure.

Deflection

The arch deflection at a point, the radius of which makes an angle, ψ (Fig. 14(d)), with the center line, is given by the expression,

$$\delta = \frac{H}{E\,I}\int_{\phi_0}^{\psi} z_1\,q\,d\,L - \frac{1}{E\,I}\int z\,s\,d\,L \quad \ldots\ldots\ldots\ldots\ldots (86)$$

in which, the integration of the second term is from ϕ_0 to ψ, when ψ is greater than β, and from ϕ_0 to β when ψ is less than β.

Referring to Fig. 14(b), Fig. 14(c), and Fig. 14(d):

$$q = (\text{line } O\,G) + (\text{line } G\,H) - (\text{line } O\,Q) + (\text{line } B\,F) - (\text{line } F\,E)$$

$$= \frac{r\sin\phi_0}{\phi_0} + \frac{M}{H} - r\cos\phi + \frac{{\rho_1}^2\sin\phi}{r\tan(\phi-\psi)} - \frac{\rho^2\cos\phi}{r} \quad \ldots\ldots\ldots\ldots (87)$$

$$s = (\text{line } S\,R) + (\text{line } A\,T) + (\text{line } V\,D)$$

$$= r\sin(\phi-\beta) + \frac{{\rho_1}^2\cos(\phi-\beta)}{r\tan(\phi-\psi)} + \frac{\rho^2}{r}\sin(\phi-\beta)$$

First, integrating the case of ψ greater than β:

$$\delta = -\frac{H\,r^3}{4\,E\,I}\left[4\,\text{vers}(\phi_0-\psi)\left(\frac{\sin\phi_0}{\phi_0} + \frac{M}{H\,r}\right) + \left(1 - \frac{t^2}{6\,r^2}\right)(\cos(2\,\phi_0-\psi) - \cos\psi) + 2\left(1 + \frac{t^2}{3\,r^2}\right)(\phi_0-\psi)\sin\phi\right]$$

$$- \frac{r^3}{4\,E\,I}\left[\left(1 - \frac{t^2}{6\,r^2}\right)(\sin(2\,\phi_0-\beta-\psi) - \sin(\psi-\beta)) - 2\left(1 + \frac{t^2}{3\,r^2}\right)(\phi_0-\psi)\cos(\psi-\beta)\right] \quad \ldots\ldots\ldots\ldots (88)$$

For the case when ψ is less than β, the quantity $(\psi-\beta)$ in the second term of Equation (88) becomes $(\beta-\psi)$ and the quantity, $(\phi_0-\psi)$, becomes $(\phi_0-\beta)$.

The writer has computed values of $\frac{H}{P}$, $\frac{M}{H\,r}$, and δ, for the subtended angles, 90°, 100°, 110°, and 120°, and for various thicknesses of arch (see Fig. 15). For each subtended angle, the deflection curves have been plotted for three different values of β, namely, $\beta = 0$, 15, and 35 degrees. The coefficients

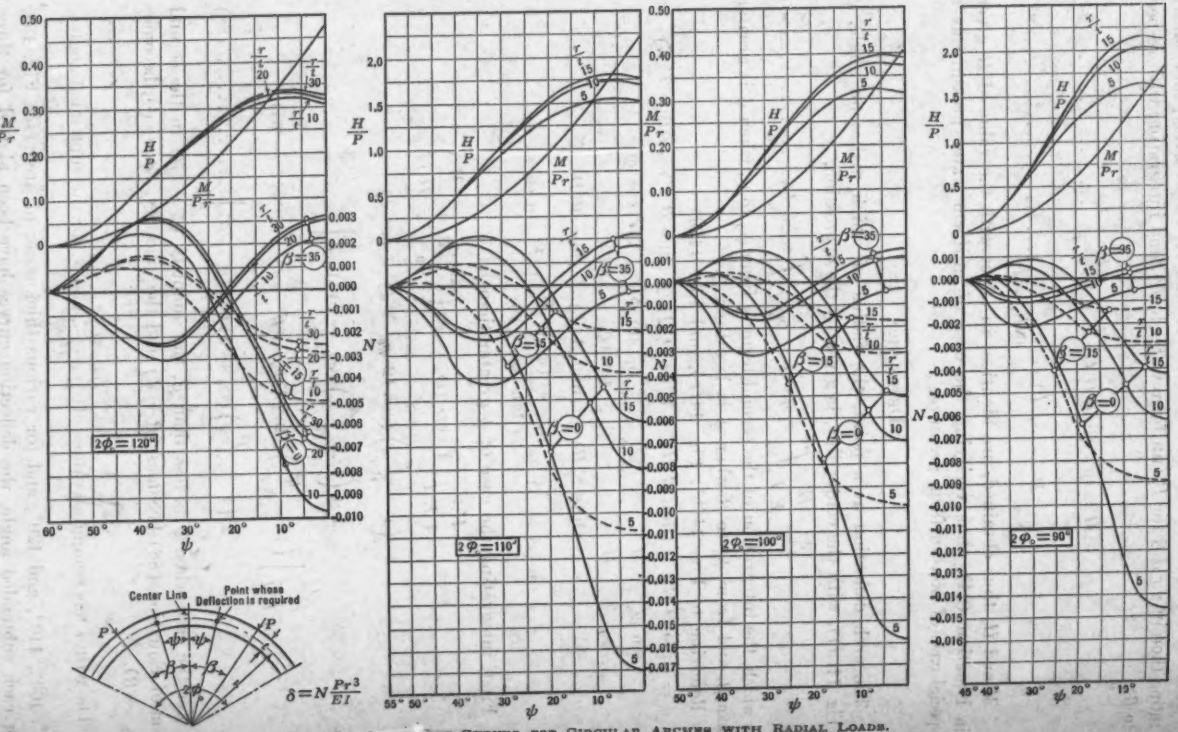

FIG. 15.—INFLUENCE CURVES FOR CIRCULAR ARCHES WITH RADIAL LOADS.

shown on the diagrams are for the imaginary case when P, r, E, and I are each unity, and for any given case the actual deflection is obtained by multiplying the coefficient by $\frac{P r^3}{E I} = \frac{12 P}{E} \left(\frac{r}{t}\right)^3$.

The values of $2 \phi_0$ and $\frac{r}{t}$ cover most cases that occur in practice, and deflection coefficients for intermediate values may readily be found by drawing subsidiary interpolation curves.

From the method of deriving the curves (Fig. 15), and by reason of Maxwell's theorem of reciprocity, it will be seen that they are influence curves for the various quantities they represent, and may be used to find these quantities for any conditions of loading; that is, either concentrated loads, uniformly distributed loads, or non-uniformly distributed loads. The last case is the one which is of immediate interest.

Fig. 16 will serve to show the method of finding the moment, thrust, and deflection in a particular case. The data assumed are as follows:

$r = 100$ ft.

$t = 6.67$ ft.

$\frac{r}{t} = 15$

$2 \phi_0 = 90°$

Water load = 3 000 lb. per sq. ft. at crown, and varying as shown in the load diagram.

$$p = p_c \frac{r_u}{r} = 3\,000 \times \frac{103.33}{100} = 3\,100 \text{ lb. per sq. ft.}$$

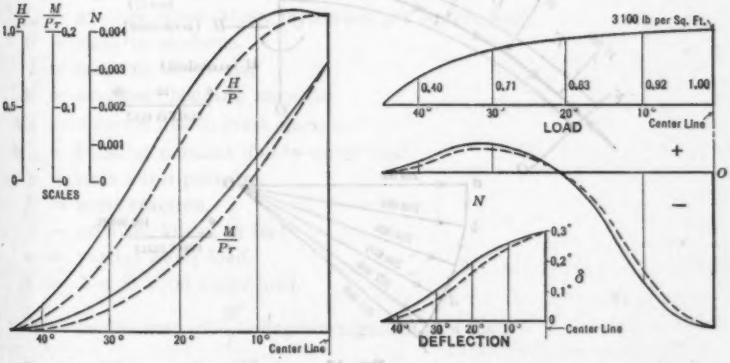

FIG. 16.—METHOD OF FINDING MOMENT, THRUST, AND DEFLECTION IN A GIVEN CASE.

Now, P can be regarded as the concentrated load pressing on the portion of arch subtended by 1 degree. Hence,

$$P = 3\,100 \times \frac{\pi}{180} \times 100 = 5\,410 \text{ lb. at the crown}$$

If P were to remain constant in magnitude, but were to move to various points of the arch, the value of $\frac{M}{H\,r}$, H, and N (for crown deflection), would be read off from the ordinates of the curves shown in full lines corresponding to the position of P. Since P reduces as it moves away from the crown, these ordinates must be reduced in the same manner. Thus is derived the dotted curves, the ordinate at any point of which would give the value of the quantity required for a concentrated radial load acting at that point, and equal in magnitude to the actual load pressing on an arc of 1° at that point. Regarding the actual load as a series of concentrated loads it is seen that the value of the quantity required, under the actual conditions of loading, is obtained by finding the total area under the dotted curves.

In the case shown the areas are: For $\frac{H}{P}$, 48 degree-lb. units; for $\frac{M}{P\,r}$, 5.02 degree-ft-lb. units; and for N, 0.0376 degree-ft. units. Hence,

$$H = 5\,410 \times 48 = 259\,000 \text{ lb.}$$

$$M = 5\,410 \times 100 \times 5.02 = 2\,715\,000 \text{ ft-lb.}$$

and, taking,

$$E = 288\,000\,000 \text{ lb. per sq. ft.}$$

$$\delta = \frac{12 \times 5\,410 \times 15^3 \times 0.0376 \times 12}{288 \times 10^6} = 0.342 \text{ in.}$$

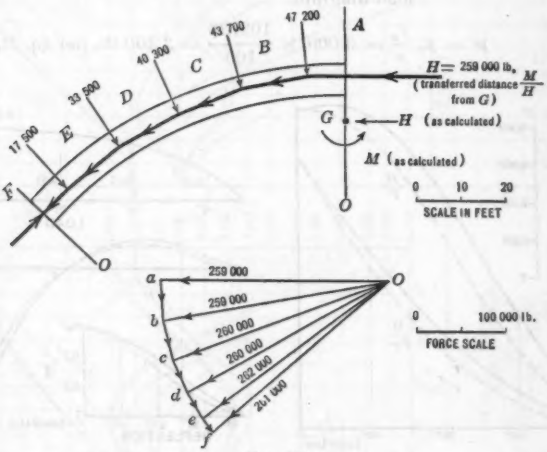

FIG. 17.

The deflection influence lines for $\beta = 15°$ and $35°$ have not been shown, but the deflections at these points can be found in exactly the same manner (Fig. 16). The developed deflection curve for the arch would be as shown in dotted lines, the corresponding curve for a uniform load of 3 000 lb. per sq. ft.

being shown in full lines. The importance of taking into account the distribution of arch load will be clear from this example.

To determine the stresses in the arch, it is necessary to sketch the conditions of loading as shown in Fig. 17, in which the water load has been replaced by concentrated loads acting on each 9° of arc. It is to be noted that five forces only were taken for the sake of simplicity. In practice, further sub-division is necessary. Now, the moment, M, was introduced to neutralize the moment caused by transferring the line of action of the thrust, H, to pass through the elastic center of gravity, G. The distance from G to the actual line of action of H is, therefore, $\frac{M}{H} = 10.47$ ft. This locates H, and the determination of the resultant force acting at any point can then be effected by the usual procedure. The value and position of the thrust at any point being known, the stresses can be found by the trapezium rule.

APPENDIX III

Notation

The following notation has been used:

a = distance between sections assumed for the purpose of analysis.
d = lever arms of partial water loads (Fig. 18).
d_R = moment arm to crest reaction.
d_z = moment arm to areas on $\frac{M}{I}$-diagram.
δ = deflection.
E = Young's modulus.
f_s = average shear stress, in pounds per square foot.
G = rigidity modulus.
I = moment of inertia.
M = resultant bending moment.
M_R = moment due to crest reaction.
M_w = bending moment due to water load.
p = unit water pressure.
R = crest reaction.
t = arch thickness, in feet.
w = partial water load.
$W = \Sigma w$ = total water load.
z = partial area of $\frac{M}{I}$-diagram regarded as a load.
Z = total area of the $\frac{M}{I}$-diagram regarded as a load $= \Sigma z$.

Arithmetical Computation of Beam Deflections

The following arithmetical method of finding the beam deflection curves is based on the well-known fact that the bending moment diagram of a beam

or cantilever loaded with its $\frac{M}{I}$-diagram, will represent, to a suitable scale, the deflection curve. This fact is derived from the elementary theory of beams, which may be summarized in the five expressions:

$$\begin{aligned} E\,I\,y'''' &= \text{load for unit length;} \\ E\,I\,y''' &= -\text{ shear;} \\ E\,I\,y'' &= \text{moment;} \\ E\,I\,y' &\text{ gives the slope; and,} \\ E\,I\,y &\text{ gives the deflection.} \end{aligned}$$

It is obvious from these expressions that the process of repeated integration by which the bending moment is derived from the load diagram will also make it possible to find the deflection from the $\frac{M}{I}$-diagram, using an appropriate scale. This is the basis of Mohr's graphical method. The writer considers that a tabular arithmetical method of doing the same thing is preferable because it eliminates inaccuracies due to errors in drawing and the work can be done very quickly by an intelligent computer, who need not have any knowledge of the theory on which the work depends.

Table 3 gives, in a convenient form, values of I, load, bending moment, etc. Consider the irregular beam, $A\ B\ C\ D$, of unit width (Fig. 18(b)) with a load diagram as shown by $E\,F\,G\,H\,I$, and the reaction, R (Fig. 18(a)). The beam is divided by any convenient number of equi-distant Sections 1, 2, 3, etc., spaced a units apart, and the points of application of the partial loads between the sections are determined, either by the simple geometrical construction or by the simple formula for finding the center of gravity of a trapezium. When the distance between sections is small compared with the total length of the beam, as is generally the case, it may be sufficiently accurate to assume the partial loads to be applied midway between the sections, except for the uppermost section, where the distance is $\frac{a}{3}$ from Section 1.

In tabulating the moments:

$$\begin{aligned} M_1 &= w_1 \times d_1 \\ M_2 &= w_1\,(a + d_1) + w_2\,d_2 \\ &= M_1 + w_1\,a + w_2\,d_2 \\ M_3 &= M_2 + (w_1 + w_2)\,a + w_3\,d_3 \end{aligned}$$

Hence, at any section simply add the progressive moment up to the preceding section, the progressive load multiplied by the constant distance, a, and the moment due to the partial load between the section considered and the preceding section. By making a equal to 20 ft. and assuming that the partial loads act midway between the sections, the arithmetic is reduced to the greatest simplicity.

The bending moment caused by the crest reaction R, is the product of the force and its distance from the section considered. This bending moment is thus simply computed for the various sections and deducted from the "water

moment", M_w, giving the resultant moment, from which $\frac{M}{EI}$ is found. These values are then regarded as the ordinates of the new load diagram, and the same process is repeated, in this case starting at the bottom and working upward.

Table 3 shows the method of computing points on the deflection curve for the beam dimensions and loads shown in Fig. 18, only three sections being taken for the sake of simplicity. It will be seen that in this method allowance can very easily be made for any non-uniformity in dimensions or loads. Thus, if the ratio of thickness to radius of curvature is large, the value of I given by Equation (44) may be corrected by the use of the curve given in Fig. 3.

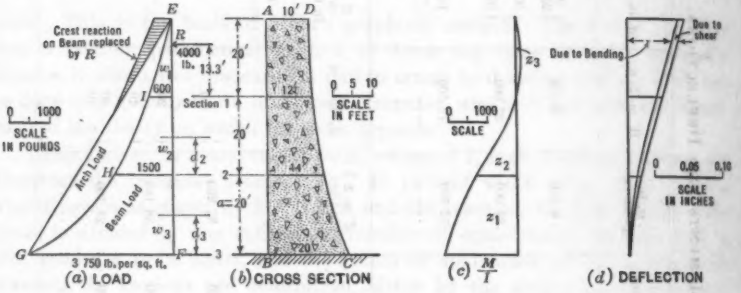

FIG. 18.—BEAM LOADS AND DEFLECTIONS.

Shear deflection is computed separately where necessary, by taking in turn the portions of beam between each pair of sections, and considering each portion subjected to a uniform shear stress equal to the average net load

DISCUSSION

WILLIAM CAIN,* M. AM. SOC. C. E. (by letter).—The author has advanced the solution of the arch dam very materially by his analysis and the construction of the many diagrams as an aid in effecting the extended numerical computations required. The solution is a practical one for the dam of uniform thickness when the structure is not cracked or subjected anywhere to greater tension than the concrete can stand. However, if there is sufficient tension at certain sections to cause cracks where a load is suddenly applied, it may be best to consider these cracks in order to be on the safe side; although for the very slow application of the water load, as the author contends, the "plastic flow" of concrete will modify results and perhaps at some sections prevent "the tensile stresses from reaching the point indicated by theory." This is a consoling theory, but its realization was not much in evidence at the Stevenson Creek Experimental Dam where a large number of cracks formed. The theory must fit the facts.

As nearly all dams are not fixed at the base, in the sense of supplying sufficient tensile resistance there, cracks will occur at the base and a theory which ignores them cannot give correct results.

In the paper entitled "Analysis of Arch Dams by the Trial Load Method,"† by C. H. Howell, M. Am. Soc. C. E., and the late A. C. Jaquith, Esq., the parts of the sections of both arches and cantilevers in tension are neglected, and only the part of the section in compression is regarded as effective in computing moments. This, of course, is going to one extreme, for concrete can resist a tension of 100 to 200 lb. per sq. in., and the possible modification due to plastic flow is neglected, but the hypothesis is on the safe side. In fact, considering other influences that are usually neglected, such as shrinkage, variations in E, water-soaking, and the elastic yielding of the foundation and abutments, it seems best to take the extreme view and consider as effective, for resistance to moments, only the part of a section in compression, particularly where the supposed crack covers a large part of the cross-section.

The author's analysis makes use of the ellipse of elasticity and thus abbreviates certain developments, and especial thanks are due him for the many labor-saving diagrams presented. For a dam that remains intact under the loads and temperature changes, the solution is complete, and even when cracks may be expected, the solution is valuable in a preliminary investigation. As the author affirms, the application of the method to many arch dams, leads to the conclusion that the normal load on a horizontal arch is not uniform.

One phase of the author's method is not clear. It is well known that there is one point on any assumed vertical beam (or cantilever),‡ considerably below the crest, where all the water load is carried by the horizontal arch and

* Prof. Emeritus, Univ. of North Carolina, Chapel Hill, N. C.

† See p. 1191.

‡ Point K, Fig. 15, in the writer's discussion of the paper entitled, "Gravity and Arch Action in Curved Dams," by Fred A. Noetzli, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 74.

none by the vertical beam. In Fig. 5 or Fig. 18 no such point seems in evidence.

The writer has computed by the work method,* the horizontal thrust, P_0, and the moment, M_0, at the crown for the circular arch of uniform thickness, t, and the central angle, $2\,\phi_0$, as well as the radial deflection anywhere for the two symmetrical radial loads, P, each making the angle, β, with the crown section (Fig. 15), but the resulting formula for deflection was found to be more cumbersome than the one derived by the author. The formula for the horizontal thrust, P_0, is,

$$P_0\,D_n = [(\phi_0 - \beta)\sin\beta - \sin\phi_0 \sin(\phi_0 - \beta)]\left(1 + \frac{k^2}{r_n{}^2}\right) + 2.88\,\frac{k^2}{r^2}[(\phi_0 - \beta)\sin\beta + \sin\phi_0 \sin(\phi_0 - \beta)] + 2\,\frac{\sin\phi_0}{\phi_0}[1 - \cos(\phi_0 - \beta)]$$

in which,

$k^2 = \frac{1}{12}\,t^2$; r_n = radius of neutral axis;

$\frac{k^2}{r_n{}^2} = \frac{1}{12}\left(\log_e \frac{r_e}{r_i}\right)^2$;

r_e = radius of extrados;

r_i = radius of intrados; and,

$$D_n = (\phi_0 + \tfrac{1}{2}\sin 2\,\phi_0)\left(1 + \frac{k^2}{r_n{}^2}\right) - \frac{1 - \cos 2\,\phi_0}{\phi_0} + 2.88\,\frac{k^2}{r_n{}^2}(\phi_0 - \tfrac{1}{2}\sin 2\,\phi_0)$$

The thrust, P_0, is assumed to be exerted at the center of the crown joint and the corresponding moment there, counter-clockwise moments being positive, is:

$$M_0 = P\,r_n\,\frac{1 - \cos(\phi_0 - \beta)}{\phi_0} - P_0\,r_n\left(1 - \frac{\sin\phi_0}{\phi_0}\right)$$

The author takes the horizontal thrust, H, as acting at the elastic center of the arch with a corresponding moment,

$$M = P\,r\,\frac{1 - \cos(\phi_0 - \beta)}{\phi_0}$$

This shows the relation between M and M_0. Presumably, when the mean radius, r, is substituted for r_n, P_0 should equal H.

As a check on the formulas for P_0 and M_0, $p_e\,r_e\,d\,\beta$ (p_e being the unit load on the extrados), was substituted for P and the result integrated between the limits, $\beta = 0$ and $\beta = \phi_0$, to give P_0 and M_0 for the full normal load, and the results were found to agree exactly with previously derived formulas.†

* The derivation being similar to that used in *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), pp. 529, 541.

† *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), Equations (103) and (105), p. 531.

In the formula for P_0, the term having the factor, 2.88, shows the influence of shear; and since there is some uncertainty as to its numerical value the figure, 3, can be substituted for 2.88, to agree with the author's assumption. The hope of the designer is that some method of shortening the work materially by means of curves will be devised. In that direction, the author has gone a long way, and he will receive the thanks of the profession.

B. F. JAKOBSEN,* M. AM. SOC. C. E. (by letter).—In Appendix I the author gives the derivation of formulas for stresses, adapted from the work of Professor Guidi. These formulas apply for thin arches only, because of the assumption that the elastic center of gravity coincides with the center of gravity of the geometrical axis (see Fig. 7 and Equation (15)).

The distance, $O\,G$, is the writer's A', and this is:†

$$A' = r_n \frac{\sin \phi_0}{\phi_0} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (89)$$

in which, r_n is the radius to the neutral axis and ϕ_0 is one-half the central angle. When r_m is the mean radius, or the radius of the geometrical center line, then:‡

$$r_n = r_m - c \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (90)$$

and,

$$c = \frac{k}{1 + k} r_m$$

and for a rectangular section,

$$k = -1 + \frac{r_m}{t} \log_e \left(\frac{r_e}{r_i}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (91)$$

in which, r_e and r_i are the radii of the extrados and intrados, respectively. The assumption, made by the author, that $c = 0$, is true, or approximately true, only for thin arches, as was shown by the writer and also by William Cain, M. Am. Soc. C. E.§ The author also assumes that the trapezium law (see Equation (25)) is correct; this also is approximately true only for thin arches,‖ as previously shown by the writer.

The derivation of stresses, as given by the author in Appendix I, is based on the same assumptions as were made by Professor Cain,¶ and the results, therefore, should be identical. As a check, assume an arch for which $\frac{t}{r} = 0.2$ and one-half the central angle, ϕ_0, = 45 degrees. From Equation (22) is found, $K_0 = 1.0267$ and from Equation (34), $f_1' = -11.98\ p$, whereas Professor Cain's formulas give $12.295\ p$, a difference of less than 3%, which probably is due to inaccuracies in the calculations. To the writer's way of thinking, Professor Cain's derivation is simpler and clearer, and the same holds

for the writer's own derivation, as given in the paper referred to. That may be only a personal preference and is at any rate immaterial, the essential point being that the author's equations are true only for thin arches, such as $\frac{t}{r}$ less than 0.3. The same remark applies to his calculation of stresses due to temperature variations and to his calculations for deflections.

In investigating the deflection produced by non-uniform water pressure, he assumes that the load is symmetrical and that the two semi-arches are symmetrical also. The assumption that the load is constant for any arch is undoubtedly always incorrect, and so is the assumption of symmetry (see, for example, Fig. 1(*a*) and Fig. 1(*c*)). The writer's experience with the design of arch dams leads him to believe that it may not be worth while to attempt to take account of the non-uniform load on the arch, unless the question of symmetry is likewise taken into consideration. After all, the main purpose is to design a safe dam and, therefore, to make such assumptions as will lead to a stress determination which is first of all safe and, in addition, a fairly close approximation to the actual stresses. It is in this respect that the cylinder formula is lacking, because the stresses found are too small and sometimes much too small.

The author seems to have assumed throughout his paper that the arch load at the abutment is zero (see Fig. 5(*d*) and Fig. 5(*j*), and Fig. 16). This assumption is not correct, as the writer has pointed out in discussing another paper.* The author also assumes that the foundation is practically unyielding. The writer raised this question some years ago† and Fredrik Vogt, Assoc. M. Am. Soc. C. E., has dealt with it recently and has shown that both the cantilever deflections and the arch deflections are materially increased by the yielding of the foundation‡ and that the division of load between the cantilevers and the arches is influenced by the yielding of the foundation to a considerable degree. The measurements on the Stevenson Creek Test Dam show yielding of the foundation, which checks closely with the formulas of Dr. Vogt.§ The author also neglects shrinkage, but as the writer has recently dealt with this quite extensively,‖ there seems to be no necessity for repeating it. The report on the Stevenson Creek Test Dam also shows that shrinkage produced a very considerable cracking of the dam, and it is not clear to the writer that this can be neglected as being inconsiderable in calculating the stresses.

The author suggests that arch dam design may be improved by varying the radius of the horizontal arches, in order to adapt them better to the non-uniform arch load. Stucky¶ assumes that the center line of the arch coincides with the funicular polygon and that, therefore, generally the center line is not an arc of a circle. He does not, however, investigate the problem, but

¶ "Etude sur les barrages arqués," Lausanne, 1922, "Calcul des arcs," p. 13.

states that in most cases the center line will vary so little from a true circle, that it may be assumed to be circular. Some years ago, after reading the paper by C. S. Whitney, M. Am. Soc. C. E., entitled "Design of Symmetrical Concrete Arches",* the writer made several attempts to determine the most economical shape of the center line. He came to the conclusion that due to the many uncertainties, such as shrinkage, temperature variations, yielding of the foundation, etc., the problem is too complicated and moreover that the shape of the most economical center line will vary as the volume of concrete, due to temperature variations, shrinkage, time effect, etc., so that little if anything can be accomplished with any degree of certainty.

The possibility of improving arch dams lies in the direction of a rational grouting of the contraction joints. In this way the dam may be made into a monolithic structure, which will have compressive arch stresses in places when the reservoir is empty; but it is not of vital importance to know whether the stress is 500 lb. per sq. in., or 10% more or less. It is important, however, to know that tension does not exist, since concrete cannot be depended on to resist tension. Dr. Vogt has introduced a system of grouting, which permits of varying the grouting pressure so that, for instance, a low grouting pressure is applied at the intrados at the abutment, where the compression would otherwise be high, and a high grouting pressure can be applied at the extrados of the abutment where otherwise a considerable tension may develop. It seems to the writer that such a system of grouting would be of considerable value in perfecting rational design and in the construction of arch dams.

The author correctly states that the cantilevers must be considered as having vertical radial limiting planes and not vertical parallel planes, as is generally assumed. This is of especial importance in gravity dam design, as the writer has shown.†

The author's Fig. 2 should be of assistance in determining the division of the water load between cantilevers and arches. If an approximation can be obtained on which to base the first set of calculations, these may be materially shortened, and even if absolute agreement is not reached, the result may be close enough for a stress determination.

PAUL BAUMAN,‡ M. AM. SOC. C. E. (by letter).—This paper is of particular value as it represents the latest results of arch dam research from all over the world. If properly applied, this method of analysis will make possible the determination of maximum stresses with sufficient accuracy to satisfy the most conservative requirements of engineering design. These requirements pertain to engineering practice and must be kept apart from purely scientific requirements as long as dam designing is done by engineers and not by physicists.

The elastic behavior of an isotropic substance is fully described by the modulus of elasticity, E, and the coefficient of transverse contraction, m (Poisson's ratio). The stresses in such a substance may be determined by the commonly known formulas. For anisotropic substances obeying Hooke's law, however, E and m must be replaced by twenty-one different constants

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), Article IV, p. 966.

‡ Designing Engr., Quinton, Code & Hill, Los Angeles, Calif.

which will quickly make the derivation of respective formulas impossible for practical use. What it would mean to make a theoretically exact analysis of a body of concrete, such as an arch dam, may be realized if consideration is given to the fact that concrete is not only anisotropic, but that it misbehaves with regard to Hooke's law. The dam designer, therefore, must be thankful for simple formulas, provided they are on the side of economy and safety. The stresses thereby determined in various points of the structure must then be considered as average stresses of a certain zone around these points.

The tests on the Stevenson Creek Dam have shown that the elastic theory holds good for relatively thin arches, which is a corroboration of many tests on bridge arches previously made in the United States and abroad; but the Stevenson Creek Dam is not representative of a high arch dam, and neither is the stress distribution as shown by the tests. The writer believes that the flow or plasticity of concrete in a high, massive arch dam of considerable volume alone will materially affect the load and the stress distribution. This will be a favorable influence due to its equalizing tendency.

The assumption of unyielding arch abutments is justifiable if the rock that forms the abutments is solid and is at least as strong as the concrete in the arch. It would not be in accordance with good engineering judgment to build an arch dam at a site not conforming to this condition. Even a gravity dam with sufficient curvature to permit arch action would be an unwise selection because the arch pressure of the top part is at times likely to be much in excess of the bottom pressure of the cantilever of maximum height. Consequently, a displacement of the arch abutments—with its well-known destructive effect on a hingeless non-reinforced arch—is quite possible.

The designer is often asked to prepare a preliminary design of an arch dam for the purpose of a cost estimate within such a short time that an accurate analysis is out of the question. It is then necessary to use a short cut which leads to both a safe and an economical result. The time element enters into the proposition beginning with the design! The number of sections for which the deflections are analyzed must then be reduced to a minimum, possibly to sections through the center and the quarter-points, or even to just one section through the line of maximum height. In the case of extremely short notice the writer has found that, in designing a dam, as much as 300 ft. in height, for arch action only, allowing an initial stress of 400 lb. per sq. in. at the crown and 365 lb. per sq. in. at the springing line, the volume of concrete will compare favorably with that obtained through accurate design for dam sites of ordinary, that is, parabolic, shape. The tensile stresses in the vertical beam which may be disclosed by an accurate design should never cause much concern inasmuch as the reinforcing steel required to take care of them will seldom exceed 1% of the cost. An investigation of the Sawpit Canyon Dam of the Los Angeles County (Calif.) Flood Control System, for example, has shown that the tensile stresses in the vertical beam due to simultaneous influence of full water load, shrinkage, drop in temperature, and elastic yield of abutments, could have been safely provided for with $1 700 worth of reinforcing steel (less than 0.3% of the cost). Since the introduction of reinforced concrete, the fear of tensile stresses is unwarranted.

The writer has often used the ellipse of elasticity both in bridge and dam design and, therefore, is pleased to see it used by the author. While the equations for elastic thrust and deflections due to uniform load are not simpler than those obtained by the work method, the elastic ellipse affords an excellent analysis of thrusts and deflections due to non-uniform and non-symmetric loads. In the case of a circular arch under uniform load (see Fig. 19), assume that the arch encastré at the right end and free at the left, is perfectly rigid. Obviously, then, the only condition for equilibrium is that the tangential reactions to the center line of the arch at each end, if combined with the resultant of the load, must form a closed triangle. Starting from the free end and letting one arch element after the other become elastic, the theory of the ellipse of elasticity shows that each element, under the influence of the resultant, N, of all the forces acting at a distance, S, from its center of gravity, will undergo an angular displacement, $d(\Delta\delta) = N S\, dg$. This angular displacement or rotation takes place about the antipole of the force, N, with respect to the ellipse of elasticity of the element. These elemental rotations may be considered as weights acting at the antipole of each element. If, therefore, the whole arch has become elastic, its angular displacement must be the sum of all the elemental displacements and must take place about the center of gravity of the elemental rotations acting as weights.

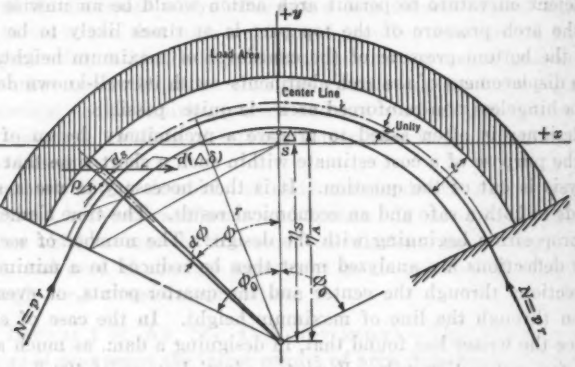

FIG. 19.—CIRCULAR ARCH, UNIFORMLY LOADED.

The supplementary force, ΔH, necessary to establish equilibrium of the elastic arch, may be found from the conditional equation:

$$\Delta H f \int_0^{\phi_0} d g = \int_0^{\phi_0} d(\Delta\delta)$$

or,

$$\Delta H = \frac{\int_0^{\phi_0} N S\, d g}{f \int_0^{\phi_0} d g} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (92)$$

in which, f is the normal distance of ΔH from the elastic center of the whole arch.

For a circular arch under uniform load the line of pressure coincides with the center line and $S = 0$. To make Equation (92) applicable it is necessary to move the line of pressure concentrically up or down by a constant distance, S, which, if made unity, at once disappears from the equation.

Therefore,

$$\Delta H = \frac{N \int_0^{\phi_0} d\,g}{f \int_0^{\phi_0} d\,g} = \frac{N}{f} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (93)$$

Using the author's notation:

$$N = p\,r$$

$$f = \frac{i_x^2}{a} = \frac{I_x}{a \int_0^{\phi_0} d\,g}$$

$$a = \eta_A - \eta_S \text{ (Fig. 19)}$$

$$\eta_S = \frac{r \sin \phi_0}{\phi_0}$$

$$d\,(\Delta\,\delta) = r\,p \times 1\,d\,g$$

$$\eta_A = \frac{\int_0^{\phi_0} \left(r + \frac{t^2}{12}\right) \cos \phi\, d\,(\Delta\,\delta)}{\int_0^{\phi_0} d\,(\Delta\,\delta)} = \frac{\left(r + \frac{t^2}{12}\right) r^2\,p}{E\,I} \frac{\int_0^{\phi_0} \cos \phi\, d\,\phi}{\frac{r^2\,p}{E\,I} \int_0^{\phi_0} d\,\phi}$$

$$= \frac{\left(r + \frac{t^2}{12}\right) \sin \phi_0}{\phi_0}$$

Therefore,

$$a = \eta_A - \eta_S = \frac{\left(r + \frac{t^2}{12}\right) \sin \phi_0}{\phi_0} - \frac{r \sin \phi_0}{\phi_0} = \frac{t^2\,l}{12\,L}$$

and,

$$f = \frac{12\,I_x\,L}{t^2\,l \int_0^{\phi_0} d\,g} = \frac{I_x\,E\,t^3}{t^2\,l} = \frac{6\,r^2\,K_0}{t^2}$$

Introducing these values,

$$\Delta H = \frac{p\,t^2}{6\,r\,K_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (94)$$

which is identical with Equation (24).

The real value of the foregoing theorem lies in its application to arches under non-uniform, non-symmetric loads. ΔH, therefore, no longer acts along the x-axis, but lies obliquely to it, producing a component in both the x and the y-axes. A graphical analysis will then give quickest results. Such an analysis is shown in Fig. 20. The arch is divided into elements of equal and

finite length and their centers of gravity, elastic weights, Δg, ρ, and ρ', are determined. The center of gravity of the elastic weights of the whole arch is then determined and through it, the x and y-axes as principal axes of inertia of the arch. Major and minor axes of the ellipse of elasticity of the whole arch are then computed and plotted, and the ellipse is drawn, thereby establishing a scale of the elastic properties of the arch which are constant for one and the same arch and, therefore, are not affected by any load on the arch.

The elemental division lines are now extended into the load area, and the elemental loads are computed and combined in a convenient scale with an arbitrary pole to a force polygon. The corresponding funicular polygon is then drawn in any position, observing, however, for the sake of simplicity, that it does not intersect the arch axis. After determining the antipoles of the forces (line of pressure), with respect to the elemental ellipses of elasticity, and letting the elemental rotations, $\Delta\delta = N s \Delta g$, act at the antipoles as weights parallel to both the x and the y-axes, their center of gravity, A, may be found. As A, also, is the antipole of ΔH with respect to the ellipse of elasticity of the whole arch, the position of ΔH is at once determined and its magnitude is:

$$\Delta H_N = \frac{\Sigma \Delta \delta}{f \Sigma \Delta g} \qquad (95)$$

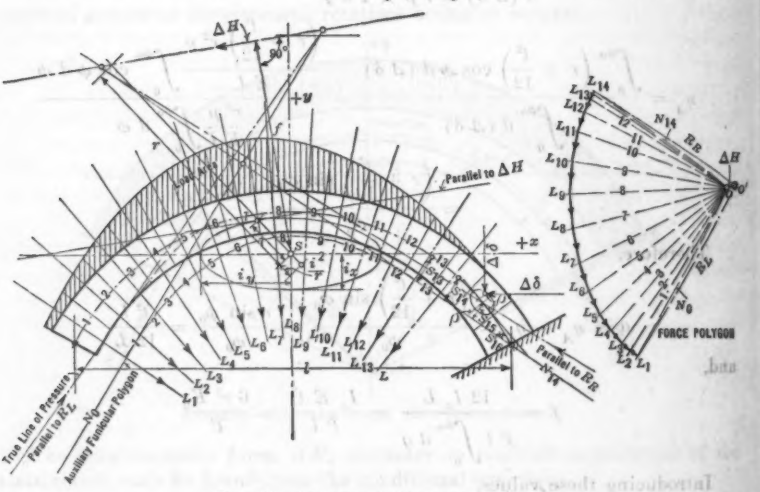

FIG. 20.—GRAPHICAL ANALYSIS OF ARCH.

By plotting ΔH from Pole O negative, that is, contrary to its direction of action, the true pole, O', is established. The two force polygons, the temporary and the true one, are affined with ΔH as their axis of affinity. The true line of pressure, therefore, is found by remembering that corresponding rays (forces) intersect on the axis of affinity. For a change of temperature of $\pm \Delta T°$ Fahr.:

$$\Delta H_T = \frac{\pm \Delta T \alpha E l}{\Sigma \Delta g i_x^2} \qquad (96)$$

For relatively thin arches it is permissible to use $I_x = \Sigma y^2 \Delta g$ and $I_y = \Sigma x^2 \Delta g$, whereby a material reduction in computation is effected. This approximation gives somewhat smaller values for I_x and I_y and, therefore, is on the side of safety.

A. Floris,* Esq. (by letter).—The method of determining stresses in a dam by using the conception of combined cantilever action and arch action is comparatively well known. One investigation, dealing with the arch crown alone, dates back to 1889,† and several attempts have been made to determine the stresses in other points besides the crown. The author's method of analysis was applied to the design of the La Jogne Dam‡ in Switzerland, and to several other dams§ of the U. S. Bureau of Reclamation.

Professor C. Guidi also gives several sets of equations‖ for the determination of stresses at various points of the arch, using the cantilever and arch action theory. He states, however, that although the solution of these equations presents no special difficulty, they are of little practical value because the number of the unknowns to be determined is too great. Consequently, in order to simplify the analysis, Professor Guidi has assumed the distribution of the water pressure to vary according to a parabolic law with a full water pressure at the abutments, diminishing to three-quarters of this pressure at the crown. The cantilever action is entirely neglected in this case and the elementary arch is analyzed as an independent unit. This assumption is based on the results of his theory¶ and tests‖ in the case of a dam site with a rectangular shape.

The author's trial-load method seems quite laborious as indicated by the incomplete analysis presented in the paper. The lack of detail is a great disadvantage to those who desire to follow the method closely. On the other hand, complete derivations of some of the formulas presented have been published by Professor Guidi.

The practical importance of these formulas, based on the theory of the ellipse of elasticity, may be questioned when compared with other well known analytical methods.

The author also submits Professor Guidi's diagrams** (modified and improved), for the determination of the stresses in an arch of constant thickness due to uniform water pressure and to a change in temperature. As a means of determining the effect of non-uniform water pressure on the stresses, the author has extended Professor Guidi's influence lines†† to cover some special

cases. This is perhaps the most valuable part of the paper, which will serve, somewhat, to familiarize American engineers with Professor Guidi's scientific investigations on the design of arch dams.

FREDRIK VOGT,* ASSOC. M. AM. SOC. C. E. (by letter).—Under "Proposals for Improvements", the author has emphasized varying the radius of curvature as the best way to make the arch better able to sustain the non-uniform load to which it is subjected. He refers to the Italian Government regulations which state that it is desirable to vary the curvature as may be required in order to maintain the thrust axial; but these regulations give no indication as to how this should be done.

In fact, it is quite impossible to solve the problem of maintaining the thrust axial and thereby to equalize the arch stresses by varying the curvature. The stress distribution may be improved in that way, but the stresses cannot be equalized as assumed in the Italian rules. Imagine that, for a certain shape, the thrust due to water pressure is axial at all points of the arch, and that no stresses existed before applying the load. With this axial thrust the arch would be compressed but not bent; the total length of the chord would thus be reduced. To make the arch fit the abutments a rib-shortening pull must be applied. This force is eccentric at all except two points of the arch and, therefore, it produces bending moments and bending stresses. It seems as if this well-known fact is overlooked sometimes.

In order to obtain axial thrust and uniform stress distribution under load, it is necessary to apply initial stresses in the arch. Heating the arch would do that in an ideal manner, but that is, of course, out of the question. Swelling of the concrete also would do it. However, the fact that the contraction joints in dams can be grouted after some time shows that the shrinkage due to chemical action in the concrete and to cooling from the high setting temperature more than equalizes the swelling due to water-soaking; the final result is shrinkage even after the dam is entirely water-soaked. The cracks in many dams without joints show that the resulting shrinkage is usually greater than the extensibility of the concrete in tension. This condition means that the non-uniformity of the arch stresses is increased.

The question of how to equalize these arch stresses is of great importance since a thin arch with uniform stress distribution can carry the same load as a thicker arch with non-uniform distribution. The efficiency of arches will be highly increased if the stresses can be equalized and thereby a saving in material can be attained.

The writer can see no other way to obtain initial stresses for equalization of the final stresses than by use of a multiple-pressure grouting.† A division both vertically and horizontally of some of the contraction joints into compartments and the grouting of the different compartments under different pressures make it possible to obtain initial stresses distributed in about the same way as the stresses due to a heating of the dam. By means of such initial stresses in the arch not only can the arch stresses under load be approx-

* Cons. Engr., U. S. Bureau of Reclamation, Denver, Colo.

† As outlined in his discussion of the paper entitled "Analysis of Arch Dams by the Trial Load Method," by C. H. Howell, M. Am. Soc. C. E., and the late A. C. Jaquith, Esq., see p. 1272.

imately equalized, but the division of load between arches and cantilevers can also be checked in order to reduce the cantilever load as much as may be found convenient.

F. H. CONSTANT,* M. AM. SOC. C. E. (by letter).—This paper is a continuation of the subject of the solution of arch dams by the trial load method, based on equal deflections of the horizontal arch and the vertical beam elements at every point of the dam. The method described was first suggested by William Cain, M. Am. Soc. C. E.† It was later developed by F. A. Noetzli, M. Am. Soc. C. E.,‡ for the crown section only, under the assumption that the water load is uniformly distributed on each horizontal arch, and that the vertical beam is a cantilever fixed at the base. While the Noetzli method is also applicable to the case in which the vertical beam is hinged at the base, the additional condition introduced—that of zero moment at the base—greatly complicates the solution by trial. It may almost be said at the outset that the use of the trial method pre-supposes a dam with a fixed base. It can be expected, when the necessity for so doing is recognized, that efficient means for anchoring the dam to the bed-rock will be devised.

It was apparent immediately after Mr. Noetzli's paper was published, that there is no basis for the assumption of a uniform water load, and that the actual distribution cannot be determined by a study based merely on a coincidence of deflections at one section only. The paper§ by C. H. Howell, M. Am. Soc. C. E., and the late A. C. Jaquith, Esq., which met these defects squarely, and which demonstrated the practicability of the trial method in actual design, was "a long step forward". Mr. Sutherland's paper is a continuation of the same theme, and as, in the writer's opinion, the trial method, based on coincident deflections at every point of the dam, is the only practical solution of the problem, it is very welcome. Each contribution along this line helps to make clear some of the uncertainties and offers valuable suggestions to the designer. What is needed now is a definite outline of procedure, absolutely reliable formulas, reduced to their simplest terms and free from integral and other operating signs, and some preliminary idea of the water load distribution on the horizontal arches.

Each of the last two papers mentioned, gives valuable information in regard to water load distribution for actual dams; that by Mr. Sutherland, in particular, for the Salmon Creek Dam. It is interesting to note that he finds it is nearly uniform near the top (at Elevation 1 151), but that it becomes parabolic about one-third the way down (Elevation 1 103). Messrs. Howell and Jaquith also obtained a nearly uniform distribution on the top arch. The author states: "It will be found that, for the lower arch sections, the load falls away rather rapidly from the center, whereas for the higher arch sections the loading varies less from a uniform distribution". This is valuable information for preliminary trials of future arch dams. More data of this kind are needed.

§ "Analysis of Arch Dams by the Trial Load Method," see p. 1191.

On account of the variation of the water load between the top and the lower arch sections, only formulas that will give influence deflection curves are of value. The author develops such formulas in Appendix II and has translated them into curves (Fig. 15), which (for the data on which the latter are based), are very valuable. Ultimately, it may be desirable to prepare a comprehensive set of such curves covering a wide variation of data, in order that the designer may be able to select the necessary influence lines from the curve without the labor of computing them from the formulas. The explanation of the use of curves is one of the valuable contributions of this paper.

The writer has previously given formulas for the horizontal thrust and bending moment at the crown and radial deflection at any point of an arch that is fixed at the ends and subjected to a pair of symmetrically placed radial unit loads.* They were applied to the Stevenson Creek Dam to obtain influence values for deflections at each 10-ft. point for each 10-ft. horizontal section between the crest and the lowest point of the dam. A few experienced computers, using a calculating machine, and systematically tabulating results, can get all these values in two or three days.

The influence deflections thus obtained† were found to satisfy Maxwell's principle of reciprocal deflections fairly closely; that is, having two deflection influence curves—for example, one for the 10-ft. point and the other for the 30-ft. point of an arch—the y-ordinate at the 30-ft. point of the first curve was equal to the y-ordinate at the 10-ft. point of the second curve.

The problem of the arch dam is still further complicated by the effects of temperature variation, shrinkage, etc., and much more study must be given to it before a final method of design is reached.

R. A. SUTHERLAND,‡ ASSOC. M. AM. SOC. C. E. (by letter).—Speaking of plastic flow, Professor Cain has stated that "this is a consoling theory, but its realization was not much in evidence at the Stevenson Creek Experimental Dam * * *". The rate of loading in those experiments was, relatively speaking, instantaneous, and cracking was to be expected. In the "high" arch dams (more than, say, 150 ft.) with which this paper dealt, the rate of loading is generally slow, and plastic flow is a factor which must be considered. The writer's method of computing stresses under two extreme conditions corresponds with assuming: First, that the beams or cantilevers are cracked; and, second, that they are not cracked. By taking mean stresses a reasonable compromise is effected, which is the most that can be done at present. No theory can fit all the facts when dealing with such an imperfectly elastic material as concrete.

Professor Cain has shown previously§ that at one point on any assumed beam "all the water pressure is carried by the arch and none by the cantilever." The existence of such a point is, however, not incompatible with Figs. 5 or 18. It should be emphasized that the "crest reaction" load shown in Figs. 4, 5, and 18 is not an additional load on the dam, but simply part of the water load

* See p. 1242; see, also, discussion by William Cain, M. Am. Soc. C. E., p. 1265.
† See p. 1242, Equation (61).

§ See p. 1265.

on the vertical beam transferred as a reaction to the crest support. To complete the load diagram, as far as the vertical beam is concerned, a horizontal arrow should be inserted at the base, directed up stream, to represent the remaining beam reaction and equalize the forces acting up stream and down stream. The effect of the crest reaction shown in Figs. 4, 5, and 18, is that, near the crest, certain loads due to part of the water load are forcing the beam down stream, while other loads due to the interaction of beam and arch are forcing the beam up stream. At one point, these forces will be equal, and the net force on the beam will be nil. This point will correspond with Professor Cain's point, *K*.*

Mr. Jakobsen points out that the formulas given by the writer are correct only for relatively thin arches, such as $\frac{t}{r}$ less than 0.3. This does not prevent their use for the majority of arch dams with relatively small error. It can easily be shown that the condition, $\frac{t}{r} < 0.3$, is very nearly equivalent to the condition that the depth is less than $\frac{3}{8} f$, in which, f is the cylinder stress, in pounds per square inch. Taking a usual value of 300 lb. per sq. in. (about 20 long tons per sq. ft.), this condition holds for plain arch dams up to 180 ft. high, and for higher constant-angle arch dams. For dams of greater height arch action is small in the lower part and errors made will be relatively unimportant even if $\frac{t}{r}$ is excessive.

Mr. Jakobsen has shown that the writer's assumption of zero arch load at the abutments is incorrect. This is an important point in the theory of arch dams in so far as the resultant arch stresses at the abutments are concerned. It will not, however, have an appreciable effect on the deflections, on which the writer's method of load distribution depends, because the arch deflection ordinates fall away to zero so rapidly at the abutments. This will be clear from Fig. 5 (*d*), (*e*), (*j*), and (*k*), in which the arch deflection curves would be scarcely altered even if the arch load were given an appreciable value instead of zero at the abutment. The result on the arch stresses will be more important and will tend to increase the intradosal stresses at the abutment to more than those found by the writer.

The writer does not agree with Mr. Jakobsen that shrinkage has been neglected in the paper, since the manner of allowing for this was fully dealt with in the section entitled "Temperature and Shrinkage". Since nearly all large arch dams are now built with vertical joints, shrinkage stresses are less important than in the case of a small dam like that of Stevenson Creek.

Mr. Bauman's interesting and constructive discussion emphasizes the utility of the ellipse of elasticity in the analysis of thrusts and deflections due to non-uniform and non-symmetrical loads. He also shows that the cost of reinforcing steel required to take such tensile stresses as do occur in an arch dam is a very small percentage of the total cost. In spite of this the practice of reinforcing large arch dams has seldom been followed, probably on account of

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 74, Fig. 15.

the difficulty of anchoring the bars adequately into the foundation, and of avoiding interference with the pouring of the concrete in bays. Most investigations on arch dams have aimed at devising methods of avoiding or reducing tension rather than accepting and providing for it, but the writer believes that the possibility of reinforcing arch dams might be profitably discussed.

Dr. Vogt states that the system of multiple-pressure grouting appears to be the only method of equalizing final arch stresses. This method would give ideal results for only one given set of conditions of water load and temperature, but it appears to hold out considerable promise in the direction of increased economy and security of arch dams.

The writer agrees with Professor Constant that the trial-load method should be founded on the assumption of fixed base. While the elastic yielding of the foundation rock is equivalent in some measure to pivoting at the base, the effect of such action is to reduce beam loads, and hence is on the side of safety.

Professor Constant puts forward a plea for "some preliminary idea of the water load distribution on the horizontal arches". The writer believes that this will be done in time, by determining the distribution for various standard profiles of site, such as were referred to in the writer's discussion of the Stevenson Dam tests.*

In fact, once a method of procedure is adopted as satisfactory, there is no reason why the design of arch dams should not be standardized for various site profiles, heights, and crest spans, the designs, of course, being based on a certain theoretical stress. This would entail an enormous amount of work, but would be of great benefit in the preliminary design of dams, and would make immediately available to all engineers the results of the research work which has been done by various organizations with extensive resources.

Paper No. 1720

SILTING OF THE LAKE AT AUSTIN, TEXAS*

By T. U. Taylor,† M. Am. Soc. C. E.

With Discussion by Messrs. L. M. Lawson, C. H. Eiffert, Oren Reed, Charles Schultz, John B. Hawley, H. F. Robinson, Julian Montgomery, Kirk Bryan, J. C. Stevens, P. A. Welty, Banks McLaurin, R. G. Tyler, E. C. H. Bantel, R. F. Walter, William Jenner Powell, R. I. Meeker, and T. U. Taylor.

In 1890, cross-sections of the old lake formed by the Austin Dam were taken at different points, as shown in Fig. 1 and in Table 1. The crest of the old Austin Dam was 60 ft. above the toe, or apron of the down-stream face, whereas the overflow crest of the new dam is 9 ft. lower, or 51 ft. above the toe.

The water first flowed over the crest of the old dam in May, 1893, and there were at this time 79 537 303 cu. yd., or 49 300 acre-ft. of water in the lake, rising to the level of the crest of the old dam. In February, 1900, there were 41 528 810 cu. yd., or 25 741 acre-ft. Thus, the water capacity of the lake in February, 1900, was only 52% of the capacity of that in May, 1893. If these volumes are estimated in depths on a square-mile base, the result is, in 1893, a volume of water equal to a depth of 78.6 ft. and, in 1900, an equivalent depth of 38.4 ft. of this was silt. This was the result from May, 1893, to January, 1900, a period of 6.75 years.

Table 1 shows the maximum and mean depths of water for 1893 and 1900; the maximum and mean depths of silt for 1900; and the percentage of silting at the respective stations.

The maximum depth of silt is not always equal to the differences of the maximum depths of water for 1893 and 1900 because the silt has shifted at several points. This was very noticeable at Station 12.525, known as Santa Monica, or Sulphur Springs. The column of percentages is the ratio that the cross-section of 1900 (of silt) bore to the original cross-section of water.

* Published in February, 1928, *Proceedings*.

† Dean of Eng., Univ. of Texas, Austin, Tex.

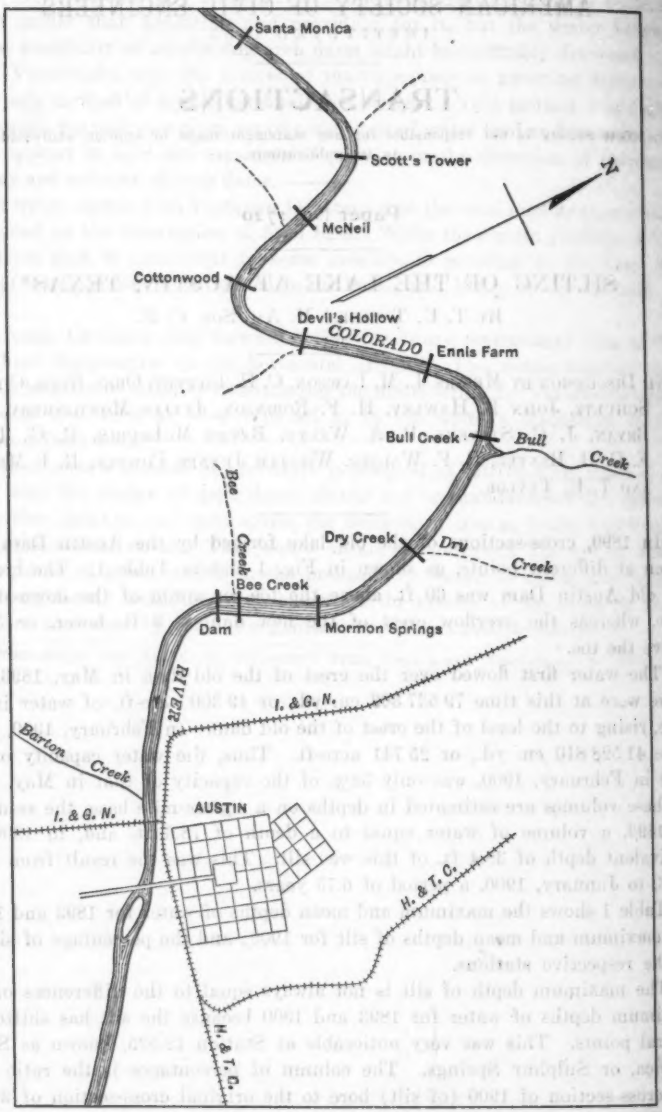

FIG. 1.—MAP SHOWING LOCATION OF AUSTIN DAM.

Thus, at Santa Monica Springs (Station 12.525), 78.9% of the original cross-section has been filled in 6.75 years.

Between Stations 0 and 17.75, the silt in 1900 was a fine, impalpable, absolutely gritless deposit. From Station 17.75 to the head of the lake, there was a distance of nearly 3 miles where the silt consisted largely of sand.

The Pedernales River traverses sandy valleys and enters the Colorado River several miles above the head of the old lake, and at flood stages it is heavily charged with sand. When these flood waters strike the relatively still waters of the lake and the velocity is checked, this heavy sand is deposited. At occasional points below the head of the lake, small bars of sand were found near the mouths of small canyons or creeks. The cross-sections of the old lake are shown in Fig. 2. The vertical scale is ten times the horizontal. (See, also, Table 2).

From March 15 to April 17, 1899, the water level of the lake was a little more than 10 ft. below the crest of the dam. The water again commenced to overflow on April 21, 1899, when the river rose to a height of 9.8 ft. above the old crest. This flow continued until June 2, 1899, and its result on the cross-sections near the head of the lake was marked. The sections at Stations 13.425, 14.725, 16.225, and 17.725 were scoured out from 2 to 3 ft. deeper than the sections of 1897, and, at Station 14.725, a sand-bar was deposited on the inside (left) of the curve of the river, which contracted the channel to less than one-half its former width.

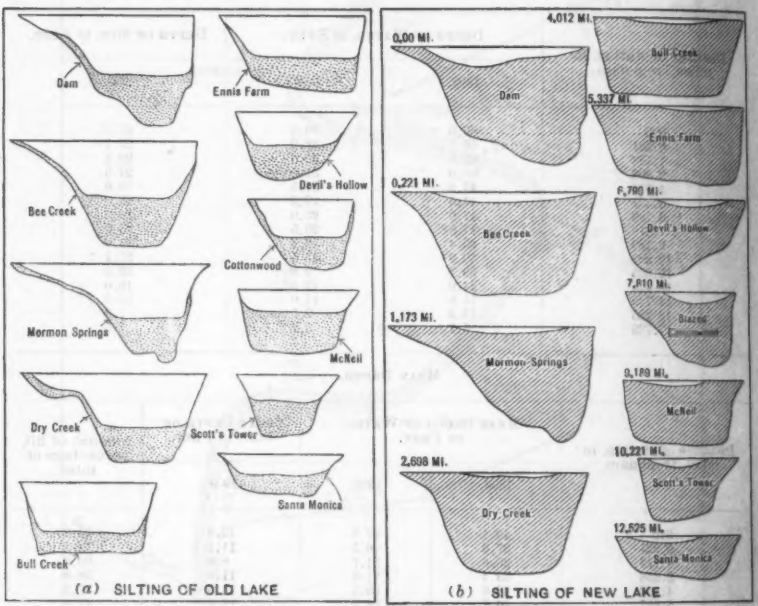

FIG. 2.

From above Colorado City, Colo., on the Texas and Pacific Railroad, the river flows through a hilly country for 300 miles, and absorbs in its course the waters of the Conchos, the San Saba, the Llano, and Pecan Bayou, as well as those of the Pedernales. All the country drained by these tributaries is hilly, with the exception of a few miles along the head of the Colorado and the Conchos Rivers.

SILTING OF NEW LAKE AUSTIN

The contract for the present Austin Dam was let in 1911, and the dam was partly completed by the summer of 1913. In September of the same year, the lake was filled with water up to the present spillway, which is 51 ft. above the toe of the old dam. This datum was the one usually adopted. The

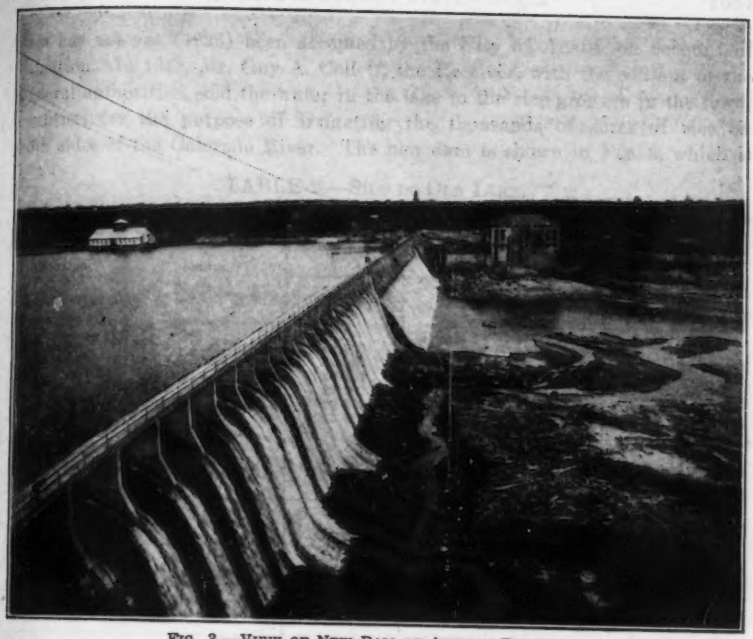

FIG. 3.—VIEW OF NEW DAM AT AUSTIN, TEXAS.

dam has not yet (1926) been accepted by the City of Austin on account of litigation. In 1918, Mr. Guy A. Collett, the Receiver, with the consent of the Federal authorities, sold the water in the lake to the rice growers in the lower counties, for the purpose of irrigating the thousands of acres of rice on both sides of the Colorado River. The new dam is shown in Fig. 3, which is

the water farther toward the main channel to the west. Fig. 4 is a view looking west from the top of the new dam.

During the latter part of the summers of 1922, 1924, and 1926, the writer made measurements of the cross-sections of the present lake at the old stations, and found the results to be as given in Table 3, and as illustrated by the cross-sections in Fig. 2(*b*).

Theory of Silting of Lake Austin

The silting of reservoirs for purposes of comparison is best reduced to heights or depths on a square-mile base. To derive an expression for the quantity of silt deposited in a given time, let x = the depth, in feet, of silt deposited by each foot in height per year; and h = the original depth of water in the reservoir. The depths of water at the end of 1, 2, 3, and n years are:

At the end of 1 year, depth of water = $h\ (1-x)$
At the end of 2 years, depth of water = $h\ (1-x)^2$
At the end of 3 years, depth of water = $h\ (1-x)^3$
At the end of n years, depth of water = $h\ (1-x)^n$

Hence, if d = the depth of water at the end of n years,

$$d = h\ (1-x)^n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

This will not be true for any reservoir in which there is an appreciable current acting on the bottom of the basin, that is, on the upper surface of the silt. In the old lake at Austin, the lake level could sink to 10 ft. below the crest of the dam, and still have a fair current in the penstocks, as the bottom of the forebay was 12 ft. below the crest of the old dam.

The measurements on the new lake were carried no farther up the lake, for the reason that the next station above Santa Monica was filled entirely with sand. In fact, sand was encountered about ½ mile below Santa Monica, or at a point 12 miles from the dam. Table 3 includes only the fine gritless mud. The volume of water in:

1913 = 32 029 acre-ft.
1922 = 5 362 acre-ft.
1924 = 2 901 acre-ft.
1926 = 1 477 acre-ft.

If these are reduced to the depths, in feet, on a square-mile base, the volume of water in:

1913 = 50.05 ft.
1922 = 8.38 ft.
1924 = 4.53 ft.
1926 = 2.31 ft.

$$\text{Ratio of water volumes} = \frac{\text{Volume of 1926}}{\text{Volume of 1913}} = 0.0461 = 4.61\%$$

Thus, in the thirteen years the Austin Lake has filled 95.39% of its volume as measured in 1913. The water has now (1926) 4.61% of the volume it had in 1913.

In Equation (1), $h = 50.05$, and the depth of water = 2.31. Hence,

$$50.05\ (1 - x)^{11} = 2.31$$

and,

$$x = 0.20$$

That is, on an equal base, an average of 20% of silt was deposited each year. Fig. 5 illustrates the relative quantity of silt and water in September, 1926.

Drift

The Colorado River of Texas, with its tributaries, traverses nearly 2 000 miles of wooded territory, and every rise brings its sinuous ribbon of drift, which ranges in width from 40 to 200 ft. When the first drift strikes the gates or buttress walls of the Austin Dam, it spreads out over the entire width of the lake, and banks up behind, until the complete surface of that part near the dam is covered with drift from shore to shore. At times, this covers an area more than ¼ mile wide and ½ mile long.

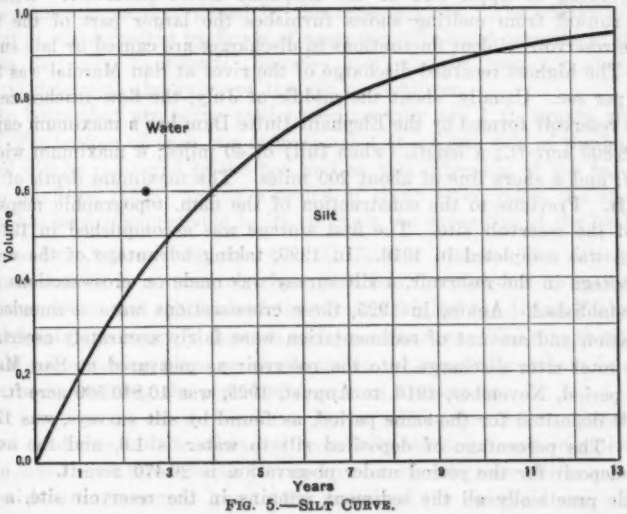

Fig. 5.—Silt Curve.

Fig. 4 was taken from the top of the dam, looking northwest. A line, joining the man in the foreground with the building on the right, points straight up the river. This drift sometimes covers an area of 80 acres, and the velocity of the water in the lake gradually compacts the drift toward the dam, making it more and more dense.

As the water recedes and the lake level sinks, the part of the drift between the man and the power-house rests on the alluvial soil beneath—the result being that the silt near the dam is in reality mud reinforced with sticks, débris, and all manner of floating logs.

In the background is noticed a strip of driftless water. This water is in Bee Creek, above which the silt is almost free from drift, because the velocity of the water in the lake compresses the drift area into that section between the creek and the dam.

DISCUSSION

L. M. LAWSON,* M. AM. SOC. C. E. (by letter).—The author has described one of the important features of the storage of water in the Southwest where inflows carry a large percentage of sediment. An opportunity for similar study presented itself in the creation of the Elephant Butte Reservoir on the Rio Grande. The Elephant Butte Dam forms one of the largest reservoirs in the United States for irrigation, and during the writer's superintendency of the Rio Grande Project (of which this dam is the main storage feature), two silt surveys were made and interesting data collected on the amount of sedimentation.

The Rio Grande, which is the source of the water supply for the Rio Grande Federal Irrigation Project, rises in Southern Colorado and has a drainage area of 30 000 sq. miles above San Marcial, N. Mex., which point is the beginning or upper end of the Elephant Butte Reservoir. While the spring run-off from melting snows furnishes the larger part of the inflow into the reservoir, violent fluctuations in discharges are caused by late summer rains. The highest recorded discharge of the river at San Marcial was 33 000 cu. ft. per sec. Usually, about the middle of July, the flow reaches zero.

The reservoir formed by the Elephant Butte Dam has a maximum capacity of 2 638 800 acre-ft.; a length (when full) of 40 miles; a maximum width of 6 miles; and a shore line of about 200 miles. The maximum depth of water is 200 ft. Previous to the construction of the dam, topographic maps were made of the reservoir site. The first storage was accomplished in 1915 and the dam was completed in 1916. In 1920, taking advantage of the unusual large storage in the reservoir, a silt survey was made on cross-sections previously established. Again, in 1925, these cross-sections were re-sounded and the location and amount of sedimentation were fairly accurately ascertained.

The total river discharge into the reservoir as measured at San Marcial, for the period, November, 1916, to August, 1925, was 10 840 500 acre-ft. The total silt deposited for the same period, as found by silt surveys, was 177 740 acre-ft. The percentage of deposited silt to water is 1.6, and the average annual deposit for the period under observation is 20 470 acre-ft.

While practically all the sediment remains in the reservoir site, a large percentage is deposited above the ordinary usable storage elevation.

C. H. EIFFERT,† M. AM. SOC. C. E. (by letter).—The rate at which the capacity of the Austin Reservoir has been reduced is truly remarkable. In the retarding basins of the Miami Conservancy District the rate of silting is comparatively very small.

The manner of silting in these basins will differ greatly from that described by Dean Taylor. Water is stored only temporarily during floods. Most of the time they are entirely empty, and practically all the included area is good agricultural land and is farmed every year. To this farm land the deposit of silt is of great value as fertilizer.

* Commr., U. S., International Boundary Comm., El Paso, Tex.
† Chf. Engr., The Miami Conservancy Dist., Dayton, Ohio.

The annual rate of deposit will not be uniform because the number of floods and their intensity differ considerably from year to year. The amount of silt carried will undoubtedly vary quite a little according to the season at which a flood occurs and also according to the intensity of the rainfall and the condition of the soil and crop growth at the time of flood. During the intervals between floods there will be a great many local rains, which, while they will not cause back-water in the basin, will result in considerable run-off and local erosion, thus tending to remove much of the silt deposited by back-water.

In two of the basins where the rate of silting is likely to be greater than in the others, a number of cross-sections have been taken. This work will be repeated from time to time and the amount of silt remaining as a permanent deposit will be determined. In addition, a number of silt-catching boxes have been installed. By means of these it is intended to obtain the actual amount of silt deposited by individual floods for comparison with the amount remaining permanently as determined by the cross-sections. The variation in the amount of silt deposited by floods of approximately equal severity at different seasons may also be found. Samples may also be used for analyses in order to determine the value of the silt as fertilizer.

The boxes that are being used experimentally are 1 ft. square and 6 in. deep. The bottom of each box extends out 1 ft. on one side of the box. The deposit will be measured in the box and on this extension of the base.

To this time (1928) during a period of about seven years, the amount of silting has been inappreciable in its effect on the capacities of the basins.

OREN REED,* ASSOC. M. AM. SOC. C. E. (by letter).—The silting of the Austin Reservoir in a relatively short time is a forceful demonstration of the enormous débris and silt load of the rivers draining the Great Plains. The value of a storage reservoir depends on its permanency. The rate at which erosion of soil is taking place on the basin of the supplying stream is a major factor in determining the period of service of a reservoir.

In many cases, as at Elephant Butte, silting has been accepted as a natural condition and its effect has been fully taken into consideration. The loss in investment through the silting up of a storage reservoir is small when compared with the actual loss to the region of the reservoir site. For this reason, it is of paramount importance that, wherever it is possible, the permanence of a reservoir be assured through adequate protection of the stream basin from erosion.

The Colorado River (of Texas) heads in Eastern New Mexico near the Texas line, at an elevation of less than 4 000 ft. It flows southeastward and crosses the Balcones fault zone a short distance above Austin. The Balcones escarpment is the result of an enormous geologic fault that extends across the entire State from the Red River to the Rio Grande. It marks a sudden change from the gently sloping Rio Grande Plain to the eroded plateaus. The clay soil cover of the water-shed supports a fair growth of scrub timber. The head-waters of the Colorado flow in the deeply fissured limestone of the

* With Swedish Gen. Elec. Co., Vesteras, Sweden.

central plateau and are normally clear. They carry, however, during periods of flood, an enormous quantity of silt eroded from the gorges and channels of the small streams which indent the plateau region. The silt burden has been roughly estimated at 1% of its volume.* Wide fluctuations between minimum and maximum flow are caused by periods of intense rainfall.

It is generally accepted that a forest is an excellent agency to prevent soil erosion. The streams in the Western States, that have their sources in the forested mountains, are largely clear, or of prevailing low turbidity, until they enter the treeless plains. The thin soil cover and low rainfall in the Upper Colorado Basin are not favorable to the growth of a forest cover. In many places it is impossible to maintain a sufficient cover of shrubs and grasses to afford even moderate protection against erosion of the soil.

The use of check dams or settling basins on the head-water streams however, would be of great value. Rough alluvial lands which have been injured by gullying during floods, or upon which sand or gravel bars have been deposited, could be flooded by low and inexpensive dams. Most of the débris and silt carried by the stream would be thus deposited by natural elutriation. For several years check dams have been used to control the flood flow of the upper water-sheds of certain torrential streams in Southern California.† This was an adaptation of the Swiss and Austrian method of torrent control by means of these dams. Channel rectification and levee protection in the Upper Rhine Valley were largely futile until such dams were built to lessen the work of erosion.

All protective cover, whether of grass, brush, or forest, on the head-water streams should be carefully maintained and bank protection should be utilized where economically feasible. For the Great Plains, from Texas northward, about the only practicable means of reducing soil erosion and silting of reservoirs and watercourses is to construct and maintain a comprehensive system of check dams on the head-water streams. The flood flow which at present causes enormous damage to property and life at frequent intervals, would be in part absorbed and retained in ground storage. The increased ground storage would be reflected in a higher minimum flow in the rivers.

CHARLES SCHULTZ,‡ M. AM. SOC. C. E. (by letter).—Because of the nature of civil engineering work, it is not often that engineers are afforded the opportunity to secure records, extending over the long periods of time, as given by the author. Certainly, this paper should make engineers consider this feature of design of reservoirs before proceeding with the expenditure of public moneys. Very little has been written on this subject, and to one who has never had occasion to deal with this problem its possible seriousness seems almost unbelievable.

In 1914, the writer designed a dam in McKinney, Tex., to furnish water for a small country club. The dam (100 ft. wide) was located along a deep ravine, having been constructed to hold back 18 ft. of water and to form a

‡ Tulsa, Okla.

lake ¼ mile long. As this was fed by small springs, no measurement was taken of the drainage area, which was flat, rolling, black land country, such as exists in a belt of land 100 miles wide, extending from the Red River to the Gulf of Mexico. This drainage area was approximately 1 000 acres, and in 10 years the run-off carried enough silt to fill the entire lake, which had to be abandoned. The average rainfall was approximately 40 in., and most of the territory was cultivated farm land.

On another occasion the writer constructed a levee in this same county, along Pilot Grove Creek, a tributary of the Trinity River, which has a width between hills of approximately 1 mile. The creek above this point was approximately 15 miles long, and carried so much silt that along the entire bank where the levee was constructed there was a fill of approximately 4 ft. that had been made since cultivation had begun, and stumps were encountered 4 ft. under the surface.

It is true that most rivers do not carry as much free sediment as some of the rivers in Texas, where the rate of rainfall is severe at times and the soil so light as to be easily washed away. However, this paper will remind engineers that these conditions should be studied and taken into account.

JOHN B. HAWLEY,* M. AM. SOC. C. E. (by letter).—This paper is the result of continuous observation and study by Dean Taylor during more than thirty-five years. He has repeatedly addressed Texas societies and associations, calling attention to the element of siltation and its menace to the success of water-storage projects. Data presented in the paper may be confidently accepted as accurate.

The author has not fully described the character of the drainage area of the Colorado River above Austin. Fig. 6 shows this region, with its areal geology, and the drainage area of the West Fork of the Trinity River above the Fort Worth water supply reservoir, "Lake Worth".

The total drainage area of the Colorado above Lake Austin is approximately 38 000 sq. miles; that of the Trinity above Lake Worth is 1 800 sq. miles. The areal geology, cultivated districts, and axial slopes of the two areas are quite similar; Austin being characterized by Comanchean (Lower Cretaceous), Permian, Pennsylvanian, Later Cenozoic, and the "Central Mineral Region" (Archæan), and Fort Worth by Comanchean, Permian, and Pennsylvanian.

On the Austin drainage area, the part designated "Central Mineral Region" (about 3 000 sq. miles) may be considered, for run-off and siltation purposes, as of the same general character as the Pennsylvanian. The upper 10 000 sq. miles (Later Cenozoic) has a mean annual rainfall of only 15 in.; many of the tributary creeks never reach the main stream at all, but lose themselves in sand flats and "sinks". It would seem improper as a siltation feature, therefore, to include this area. After deducting it, 28 000 sq. miles remain, for purposes of this discussion.

The average mean annual rainfall is approximately 24 in. The mean annual silt (for the two periods reported on by Dean Taylor) is about 2 800 acre-ft., or 0.1 acre-ft. of silt per sq. mile per annum. The Lake Worth drain-

* Cons. Engr., Fort Worth, Tex.

age area is 1 800 sq. miles; the mean annual rainfall is (approximately) 28 in.; and the mean annual siltage since 1916, according to the U. S. Geological Survey and Texas Board of Water Engineers (approximately), 0.5 acre-ft. of silt per sq. mile per annum. This result was determined by "core soundings", because only a few original cross-sections of the lake basin were available.

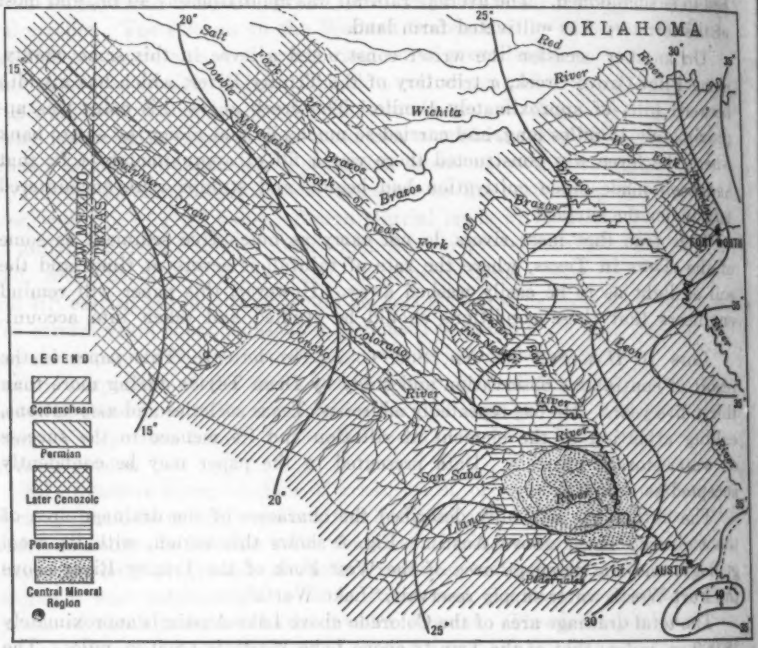

FIG. 6.—DRAINAGE AREA, COLORADO RIVER, ABOVE AUSTIN, TEX., AND OF TRINITY RIVER ABOVE LAKE WORTH.

The difference in character of the areal geology of the two areas is slight; the 4-in. difference in rainfall is scarcely sufficient to account for the vastly larger rate of siltation at Lake Worth. Medina Lake, 40 miles northwesterly from San Antonio, Tex., lies, with its entire drainage area (600 sq. miles), in the Comanchean rocks. Its axial slope is much steeper than that of the Colorado; its mean annual rainfall is about 28 in.; and its rate of siltation, about 0.3 acre-ft. per sq. mile per year. This drainage area is almost contiguous to the southern "divide" of the Colorado.

Personal inspection of substantially the entire Medina water-shed, in 1915, leads the writer to believe that the siltation rate at Medina Lake is naturally much less than at Lake Worth, due to the almost uniformly rocky nature of the Medina area.

Examination of Fig. 2(*a*) indicates that even the old lake merely offered a rather large "channel section" for carrying storm waters, the velocity of which would probably be sufficient to carry a large proportion of fine silt over

the dam. Fig. 2(*b*) clearly shows that current velocities in times of flood were doubtless ample to transport all but the largest and heaviest silt particles over the spillway.

The Austin structure is substantially a "channel dam" and the lake created by it is merely a "channel lake" (Fig. 1). On the Clear Fork of the Trinity, southwesterly from Fort Worth, are three "channel dams", built in 1895. The drainage area above the upper one of these dams is about 500 sq. miles. The geology is Comanchean, with an axial slope of 8 to 10 ft. per mile. The mean annual rainfall is 28 in. The river channel is 26 ft. deep and the dams are 14 ft. high.

The first flood, after completion of these dams, left about 18 in. of silt deposit in each dam. The next flood carried out the silt left by its predecessor, and made a new deposit—and so on to the present time. In 1927—thirty-two years after construction—there is no more silt behind these dams than after the first flood.

In recent years, the writer has observed, at intervals, the discharge of the Colorado River over the crest of the Austin Dam. Its great turbidity and "soupy" nature, which is at times 15 000 to 20 000 parts per million, strongly supports the writer's idea.

If the floods from more than 30 000 sq. miles of catchment area have resulted in a siltation of only 2 800 acre-ft. per annum (instead of double or thrice this amount), it seems fairly clear that the bulk of the silt brought down by large river discharges must have passed over the dam. It would further seem that, had the impounded water body been of such contour as to constitute a "lake" in the usual concept of such a body, instead of a deepened river channel, its 50 000 acre-ft. capacity might have been 95% silted in 6 to 8 years.

Perhaps a 500 000 acre-ft. reservoir would have been the basis of an economically practicable project at Austin, but the one constructed never was, and never can be, an economic success because of an over-sized water-shed and an under-sized lake. A power company now contemplates constructing two 2 000 000 acre-ft. reservoirs farther up the river. Such reservoirs might help the situation at Austin Lake.

H. F. ROBINSON,* ESQ. (by letter).—In connection with the observations of the author, the status of the silting problem at the Zuni Reservoir in New Mexico is of interest.† The conditions affecting the two cases are quite dissimilar. At Austin, there is a long, narrow reservoir in a perennial stream and, at Zuni, a reservoir almost circular in shape is formed in the bed of an ephemeral stream which is supplied by a very uncertain rainfall and run-off. In both cases large quantities of silt have been brought in and deposited, at Austin, 95.39% of the storage capacity in 13 years, and at Zuni, at the 990-ft. contour, 94.89% in 22 years.

The showing of such immense quantities of silt being brought into reservoirs, under dissimilar conditions, when constructed in stream channels, espe-

* Superv. Engr., U. S. Indian Irrig. Service, Albuquerque, N. Mex.

† See, also, *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 868.

cially in this western country where erosion is increasing from year to year, is not only astounding, but alarming.

From his observations on the Zuni Reservoir, the writer cannot quite agree with the theory of silt deposit advanced by Dean Taylor. Ordinarily, the amount of silt deposited in a reservoir depends on (*a*) the quantity of water coming into, or passing through, the reservoir; and, (*b*) the amount of silt carried by the water. The latter is a variable figure depending on many things, including the character of the drainage area. Under the conditions existing at both reservoirs there is coming into, or through, the reservoir a certain quantity of water each year, which water will carry an unknown but variable amount of silt. It would seem that irrespective of the size of the reservoir (within reasonable limits), with a given quantity of water going into or through it, there would be deposited a similar volume of silt; and as the area of the reservoir was reduced, the deposit of silt would be greater in depth in each period.

Of course, a given quantity of water coming into a large, empty reservoir and remaining there would deposit a greater amount of silt than would the same quantity of water flowing into a reservoir already full, or partly full, and passing over the spillway or dam, carrying a portion of its silt. However, this would be only one minor factor affecting the result.

The "Theory of Silting", as stated by the author, would seem to take none of these factors into consideration, but rather to assume that, knowing the capacity of the reservoir before and after silting and the period elapsing, the rate of deposit is wholly a function of the capacity of the reservoir.

The records of the Zuni Reservoir (Table 4) seem to indicate an irregular deposit which has no reference to the capacity of the reservoir and only indirectly as to (*a*) the quantity of water, with (*b*) the silt content being almost undetermined. The curve of silt deposited annually will be practically a straight line (see Fig. 7*) rather than a curve as shown in the author's Fig. 5.

It is perhaps advisable to give the conditions that have been found at Zuni. After the failure of 1909 the weir was built to Elevation 991, but since then a permanent weir of concrete has been constructed to Elevation 997 and stop-planks can be used to raise it to the original 1 000-ft. elevation.

Silt Deposit.—The quantity of silt brought into the reservoir has been very great. Records are now complete to January 1, 1928, a period of approximately 22 years (Table 4). With the water surface in the reservoir at Contour 990, there is only 5.29% of the capacity left. The amount of silt brought into the reservoir, however, has been greater than this would indicate, the excess being deposited between the 990 and 1 000-ft. contours. The total capacity at Contour 990 was 10 230 acre-ft. The total silt deposit in the reservoir on January 1, 1928, was 11 940 acre-ft. The area of the reservoir at the 990-ft. contour is 512 acres and at the 1 000-ft. contour, 620 acres. The capacity remaining at the 1 000-ft. contour is 26.9% of the original capacity of 15 811 acre-ft. at that height.

* See, also, *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 871, Fig. 1.

The first attempt to determine the amount of silt coming in was in June, 1910, when soundings were taken from a boat, and at intervals thereafter soundings were made through the ice, usually in January. There are only a few weeks in any winter when the ice is thick enough for this purpose and in several years it was impossible at any time in the winter to get out on the ice. This was the case for the several years of no record (Table 4).

In making these soundings the same base line was used each year and the surface of the reservoir was divided into squares 300 ft. on the side. This assured that the soundings for each year were made at practically the same spot and the records, therefore, are unusually close. From these soundings contour plats were made from which the amount of silt deposited was computed. Table 4 shows in detail the silt deposited by periods and the total run-off entering the reservoir for the same periods. The capacity of the reservoir at Contours 990, 1 000, and 1 010 are shown, with the percentages remaining of the original capacity at each of the periods under consideration.

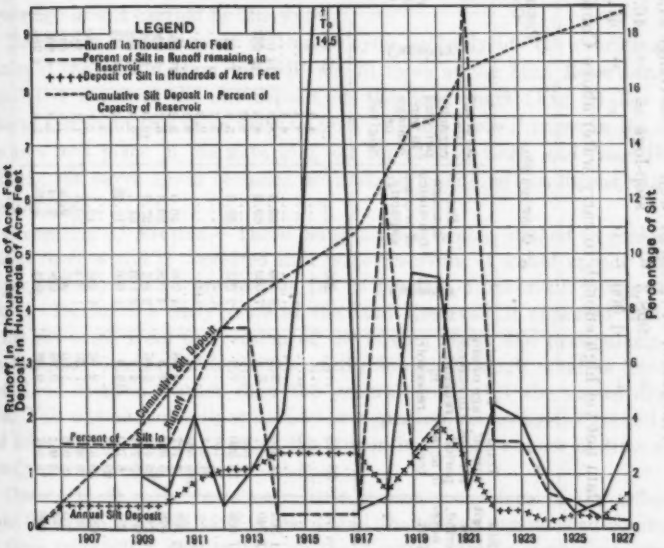

FIG. 7.—SILT PROBLEM OF THE ZUNI RESERVOIR AT THE 990-FOOT CONTOUR.

The reservoir may be considered defined by the 990-ft. contour. Many of the data have been recorded in Fig. 7. In order to compare the various elements, the run-off is expressed in thousands of acre-feet, the deposit in hundreds of acre-feet, and the percentage of silt in the run-off which remained in the reservoir. This may assist in an understanding of conditions and of the original statement* that "the percentage of silt carried by the water is in a certain inverse ratio to the magnitude of the run-off, within, as yet, undetermined points."

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 888.

* January, 1908, to June, 1910.
† June, 1910, to January 1, 1912.

Two important considerations that were not stated modify that conclusion. For one thing the statement is true only so long as the regimen of the run-off area remains undisturbed. Again, this statement and the data given in Table 4 refer to the percentage of silt in the run-off. This latter is not entirely true, for what is shown is the percentage of silt in the run-off which remains in the reservoir. A certain amount will remain in suspension and pass over the spillway and the part dropped in the reservoir will depend on many conditions, such as the state of the reservoir when a given run-off occurs; whether empty or full; the character of the silt, etc. Hence, the writer is not as sure as formerly that there is any intimate connection between the amount of silt carried by a particular flood and its magnitude. It should also be remembered that a part of the silt does not remain in the reservoir permanently because some is carried out with the irrigation water. It has been estimated that at least 50 acre-ft. goes out in that way annually at the Zuni Reservoir. However, the record is very clear that the greater the run-off the less will be the percentage of silt carried by the water.

The theory of silt deposit of Dean Taylor probably fits the conditions and results at the Austin Dam, but will not fit those at the Zuni Reservoir. The cumulative curve of the silt deposit on the Zuni chart (Fig. 7) lies fairly close to a straight line from 1906 to 1923. At this time changes in the drainage area took place in the nature of silt retardation work, and from 1923 to 1928 the silt curve again becomes, with slowly changing conditions, almost a straight line.

Prevention of Erosion.—There being no practicable method to remove silt once it reaches and is deposited in a large reservoir, it would appear that the proper procedure is to prevent, as far as possible, further silt being carried into it. During the early years of the Zuni Reservoir it appeared that most of the silt came from the erosion of the stream above and particularly from the branches coming in from the south, flowing through what is known as Horsehead Canyon, rather than the general erosion of the entire drainage area. This was undoubtedly caused by over-grazing, removing the ground cover, and allowing the run-off to reach the stream in a shorter space of time and in greatly augmented quantities.

During these early years very little erosion took place in the tributaries from the north. About 1922 it was found that heavy erosion had commenced on these tributaries, particularly on the Nutria. At the same time examinations led to the belief that the erosion on the southern tributaries had about reached an equilibrium and the danger of further heavy deposits from that direction was practically removed.

There are two phases of erosion in the drainage area of streams. One is the lowering of the channel bed and the retrogression of grades through the fine alluvial deposit of the valleys, which continues until bed-rock or hard-pan is reached, the channel widening at the same time in proportion to its increased depth. The other, which is really a part of the same action, occurs where the stream carrying the flood has a sharp bend in which the water striking the outer bank of the curve, breaks off large masses and the eroded

* January, 1909, to June, 1910.
† June, 1910, to January 1, 1912.

material is carried down the stream. Both these conditions are usually found in the same stream.

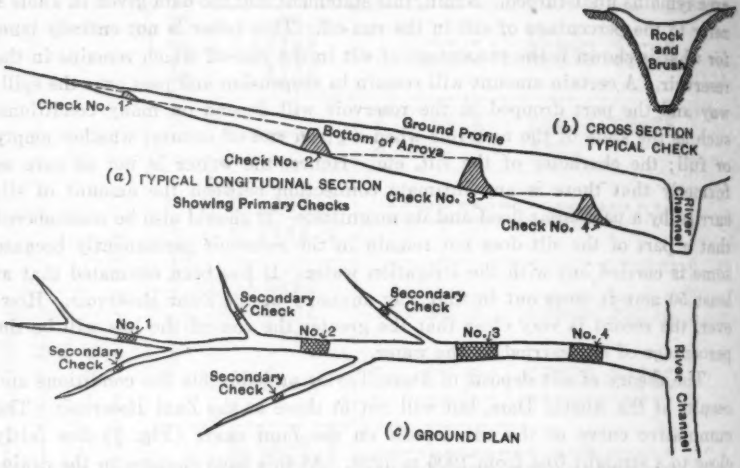

FIG. 8.—DIAGRAMMATIC PLAN OF CHECKING EROSION IN CHANNELS AS APPLIED TO THE ZUNI PROJECT.

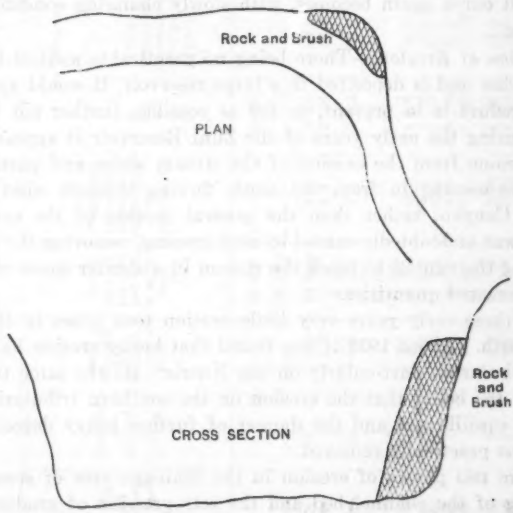

FIG. 9.—CHECKING EROSION ON SHARP TURNS IN STREAM.

It was planned to check this erosion under the first mentioned condition by constructing rock and brush checks which are placed not only in the bottom, but are carried up the banks to a sufficient height to prevent bank erosion. It was decided to place these checks close enough together to form a new grade

so that the velocity of the water will not exceed what it originally was, and the current will not erode the material (Fig. 8).

In the other case, masses of brush and rock were placed at the critical points along the side to prevent erosion. The protection at sharp bends as illustrated in Fig. 9 will not always be effective, for the simple reason that if the bottom of the arroyo is still in soft material the current will erode under the protection work; but in such cases it is only necessary (*a*) to excavate down to harder material; (*b*) to build a protection mass so it will settle with the scouring; or (*c*) to use this side protection in connection with the checks.

The erosion on the north side of the water-shed assumed alarming proportions only in 1921 and 1922, and in 1923 a small sum of money was expended in the protective work outlined. A limited amount of this work has been continued each year since, at the most critical places.

That this has been effective is shown by the fact that the reservoir capacity curve (or what is the same thing, the curve showing the silt deposit (Fig. 10)) is suddenly flattened from 1922 onward. This indicates clearly, unless several consecutive coincidences have occurred, that the protective checks and jetties are doing their work.

An extension of the control work is planned from year to year as money is available and at points indicated as necessary by further erosion.

Processes of Erosion.—As to the general problem of erosion in the Southwest, an office "Watershed Handbook" prepared by the U. S. Forest Service, Southwestern District, contains some valuable comments which may well be repeated in substance as bearing directly on the large question.

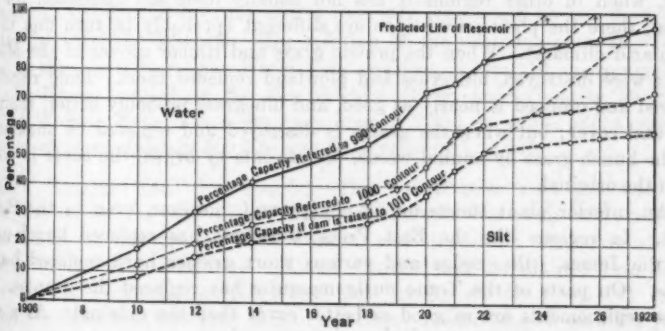

FIG. 10.—SILTING OF ZUNI RESERVOIR. CAPACITIES IN PERCENTAGES OF VOLUMES BELOW GIVEN CONTOURS.

The distinction between normal and abnormal erosion is a frequent cause of misunderstanding. A certain kind and rate of erosion, of course, exist naturally in every place, but are seldom the same in any two places. For any locality they are determined by the interplay of two forces:

1.—Resistance.—Vegetative obstruction, growth, or healing power of vegetation, kind and arrangement of soil, rocks, and débris.

2.—Disintegration.—Kind, amount, and distribution of rainfall, water flow, freezing and thawing, wind, etc.

Whenever, through a long period of time (say, a generation) these two forces approximately balance, and no material change in the configuration of the country occurs, the country may be said to be in equilibrium, and the state of erosion may be called normal. Whenever, through a similar period of time, a material change occurs (such as the disappearance of creek bottoms or gullying of slopes) the state of erosion may be called abnormal. Abnormal erosion occurs locally in the Southwest while the land is still in its virgin condition, but it was exceptional, both as to time and place, because the natural forces which upset the equilibrium (cloudbursts, for instance), were local and temporary. The natural forces for restoring equilibrium (vegetation, for instance), usually had time to "get in" their work before the upsetting process was repeated.

The artificial forces which are now upsetting equilibrium (over-grazing, for instance), are usually not local and temporary, but widespread and of long standing. Hence, the fact that abnormal erosion, once exceptional, is now general. Once self-healing, it is now cumulative. This argument does not assume that there are more or worse cloudbursts now than before the country was settled. It does assume, however, that the same number and kind of cloudbursts have more effect. For practical purposes, no distinction need be made between normal and abnormal. Any erosion that is doing damage and that can be controlled, should be controlled. There is no danger of the effort being so successful as to interfere with normal or beneficial erosion.

Why should settlement upset equilibrium on a wholesale scale in the Southwest, when in other regions it has not usually done so? Because, for one thing, there the plant successions are different (probably in turn due to the semi-arid climate). When the prairie grass and timber groves of the Middle West were destroyed, bluegrass and plowland replaced them. Land regularly plowed and cropped is nearly as good, and bluegrass probably better, than the original cover; but when the grama is destroyed and replaced by snakeweed, or the bunch-grass by annual weeds, or side-oats by brush, the cover is poorer than the original.

An inferior plant succession is not general, however, even in the Southwest. In regions like the East Pecos, bluegrass has replaced bunch-grass. On the Jemez, *valles* sedge and various short grasses have replaced bunch-grass. On parts of the Tonto curly mesquite has replaced the gramas. All these replacements are as good or better cover than the original. As a rule, however, the replacements have been inferior.

Restoration of equilibrium eventually occurs naturally, even where upsetting forces continue at work. The best example is in the region of Santa Fé, where the lower country around the Spanish settlements has been overgrazed for three centuries. The watercourses have simply eroded until they exposed enough rock and cobbles to furnish a mechanical resistance equal to the original vegetative resistance. Thus stabilized, the watercourses are proceeding to re-vegetate with alder, juniper, rabbit-brush, or whatever can grow in the rocks. The new equilibrium, however, is a relatively unproductive one from the economic standpoint.

JULIAN MONTGOMERY,* M. AM. SOC. C. E. (by letter).—Engineers who are concerned with the design and development of storage reservoirs in the southwest section of the United States should greatly appreciate this valuable contribution.

The geology of the drainage area, together with the relation between the size of that area and the capacity of the storage reservoir, are factors that designing engineers must constantly keep before them.

Familiarity with the hydrology of the Southwest reveals that the run-off of the water-sheds of the streams in that section carry considerable silt. It is not unusual for engineers engaged in the design of storage reservoirs to allow from 0.3 to 0.5 acre-ft. of siltage per year per square mile of drainage area.

The relation of the drainage area above Lake Austin, in square miles, to the storage capacity of old Lake Austin, in acre-feet, was approximately 1 to 1.6.

Lake Wichita, the water supply for Wichita Falls, Tex., was built on Holliday Creek about 1900. It has a drainage area of 135 sq. miles and a storage capacity of 14 500 acre-ft. The geology of the water-shed is largely Permian. There is considerable silt in the run-off. Yet flood waters pass over the spillway with sufficient regularity to prevent any particular accumulation of silt. Cross-sections taken in 1925 under the supervision of Dean Taylor show very little siltage in the twenty-five years. The cross-sections also show that scouring has taken place, in general, along the path of the current. At the breaks and curves along the shore line silt has been deposited. Probably the average net deposit over the entire reservoir area would be less than 1 ft. for the life of Lake Wichita. The relation of the drainage area, in square miles, to the capacity of Lake Wichita, in acre-feet, is 1 to 110, approximately.

Lake Kemp, located on the Big Wichita River, approximately 50 miles west of Wichita Falls, has a drainage area of 2 000 sq. miles and a storage capacity of approximately 500 000 acre-ft., a ratio of 1 to 250.

KIRK BRYAN,† ESQ. (by letter).‡—The quantitative data presented by Dean Taylor on the deposition of silt in Austin Reservoir add valuable information on the processes of erosion and deposition characteristic of streams in the arid Southwest. These streams may be divided into three classes:§ (1) Perennial, or those that flow nearly all the time; (2) intermittent, or those that flow only part of the time but more than a month a year; and (3) ephemeral, or those that flow only after rains and less than a month a year.

The perennial streams carry some silt at low-water stages and may be particularly active during the closing part of the flood-water period. Ephemeral and, to a less extent, intermittent streams carry silt only during floods.

---

‡ The data in this discussion formed part of a report to the Middle Rio Grande Conservancy District, September, 1927, on "Erosion and Control of Silt on the Rio Puerco, New Mexico," by Kirk Bryan and George M. Post, published by permission of J. L. Burkholder, M. Am. Soc. C. E., Chief Engineer.

§ Note the excellent definitions of O. E. Meinzer, "Outlines of Ground Water Hydrology," U. S. Geological Survey *Water Supply Paper No. 494*, pp. 57–59, 1923.

Erosion and deposition of silt by such streams are subject to changes and fluctuations quite distinct from the same processes in perennial streams. Thus, the Lower Gila in Arizona and the Rio Grande in New Mexico show a tendency to aggrade their beds, whereas their ephemeral tributaries are actively degrading their channels. This accelerated erosion, or arroyo cutting,* was begun within the memory of men now living. It has vastly increased the total quantity of silt carried by the ephemeral streams. This increased quantity of silt menaces reservoirs constructed to store flood waters. Similarly, in the valleys of the major streams, the abnormal supply of sediment chokes the channels of perennial streams, and induces a number of consequences most of which are troublesome to the works of Man.

The conditions of erosion and sedimentation on the water-sheds of the ephemeral streams have been the subject of much speculation and study with a view of determining the cause of the accelerated erosion or arroyo cutting. A theoretical analysis of the conditions indicates that, because of the increased growth of vegetation, years of large precipitation will be times of minimum erosion by running water and, consequently, times of minimum silt transfer to the lower reaches of the stream. In these periods of larger rainfall, greater quantities of water will flow down the hill slopes through the minor channels, but the erosive power of this water will be much reduced because of the increased vegetative cover. Not only does this principle seem to apply to the short periods of one or two years which frequently occur and are recorded in existing weather records, but many claim that it will also apply to longer periods. Thus, in analyzing the effect of possible fluctuations in climate in past times, this principle has been used. Periods of erosion are thought to be the result of arid climate and periods of alluviation and filling of stream channels are attributed to less arid climate. In regions of greater rainfall and on perennial streams it seems likely that the principle will not hold and the results of a change in climate may be exactly reversed.

Although this principle has been advocated by eminent men and seems sound so far as a mere analysis may go, no definite evidence has heretofore been brought forward. The experience in the operation of the Zuñi Reservoir, however, gives qualitative evidence that this principle is true.

Zuñi Reservoir on the ephemeral Zuñi River in McKinley County, New Mexico, acts as a trap to retain the sand and mud carried by the stream. The area of the water-shed above the reservoir is said to be about 650 sq. miles. Data on the river, its reservoir, and the silt problem have been published by H. F. Robinson,† Supervising Engineer, U. S. Indian Irrigation Service, who has also supplied additional information used herewith.

The silt produced by the Zuñi water-shed is variable in absolute quantity and in relation to the water entering the reservoir. Twelve determinations of

* Bryan, Kirk, "Date of Channel Trenching (Arroyo Cutting) in the Arid Southwest," *Science*, n.s., Vol. 62, pp. 338–344, 1925; "Channel Erosion of the Rio Salado, Socorro County, New Mexico", U. S. Geological Survey, *Bulletin 790*, pp. 17–19, 1927; "Historic Evidence of Changes in the Channel of Rio Puerco, a Tributary of the Rio Grande in New Mexico," *Journal of Geology*, Vol. 36, pp. 265–282, 1928; also, Swift, T. T., "Date of Channel Trenching in the Southwest", *Science*, n.s., Vol. 63, pp. 70–71, 1926; and Wynn, Fred, "The West Fork of Gila River", *Science*, n.s., Vol. 64, pp. 16–17, 1926.

† "Silt Problem of the Zuñi Reservoir," *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), pp. 868–878, and discussion, pp. 879–893.

the quantity of silt deposited in the reservoir have been made, of which seven are for single years, and five for periods ranging from 1½ years to 3½ years. If the quantity of silt for these periods be divided by the mean annual discharge from the reservoir for the same period, as shown by Mr. Robinson in Table 4,* there is obtained an average figure for the silt in percentage by volume carried in the muddy water.

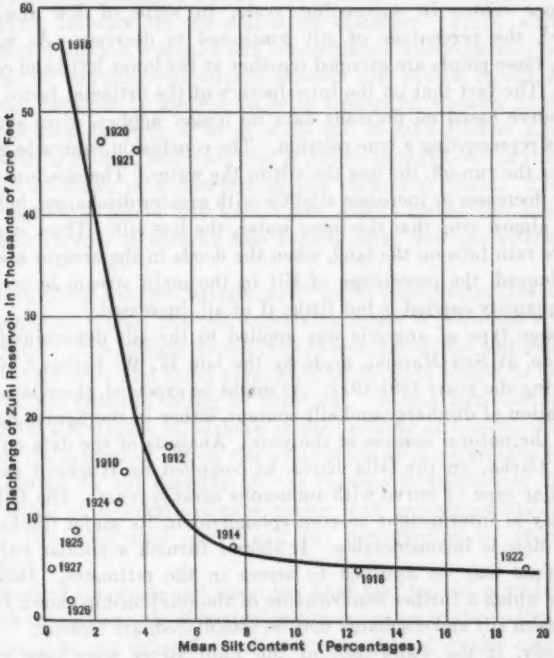

FIG. 11.—RELATION BETWEEN RUN-OFF AND SILT CONTENT.

If these mean discharges are plotted as ordinates and the percentages of silt as abscissas, as shown in Fig. 11, the points representing the periods down to 1924 show a characteristic relation between the run-off from the water-shed and the silt content of the water. The points representing 1923, 1924, 1925, 1926, and 1927, are affected in their position by the silt-control works begun in 1923. The points representing the earlier periods fall fairly close to a smooth line. The discrepancies may be due to errors in determination or to some natural condition. The period ending June, 1910, covers 3½ years, and the quantity of silt should be more accurately determined than in the period of 2½ years ending in January, 1912, represented by the near-by point; but the discharges from the reservoir for 1906 to 1908, inclusive,

* See p. 1698.

were not precisely determined and the estimate may be sufficiently in error to cause a misplacement of the point for the period, 1910. The points representing 1920 and 1921 appear to be in error as a result of miscalculation of the quantity of silt shown by the survey of 1920.

The building of structures to prevent excessive erosion was begun in 1923. On the next measurement of silt in January, 1924, the quantity deposited in Zuñi Reservoir was relatively small and the proportion of silt in the inflow fell to 2.96 per cent. In succeeding years, in spite of low run-off for the water-shed, the percentage of silt continued to decrease. As may be seen in Fig 11, these points are grouped together at the lower left-hand corner of the diagram. The fact that on the introduction of the artificial factor of silt control the curve based on previous data no longer applies, gives support to its validity as representing a true relation. The conclusion cannot be escaped that the greater the run-off, the less the silt in the water. The absolute quantity of silt either decreases or increases slightly with greater discharges, but so slightly that it is almost true that the more water, the less silt. Thus, in rainy years when more rain falls on the land, when the floods in the arroyos are larger and more prolonged, the percentage of silt in the main stream is lower, and the absolute quantity carried is but little, if at all, increased.

The same type of analysis was applied to the silt determinations on the Rio Grande, at San Marcial, made by the late W. W. Follett,* M. Am. Soc. C. E., during the years 1897-1912. As might be expected, there is no similarity in the relation of discharge and silt content, either in the figures for full years or any of the natural seasons of the year. Analysis of the data on silt at and near San Carlos, on the Gila River, as compiled by Hughes,† gave a somewhat similar type of curve with numerous erratic years. The Gila River at this locality is intermittent or even ephemeral in its major discharge, as the low-water flow is inconsiderable. It should furnish a similar curve and the erratic points may be ascribed to errors in the estimates. Data on other streams by which a further confirmation of the relationship shown for the Zuñi River between silt and discharge may be established, are lacking.

Obviously, if the water-shed of the Zuñi River were bare ground, the decrease of silt with run-off would be impossible. Some agent dependent on rainfall must intervene to prevent erosion at times of large run-off. This agent is the vegetative cover which is much reduced in effectiveness in dry years. Hence, the more rain, the more grass, and, consequently, the less erosion and the less silt carried in the streams.

Students of forestry and grazing have long contended that artificial reduction of the vegetation by over-grazing promotes erosion and increases the silt content of streams. Many writers, following this line of reasoning, have held that the destruction of grass cover by over-grazing is the cause which induced the cutting of existing arroyos. On the other hand, others hold that a change in climate by which the rainfall is reduced, will produce the same result.

* Follett, W. W., "Silt in the Rio Grande"; Commission on Equitable Distribution of Waters from the Rio Grande, Special Rept. to the Secy. of State, State Dept., 1913.

† Hughes, D. E., "Amount of Silt That Would Be Deposited in a Reservoir at San Carlos," etc., H. R. Doc. 791, 63d Cong., 2d Sess., pp. 117–140, 1914.

The data in Fig. 11 represent merely the relation of silt to rainfall. They do not specify where the silt will originate. Obviously, vegetation is most effective in decreasing erosion of hill slopes, on alluvial fans, and at the head of gullies. After the water is concentrated in the valley floors, a good growth of grass tends to spread this water and keep it spread, by which means silt is brought down more slowly. A decrease in vegetation, particularly grass, whether brought about by over-grazing or a change in climate to greater aridity, induces the formation of channels. Thus, although the general erosion decreases, a special and concentrated stream erosion may ensue.

This type of concentrated stream erosion has within recent years produced channel trenches or arroyos on most ephemeral streams of the Southwest. The cutting of arroyos, or as some call it—the Recent Epi-Cycle of erosion—seems to be due, following the principle brought out in the measurements of silt at Zuñi, to a decrease in the vegetative cover. The delicate balance of erosional forces has been upset and, whereas the streams once aggraded their valleys, or were at least neutral, they now are actively degrading them.

That over-grazing was the "trigger pull" which precipitated this accelerated erosion is apparently true, but the underlying cause is doubtless a change to a dryer climate. This change probably occurred before the settlement of the country by white men, and there appears to be no good reason to believe that a reversal of the climatic swing is imminent. Sound engineering practice dictates careful silt studies in advance of the building of reservoirs and active measures for the control of silt on the water-sheds of those already built. The successful control of silt depends on (1) reasonable restriction of grazing; (2) introduction of drought-resistant plants that are non-palatable to stock (salt cedar (*Tamarix* sp.,) etc.); and (3) construction of retarding and retaining works.

The success of the works put in on the Zuñi may lead to a tendency to put faith in such direct methods of control to the exclusion of the indirect methods which can only be put into effect after a campaign of public education and with the aid of State authority.

J. C. Stevens,* M. Am. Soc. C. E. (by letter).—The author has brought forcibly to the attention of the profession and to the world the seriousness of the silt problem in one of its most menacing forms. The loss of storage capacity, amounting in effect to nullifying large investments in storage works, is a problem the seriousness of which is realized in only a few quarters.

What is to become of the civilizations that will grow up as a result of the creation of storage works on the silt-laden streams of the West? Are lands now teeming with life and verdure doomed to revert to sagebrush and cactus? Is science powerless to halt the march of this relentless foe?

It is staggering to think that in so brief a period as 7 years the capacity of a 48 000 acre-ft. storage reservoir was reduced to one-half and that in a subsequent period of 13 years its usefulness has been practically obliterated.

* Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

P. A. WELTY,* M. AM. SOC. C. E. (by letter).—This paper gives testimony as to the seriousness of the problem of silt deposit in the canals and reservoirs of the Southwest. All streams of this region do not carry such excessive quantities of silt, but most of them do, and where this condition does obtain, it seriously affects the operation of canal systems and the life of the reservoir. There are a few reservoirs already constructed in Texas, and others contemplated, which will not be reduced in storage capacity appreciably in several centuries, and there are others built and contemplated that will be greatly reduced in capacity in an average man's life time.

During two periods, 1907 to 1909 and 1916 to 1918, while engaged as an engineer, in the Lower Rio Grande Valley of Texas, on the San Benito Project, the writer had the opportunity to observe the effects of silt on canal operation. The Lower Rio Grande Valley is a delta country that has been built up from the levels of the sea, or the Gulf of Mexico, by the deposit of silt. The river itself flows along a ridge, or backbone, which is (or was until very recently) being constantly raised in elevation along its course, by silt deposited when the river overflows its banks, and also by blow-sand. When these over-flows occur, the water leaves the channel and flows across country at right angles, approximately, to the stream. It runs into Mexico on the right side and across the delta plain toward the Gulf of Mexico on the left side in the State of Texas. As these over-flows occur without much velocity, the waters deposit their heavy loads of silt quickly. The heavier grains are dropped first, and the smaller ones next in order, and so on, some of the finer particles being carried until low depressions are reached.

There are many old former river beds of the Rio Grande (locally called "resacas") meandering through the valley, that have been built up in this manner during the past ages, until the time the river reached a point where it broke away from its channel and sought a new flow line through the lower country which, in turn, it began to raise as before. Some of these "resacas" are mentioned in United States history as being the battlegrounds during the Mexican War in 1848.

More than 500 000 acres of land are now being watered in the lower valley of the Rio Grande, in varying areas, by pumping water from the river, making lifts from 12 to 75 ft. to lands above and conducting it to lands embraced in a score or more of projects down the valley as far as Brownsville, Tex., at the lower end of the river. The plans for the San Benito Project, in Cameron County, included low-lift and high-lift pumps, and, in addition, proposed to obtain gravity-flow water for a large percentage of its lands, by taking water directly from the river. The plans were developed and the works constructed by the Chief Engineer, Mr. Sam A. Robertson.

Referring to Figs. 12 and 13, an idea of project locations can be obtained. Fig. 13(*a*) is a sketch (not to scale) of the profile of the 2-mile dredged channel conveying the waters of the river to the old "resaca" that was to become the Main Canal of the San Benito System. Fig. 14(*b*) shows the typical cross-section of the "resaca", which varied greatly in widths, between banks, from

* Dist. Engr., Bexar-Medina-Atascosa County Water Impvt. Dist. No. 1; Chf. Engr. and Gen. Mgr., San Antonio Suburban Irrigated Farms, Natalia, Tex.

250 to 1 000 ft. and in depths from 15 to 20 ft. The inside slopes of the "resaca" were from 3 on 1 to 5 on 1. The present river through the valley is more uniform and varies but little. The banks are almost vertical for at least 15 ft. from the top.

Fig. 14(*b*) also shows the conditions of the upper few miles after ten years of operation, in the quantity of silt that has been placed in the "resaca", with no thought of maintenance work for its removal.

Fig. 14(*c*) shows a sketch profile (of no regular scale) of the "resaca" and the different stages of silt deposit as it progressively built in down stream.

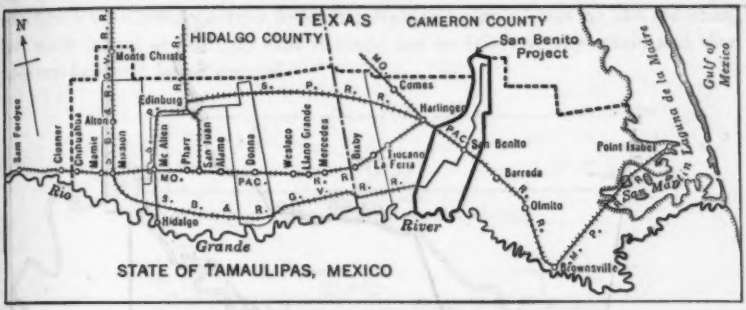

FIG. 12.—GENERAL PLAN, SAN BENITO PROJECT.

At the point marked *G* (Fig. 13), heavy service gates were installed to receive and control the waters of the river. These were operated with screw-lifts and were set in position in massive reinforced concrete walls, carried on both round and Wakefield sheet-piling. The floor of the structure was below the bed of the Rio Grande. The pumping plants were also housed in an adjoining room of this same structure, the suction pipes protruding through the river-front wall.

The profile of the dredged channel beginning at *G* (Fig. 14(*a*)), indicates a cut of 19 ft. at the river, as well as one of 17 ft. at the old "resaca", and one of 9 ft. at a point midway between the two. The finished grade of this channel was 1 in 10 000. The channel dredged along this line was 20 ft. wide at the bottom, with side slopes of 1 on 1.

While the land on each side sloped away from the "resaca", the banks of the latter and its bottom also had a uniform slope continually going parallel to the country, but because of its windings its grade was flatter than a line across country. On the San Benito Project the elevation of the plant shown at *G* (Fig. 13), was about 48 ft. above sea level, and the Town of San Benito was 32 ft.; the profile then smoothed out to sea level at the Gulf. The land had an average slope of 18 in. to the mile.

At intervals along the "resaca", and across it, an earthen dam with a roadway on top was constructed and in the dam were placed locks through which to pass barges and, also, gates with which to control the water. The locks were of reinforced concrete. Below each dam, and as the grade fell, a levee was constructed on each bank with a level grade line, starting with a zero fill and ending at the next dam with a 6 or 7-ft. fill. This plan resulted in the waters

of the Main Canal, or "resaca", being in lifts, or levels, each lower section being about 6 ft. lower than the section above. This water, being as a rule higher than the lands adjacent to the "resaca", made the irrigation of the lands easily possible. Laterals were constructed at every ½ mile, or 1 mile, along the "resaca", at right angles, approximately. These served to water lands on either side in the 40-acre units as subdivided. Some lands along the "resaca" were too high to be thus watered, as were the lands adjacent to the river, and high-line canals were located and built along the "resaca" and the river to care for such areas.

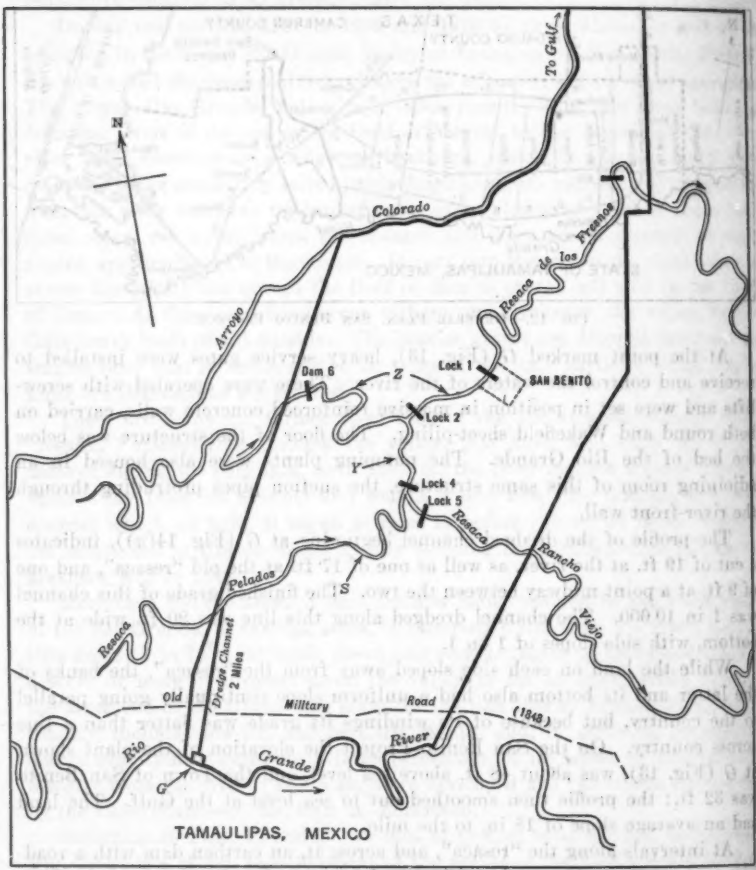

FIG. 13.—OUTLINE MAP, CAMERON COUNTY WATER IMPROVEMENT DISTRICT.

In constructing the 2-mile dredged channel it was necessary to take material from borrow-pits to build up the levees near the middle, but at each end there was excessive waste. This resulted in a channel more than 20 ft.

deep. The failure to keep up maintenance work for the removal of this silt soon resulted in this 2-mile channel becoming so full that water could be taken by gravity only when the river was "up" and, later, only when the river was at flood stage. Subsequently, it became necessary to begin the work of raising banks and making what was originally intended to be a low-line canal designed for taking gravity water, into a high-line pumping canal. This was the status when the writer came to the newly organized District on his second engagement there. This old low-line canal was further raised and strengthened so as to form a new high-line canal, and a new low-line canal was excavated through low country, thereby following Nature's plan of leaving the old channel when it had so built up that it could not be followed any more, and then seeking new and lower ground.

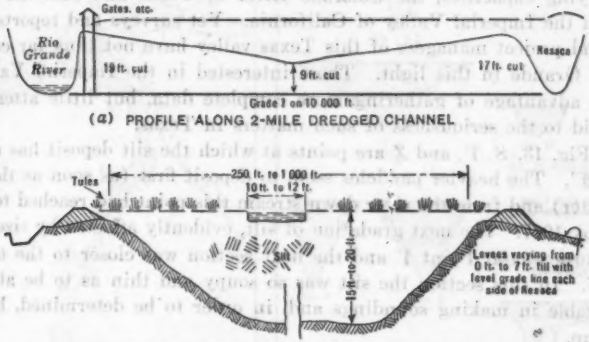

FIG. 14.—PROFILE AND TYPICAL SECTIONS.

The old "resaca" with dimensions as shown in Fig. 14 stored an immense volume of water, and while it was wasteful as regards seepage and evaporation, and was not economical because of the pumping required to fill up the bottom to a height that was usable, yet it was a great land seller and the sight of this great area of water was something that the average prospective buyer could not resist. Consequently, the project grew rapidly until it embraced about 80 000 acres of land, extending down stream along the old "resacas". This steady growth of the project down stream was responsible for the neglect in the upper sections. During the time of the so-called Border trouble, when it

seemed as if the Federal Government might intervene in Mexico, there was a period of neglect in the maintenance work caused by re-organizing into the District form of ownership and also bad financing. By 1916, no water was transferred by gravity and pumping was done only at a great additional expense for installing many re-lift pumps at the laterals. Bank-raising was continually in progress, and in order to meet the changing conditions, new pumps of greater capacity were installed at the head-gates.

For the first ten years of operating the system, the quantity of silt deposited in the 2-mile channel and in the first few miles of the upper end of the "resaca", as shown by measurements made by the engineers in February, 1917, reached a total of something less than 5 000 000 cu. yd. The results of the surveys would indicate that the Rio Grande water approaches, in silt-carrying capacities, the Colorado River of Texas and also the Colorado River in the Imperial Valley of California. Yet surveys and reports of engineers and project managers of this Texas valley have not thus far considered the Rio Grande in this light. Those interested in the Imperial Valley have had the advantage of gathering more complete data, but little attention has been paid to the seriousness of such matters in Texas.

In Fig. 13, *S*, *Y*, and *Z* are points at which the silt deposit has a decided "drop-off". The heavier particles seem to deposit first (as soon as they strike dead water) and from the river down stream this point had reached to *S* (Fig. 14(*c*)) by 1917. The next gradation of silt, evidently affected by size or some other cause was at Point *Y* and the next section was closer to the town at a point, *Z*. In this section the silt was so soupy and thin as to be almost unrecognizable in making soundings and, in order to be determined, had to be dipped up.

Below Point *Z* nothing was indicated and the elevations on land lines taken ten years previously checked measurements to the bottom. These sections of silt deposit seem to be almost level and the "drop-offs" at *S* and *Y* are rather abrupt, the change of elevation seeming to occur in ¼-mile intervals along the canal.

The upper reaches of the "resaca" had become silted to the top of the banks. In some cases the banks had to be raised, except along the channel where the water supply flowed, as indicated in Fig. 14(*b*). This channel was about 12 ft. wide and 2 ft. deep, and meandered through the tules and the silt bed. Laborers were constantly engaged in cutting tules, raising banks, and endeavoring to enlarge and keep open this small channel through which the water supply flowed. The velocity was a little better than 2 ft. per sec., which helped to keep moving the silt that was in suspension, and to carry it forward to the points, *S* and *Y*. This silted section of the "resaca" was under water when the pumps were operating and the tules caused the formation of pools of still water in which the silt would drop immediately. Consequently, this silt bed was continually being raised, which, in turn, made it necessary to keep raising the banks.

Some of the projects of the valley used old "esteros", or lakes, that functioned as settling basins. Levees were built around these lakes and the water

was discharged into them directly from the pumps, only to be admitted to the canal system after much of the silt had settled out. It was then continually necessary to remove the silt from these basins, and raise the banks.

BANKS MCLAURIN,* ESQ. (by letter).—The writer has been associated with Dean Taylor on one of the silt surveys of Lake Austin, and has lived on the banks of the Colorado River (Texas) for a life time. He is, therefore, rather familiar with the river, its topography, floods, droughts, and silt-bearing capacity. The Austin Lake stretches its crooked course from Austin into the mountains to the northwest. Those unfamiliar with the lake would conclude

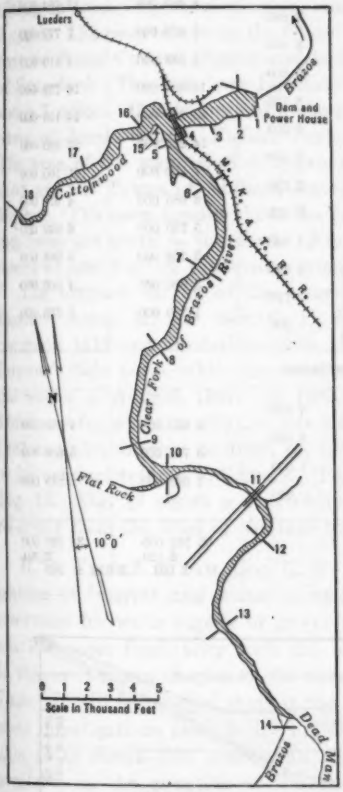

FIG. 15.

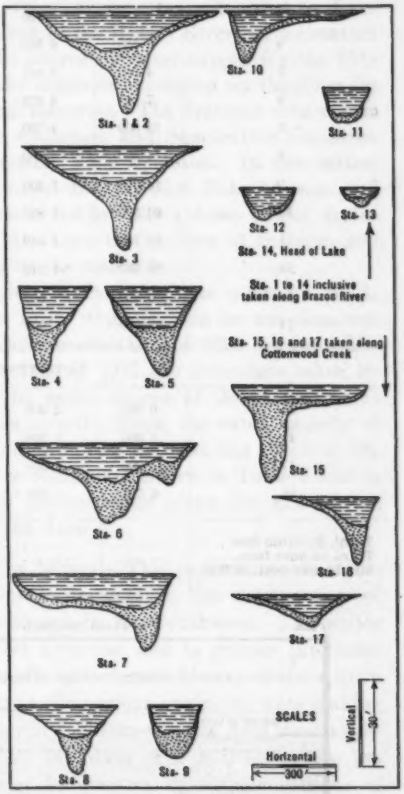

FIG. 16.

that it is a channel reservoir, but this is only partly true. It cannot be classed as a channel reservoir. Fully 50% of its area was formerly on the banks or above the top of the banks. This lake brings into strong contrast the behavior or silting of its channel part and the valley or part that covered former farm lands. Measurements of Lake Austin upset many theories and show con-

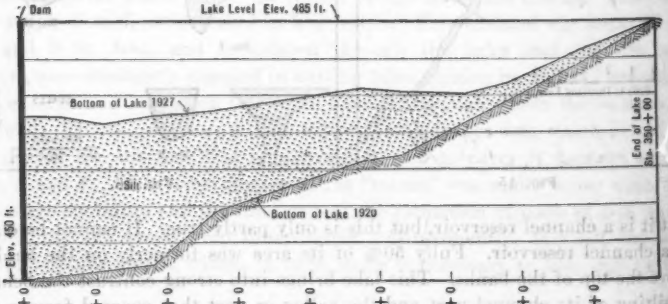

FIG. 17.—PROFILE OF LAKE BOTTOM.

clusively that the valley part of the lake was silted much more rapidly than the channel part. In many places along the 25 miles of lake shore, the silting of the valley part (not in the old river bed) has been more than 100%, and is being increased with every flood. At first, the low-lying banks were only a few feet high, but after each flood, grass, weeds, or willows spring up, and these growths catch trash, drift, etc., retard the velocity of the water, and cause the silt to drop out on the new banks. Slowly but surely the channel width is being narrowed.

Silting of Lake Penick.—Lake Penick, at Lueders, Tex., presents a case of silting in some respects similar to, and, in other respects, in contrast to, Lake Austin. The reservoir is on the Clear Fork of the Brazos River, in the eastern part of Jones County, Texas, and is the source of water supply for the City of Stamford. The dam is at Lueders, the reservoir extending up the river for about 7 miles. This is more of a channel reservoir. The drainage area covers parts of Jones, Scurry, Fisher, Taylor, Callahan, and Shackelford Counties. The area of the water-shed is approximately 2 250 sq. miles. In this water-shed are the Towns of Abilene, Sweetwater, Buffalo Gap, Roby, Anson, and Merkel. The main stream above the dam is fed by fully a dozen creeks, draining from the south to the north. Fig. 15 shows the location of the dam and reservoir and Fig. 16, the cross-sections on the reservoir.

The original survey of the reservoir and dam site was made by E. A. Burrow, Assoc. M. Am. Soc. C. E., in 1918. Construction on the dam was begun in 1918 and finished in 1920. The cross-sections of 1920 are from Mr. Burrow's field notes, while the cross-sections of 1927 are from data taken by the writer in August, 1927. In 1920, the water volume of the reservoir was 3 094 acre-ft., while, in 1927, it was 2 129 acre-ft. Thus, the water capacity of 1927 is 68.2% of that in 1920, or, in other words, the lake has silted 31.2% of its original volume in 7 years. These results are shown in Table 5 and in Fig. 16. Fig. 17 shows a longitudinal section taken along the axis of the reservoir from the head of the lake to the dam.

R. G. Tyler,* M. Am. Soc. C. E. (by letter).—This paper contains information of interest and value to engineers engaged in the construction of reservoirs for water supply or power purposes in the Southwest. The writer has had some familiarity with the local situation and is greatly interested in this most recent chapter in the unusually unfortunate history of the Austin Dam. It will be recalled that, at the time the various engineers were making their investigations prior to the building of the dam, too few data were available as to stream-flow conditions. Very few data of a reliable nature are available on the quantity of silt carried by streams in various sections of the United States. The Federal Department of Agriculture could render a most commendable service to the Engineering Profession by conducting extended investigations on this problem.

From such data as the writer has at hand, it would appear that one might expect this stream to carry a burden of about 1% of its volume, or about 18 000 acre-ft., of silt per year.† It has been estimated that the Brazos River

* Prof of San. Eng., Mass. Inst. Tech., Cambridge, Mass.

† *Bulletin No. 1430*, U. S. Department of Agriculture, p. 24.

above Waco, Tex., with a drainage area of 30 000 sq. miles, carries 3 200 000 tons of soil per year.* These streams are believed by the writer to be somewhat similar, but these estimates give the Colorado nine times the silt burden of the Brazos. The estimate for the Colorado is probably the more accurate as indicated by an analysis of the data given by Dean Taylor.

Table 6 gives the data from *Bulletin No. 1430,* of the U. S. Department of Agriculture, expressed in convenient units. It will be noted that there is an extremely wide variation in the amount of silt carried by streams in different sections of this country. The streams of the northeastern section of the United States are relatively free from silt, due largely to the nature of the tributary area.

The character of the drainage area is an important factor with reference to its silt production. With similar soil conditions, open, cultivated tracts erode more than wooded or grazing areas. In arid areas, also, where high temperatures and low rainfall discourage the growth of vegetation, the turf provides inadequate protection against erosion. These conditions prevail over a large part of the Colorado River drainage area above Austin, and are largely responsible for its high silt burden. This is a condition which has a greater effect as time goes on, due to the increased acreage coming under cultivation. Such erosion is objectionable both from the standpoint of impoverishing the denuded areas and of silting streams and reservoirs. The conservation of forests and the reforestation of denuded areas should have a beneficial effect in decreasing siltation difficulties.

* Estimated as 18 000 acre-ft.; 50% voids assumed.

Assuming that a silt burden of 18 000 acre-ft. per year is a fair value for the Colorado River, it is evident from the measurements given by the author that the quantity deposited is much less than this. For example, the average deposition per year between 1893 and 1900 was about 3 366 acre-ft., while the first year of this period may have yielded about 7 800 acre-ft., if a distribution similar to Fig. 5 is assumed. During the period, 1913 to 1922, the average deposition was 2 962 acre-ft. per year; while, during 1922 to 1924, it was 1 230 acre-ft. annually, with only 712 acre-ft. per year between 1924 and 1926. Again (see Fig. 5), the maximum silt deposit occurring in 1913 was about 6 400 acre-ft. Thus, an ever greater proportion of silt is carried over

* *Bulletin No. 1430,* U. S. Department of Agriculture, p. 24.

the dam each year, due to the decrease in the period of detention in the lake and to the corresponding increase in the velocity of water flowing through. The shape of the reservoir with its relatively small transverse section is such as to make the silting less than would occur in the more usual type, with greater lateral dimensions. This shape affects the velocity, which effect must be considered in predicting the amount of siltation.

The topography at the location of the dam has been described in various reports and papers, but there is one feature that is worthy of further comment. The valley down stream from the dam gradually widens and considerable quantities of coarse sand and gravel, comparatively free from silt, have been deposited in its upper reaches, from which material has long been taken for concrete aggregate for local construction work. This area extends to a point opposite or below the city proper and, as the valley continues to widen, the sand becomes finer and contains greater quantities of silt, so that a few miles farther down stream there is a broad valley where the soil consists of a sandy loam used for the growing of garden produce. This indicates the character of sediment carried by the stream and deposited at the point where the channel emerges from the canyon section into the valley section and the gradient flattens out from 4.2 to 1.7 ft. per mile.* An examination of this valley would give the engineer a very good idea of the type of material which the stream might be expected to bring down at flood stage. The paper indicates a somewhat similar arrangement of materials in the lake, with its sand deposits for a distance of about 3 miles above Station 17.75 and grading off into silt below that point.

In constructing reservoirs in semi-arid regions, the engineer is confronted with the problem of providing a volume sufficient to allow for silting and still give a reasonable life that, at the same time, provides a large surface area from which excessive evaporation losses occur. The writer has found cases where, with the low rainfall and percentages of run-off and the high evaporation from water surfaces encountered in the Southwest, it has been difficult to find reservoir sites which would supply a reasonable demand. The difficulty is more acute where the valleys are shallow and the reservoir volume is distributed horizontally rather than vertically. In such reservoirs there is considerable shoal water which adds very little to the available storage, but from which a depth of water of 50 to 70 in. is lost in evaporation annually. Large volume, therefore, is not necessarily a solution for the silt problem, as it introduces another problem quite as troublesome.

In some instances, especially abroad, siltation has been controlled by the construction of an upper reservoir with a by-pass around the lower or main reservoir. The water carrying the higher turbidity is by-passed and only the partly settled water is carried into the lower reservoir. A by-pass would have been out of question in the present instance, however, because of the topography.

State of Texas, has declared that all the ordinary flow of all the rivers and streams of the State has been allotted. Permits have been issued to individuals, corporations, cities, and towns, authorizing them to take from the rivers and streams quantities of water which, in the aggregate, equal their total ordinary flow. Additional permits cannot be granted. The supply is exhausted. Only the storm waters remain unallotted. These are regarded as the property of the State to be disposed of as may be decided by law.

It is also true that at times the ordinary flow of the streams is insufficient to supply present needs. The irrigation companies are constantly clamoring for more water, and many cities and towns have suffered long and severe shortages. Abilene, Dallas, Dalhart, and Elgin may be mentioned in this connection. The population of the State and its agricultural and manufacturing interests are growing steadily and the demand for water is growing proportionately. If an adequate supply is not provided, growth in population and industries will soon cease.

In a large section of the State artesian water is available and will be developed as needed, but in a much larger part there is none. Conservation and use of the now unappropriated flood waters is the only recourse left to this region. Conservation of flood waters implies the construction of reservoirs, and experience shows that these become filled with silt and are useless in comparatively short times. Table 7 shows the quantity of silt and the rate of silting in some reservoirs in the Texas and New Mexico sections.

The silt accumulation, in acre-feet per square mile of drainage area per year, is given in each case. The quantity for Lake Austin varies from 0.091 to 0.019 acre-ft. The average quantity for the 20 years is about 0.07 acre-ft. Compared with the figures for the other reservoirs listed in Table 7, this quantity is small, but the new Lake Austin has been practically filled with silt in fifteen years. During the years when the capacity of the reservoir was great, the quantity of silt stored was also great. As the capacity of the reservoir became reduced by silt accumulation, affording less opportunity for sedimentation, the quantity deposited per square mile of drainage area steadily decreased. This seems natural and logical, but there is no such decrease in the silting of the Zuni Reservoir. Here, the rate of accumulation was greatest when 70% of the original capacity of the reservoir was filled with silt. It is interesting, also, to note that the rates of accumulation in the Elephant Butte and Zuni Reservoirs are much greater than in Lake Austin. The rate for Elephant Butte Reservoir is seven times, and that for Zuni Reservoir varies from seven to twenty times, the maximum rate for Lake Austin. McKinney Reservoir has a high rate of accumulation, 0.77 acre-ft. per sq. mile of drainage area per year.

The method of preventing silting that has shown promise of success is to build dams with under-sluices through which the silt-laden flood waters may be passed. This method is said to be successful in India and Egypt. It may be that it can be adapted to Texas conditions.

R. F. WALTER,* M. AM. SOC. C. E. (by letter).—The original storage capacity of Lake Austin (49 300 acre-ft.), never represented a very appreciable

* Chf. Engr., Bureau of Reclamation, U. S. Dept. of the Interior, Denver, Colo.

proportion of the total annual flow of the Colorado River at Austin, Tex. In fact, it was only 1.4% of the average annual flow of 3 500 000 acre-ft. determined by the U. S. Geological Survey for the period from 1898 to 1922.* With so small a ratio of original storage capacity to total annual run-off on a silt-bearing stream like the Colorado River of Texas it is surprising that the original capacity was not even more rapidly depleted by silt accumulation. However, such a reservoir could hardly be expected to operate efficiently as a de-silting agency and undoubtedly large quantities of silt have been carried over the dam during flood periods. It is hoped that Dean Taylor can supply some information regarding this phase of the problem; also, regarding the maximum rates of flood flow and the velocities at which the floods passed through the lake.

The problem of storage depletion by silt accumulation is one that has often been considered by the U. S. Bureau of Reclamation, especially in connection with the investigation of irrigation projects located in the southwestern parts of the United States where the climatic, topographic, and geologic conditions are conducive to rapid rates of soil erosion and correspondingly high percentages of silt content in river flow. Percentage measurements of silt content, by sampling river flow, have been made at several stations on the Colorado River and its tributaries above Yuma, Ariz., on the Rio Grande and its tributaries, and on other silt-bearing streams of the Southwest. Actual quantitative measurements of silt accumulated in reservoirs have been made at the Roosevelt, Elephant Butte, and McMillan Reservoirs on the Salt River, Rio Grande, and Carlsbad Projects, respectively. This discussion will present the results of the measurements at the Elephant Butte and McMillan Reservoirs. The operation and maintenance of the Salt River Project was assumed by the Salt River Valley Water Users' Association in November, 1917, and subsequent silt surveys of the Roosevelt Reservoir have been made by that organization.

McMillan Reservoir.—Lake McMillan is located in the Pecos River Valley of Southeastern New Mexico, about fifteen miles from the Town of Carlsbad. The Pecos River rises in the north-central part of New Mexico, on the east side of the Truchas Range of the Sangre De Cristo Mountains. For some distance it is a typical mountain stream, flowing with a swift current through rocky canyons and carrying only such materials as may be eroded and brought in by mountain torrents. These materials settle out rapidly and are seldom transported appreciable distances after they reach the main channel. However, farther down stream, where the course of the river is through alluvial soil, more material is eroded. Below Roswell, tributary streams, draining large areas of arid, mountainous country lying west of the Pecos, bring in heavy loads of silt, so that by the time McMillan Reservoir is reached, the flow is heavily charged. The mean annual flow of the river at Lake McMillan is approximately 316 000 acre-ft., the yearly values varying from a minimum of 130 000 ft. to a maximum of 900 000 acre-ft.

* "Surface Water Supply of the United States, 1922, Pt. VIII, Western Gulf of Mexico Basins," *Water Supply Paper 548*, U. S. Geological Survey, 1925.

The construction of the original McMillan Dam—a rock-fill structure, 1 686 ft. long and 52 ft. high, with an auxiliary earth embankment, 5 200 ft. long and 19 ft. high—was completed by the Pecos Irrigation Company in the winter of 1893-94. In 1906, following the destruction of the system by floods, reconstruction of the project was undertaken by the U. S. Reclamation Service and since that time it has been successfully operated by the Federal Government. During the period from 1894 to 1903 the reservoir was operated with a spillway crest elevation of 3 258.9 ft., corresponding to a stage of 17.3 ft. on the reservoir gauge. In 1908 and 1909 the outlet works were reconstructed and the embankments repaired so that the lake level could be raised to a stage of 23.5 ft. Further enlargements were made in 1911 and 1912, and again in 1915. The present spillway crest is at Elevation 3 268.6, corresponding to a reservoir stage of 27.0 ft. Reliable topographic data of the original reservoir site were never obtained. However, such information as can be found indicates that the total storage capacity below spillway level, at the time of construction, was about 32 500 acre-ft., or about 10% of the average annual run-off at the reservoir site.

Measurements of silt accumulated in the reservoir were made by the U. S. Geological Survey in 1904, by the U. S. Reclamation Service in 1910 and 1915, and by the U. S. Bureau of Reclamation (formerly the Reclamation Service) in 1925. In the 1904 survey, which was made when the reservoir was practically empty, depths of silting were determined by auger borings, and the borings were located by plane-table.* Although some uncertainties in determining the elevation of the original ground surface must have been encountered at times, the descriptions of the survey indicate that the work was carefully done and that the final results probably possess a reasonable degree of accuracy. Later measurements of silt accumulations were made by taking cross-sections of the reservoir at intervals throughout the lengths of the silted areas, using customary surveying methods.

Table 8 contains a summary of the data on silt deposited in Lake McMillan as determined by the various surveys, total accumulations in acre-feet below certain stages being given for the periods covered by the investigations. Table 9 gives the average rates of silt accumulation, in acre-feet per year, for the different periods.

The data in Table 8 show that 41 400 acre-ft. of silt were deposited in the reservoir, below the 25-ft. stage, during the period from January 1, 1894, to June 1, 1915, a total approximately one-eighth greater than the entire original capacity of the reservoir below the 17.3-ft. stage. However, the most interesting feature shown by Tables 8 and 9 is the great reduction in silting which occurred in the reservoir proper during the period from June 1, 1915, to June 1, 1925. During this 10-year period only 3 500 acre-ft. of silt were deposited in the reservoir below the 25.0-ft. stage, giving an average rate of silt deposition of 350 acre-ft. per year as compared with an average rate of 1 930 acre-ft. per year for the period from January 1, 1894, to June 1, 1915. The reason for this marked reduction in rate of silting is that since

* Third Annual Report, U. S. Reclamation Service, 1903–04, p. 371.

about 1918 dense and extensive growths of tamarisk (also called salt cedar), have developed at the upper end of the lake. These growths have caused a spreading of the river flow above the reservoir, resulting in velocity reductions and silt deposition, and thus keeping the larger proportions of silt from entering the lake.

* January 1, 1894, to November 1, 1910.

The tamarisk is an evergreen shrub, or tree, originally a native of the Mediterranean regions, Western Asia, and India. Its somewhat showy pink and white flowers present an attractive appearance during the blooming period and, consequently, it was brought into this country for use as an ornamental shade tree. Tamarisk trees were propagated in the Pecos River Valley many years before they appeared at Lake McMillan. A clump of rather large trees was growing along the river east of Roswell, about sixty miles above Lake McMillan, some time prior to 1912, when the first tree was noticed at the upper end of the reservoir. The origin of the Lake McMillan growth is not known, but possibly the seed was brought down the river during flood periods, or was brought in by birds. L. E. Foster, Superintendent of the Carlsbad Project, describes the conditions at the upper end of the reservoir, under date of July 20, 1928, as follows:

FIG. 18.—TYPICAL TAMARISK GROWTH AT LAKE MCMILLAN, TEXAS.

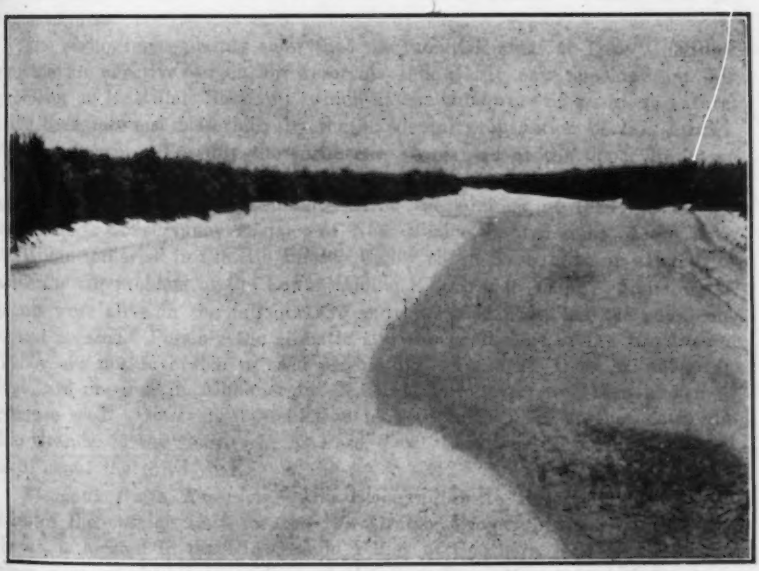

FIG. 19.—TAMARISK TREES 25 FEET HIGH ALONG THE PECOS RIVER AT THE UPPER END OF LAKE MCMILLAN.

"At the present time, the entire upper end of the reservoir is covered with a dense growth of tamarisk except for a few narrow channels. This comprises an area of about ten square miles within the flow line of the reservoir. Besides this area the tamarisk growth extends for about two miles up stream, above the reservoir flow line. This area averages about a mile wide in flood time. This flood plane is covered with the same dense growth of tamarisk as characterizes the reservoir area. The nature of the growth changes somewhat from year to year. Where water stands around the plants for more than a week, they usually die. Reforestation begins immediately after the water drains away. At the upper end of the old lake, the growth is quite uniform in age and size but as open water in the lake is approached, the growth varies considerably in size. In many places the growth is so dense as to be almost impenetrable. It ranges in height from above twenty feet down to one foot or less. The diameter of the growth ranges from the size of a pencil to six or eight inches. Just how much effect this comparatively fine, dense growth, together with the down brush, has on the velocities is not certain; but it is certain, however, that the heavier silt deposits are at the upper end of the area where such growth is most dense."

Figs. 18 and 19 are typical views of the tamarisk growth taken near the upper end of the lake on July 16, 1928. The larger trees, such as those along the river banks, are from 15 to 20 ft high. Observations at fence posts, made since 1914, show that as much as 3 ft. of silt has been deposited along the fences in some places, the greater part of which is said to have occurred during floods since 1915. Perhaps greater depths have been deposited in other places. On account of the impenetrable nature of the growth, the 1925 survey was not extended any appreciable distance into the tamarisk area.

The photographs plainly show that the tamarisk areas at Lake McMillan provide an effective screen for reservoir inflow. It now appears that silt problems at McMillan Reservoir, which at one time were of a serious nature, have been lessened materially by the accidental propagation of this foreign evergreen shrub. Possibly the shrub can be planted at the upper limits of other reservoirs, located in regions of similar climatic conditions, and there utilized to secure similar results. During the summer of 1926 the Middle Rio Grande Conservancy District of New Mexico planted some of the Lake McMillan tamarisk in the Rio Puerco Valley above Socorro, in an attempt to solve the silt problem of the Lower Middle Rio Grande Valley. Some of the plants were alive in the fall of 1927 and bore seed pods, but the pods contained no seed. Possibly the climatic and soil conditions of the Rio Puerco Valley are not favorable to seed production. Tamarisk trees, 20 to 30 ft. high, are growing in Albuquerque, N. Mex., but have never been known to produce seed. However, reproduction by seed takes place farther down the Rio Grande, in the vicinity of El Paso, Tex. Seedlings do not produce seed until about the third year.

Elephant Butte Reservoir.—The Elephant Butte Reservoir, which constitutes the storage unit for the Rio Grande Project of New Mexico and Texas, is located in the Rio Grande Valley of Southern New Mexico. The river rises on the eastern slope of the San Juan Mountains of Southern Colorado, at an elevation approximately 12 000 ft. above mean sea level;

flows east and south to the New Mexico State line; then almost due south across New Mexico to El Paso. At the Colorado-New Mexico State line the flow does not contain large proportions of sediment. However, through the State of New Mexico, tributary streams, draining large areas of arid, easily eroded soil, bring in heavy loads of material, so that by the time the Elephant Butte Reservoir is reached the flow is heavily charged with silt. The mean annual flow of the river at the upper end of the reservoir is approximately 1 200 000 acre-ft., the yearly records varying from a minimum of 240 000 to a maximum of 2 500 000 acre-ft.

The construction of the Elephant Butte Dam, a concrete gravity structure, 306 ft. high, located about 130 miles above El Paso, was completed by the U. S. Reclamation Service in 1915. Although some water was impounded in January, 1915, substantial storage did not begin until January, 1916. The reservoir above the dam is 45 miles long, has an average width of 1¾ miles, and floods a total area of approximately 40 000 acres when filled to the spillway crest, Elevation 4 407.0, on the project datum which is 43.3 ft. above mean sea level. At the time of completing the dam the reservoir had a total storage capacity of 2 638 860 acre-ft. below the spillway crest, assuming that appreciable silting did not take place within the flow line of the reservoir from the time the original surveys were made until the dam was finished. Such a capacity is approximately 220% of the mean annual run-off from the drainage area above the reservoir.

A topographic survey of the reservoir site, sufficiently accurate to determine 10-ft. contours, was made below Elevation 4 370 in 1903, and was extended to include the present flow line in 1908. Silt surveys of the upper portion of the reservoir, where practically all the silt is deposited, were made in 1916, 1920, and 1925, measurements being made by running profiles along established cross-sections spaced from ¼ to ¾ mile apart. Difficulties were encountered at times in determining the true surface of the silt deposits, due to the comparatively great depths of water, the character of the deposits, and the presence of trees, brush, or débris on the bed of the reservoir. However, the measurements were made with a great deal of care and the results are probably sufficiently accurate for the purposes intended. An exhaustive study of the chemical and physical properties of the silt was made in 1916.*

The results of the 1920 survey, as compared with the results of the 1916 survey, showed that 90 858 acre-ft. of silt were deposited in the reservoir during the intervening period of 48.7 months, corresponding to an average rate of deposition of 1 865 acre-ft. per month, or 22 400 acre-ft. per year. Comparison of the results of the 1920 survey with the original reservoir topography, taken in 1903 and 1908, indicated a total silt accumulation of 140 000 acre-ft. up to the time of the 1920 survey, practically all of which must have taken place after the reservoir began storing water. Assuming that storage began in January, 1915, the corresponding rate of silting would be 2 060 acre-ft. per month, or 24 700 acre-ft. per year. However, the Project Manager considered the values based on the original topography to be less accurate

* "Notes on Silting of Elephant Butte Reservoir," *Reclamation Record*, September, 1916, p. 423.

than those based on the 1916 survey. The total silt accumulation indicated by the 1916 and 1920 surveys amounted to 1.66% of the total inflow to the reservoir during the intervening period.

* Above project datum, add 43.3 ft. for sea-level elevations.
† Total time, 104 months.

Table 10 gives data on reservoir capacities and silt accumulations below elevations varying from 4 325 to 4 407 ft., as determined by the 1925 survey. Fig. 20 shows the effect of silting on the capacity of the reservoir.

The results of the 1925 survey indicate a total silt accumulation of 231 735 acre-ft. from the time the original reservoir topography was taken to the time of the 1925 survey, and a total accumulation of 177 740 acre-ft. during the 104 months from the time of the 1916 survey. The latter figure corresponds to an average monthly deposit of 1 709 acre-ft. and an average yearly deposit

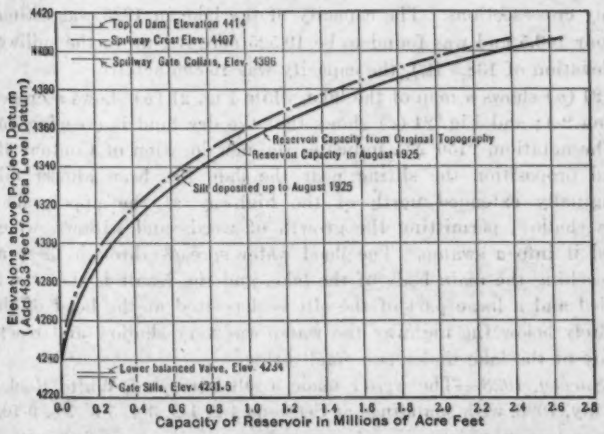

FIG. 20.—EFFECT OF SILT DEPOSITION ON CAPACITY OF ELEPHANT BUTTE RESERVOIR.

of 20 508 acre-ft. It also corresponds to 1.64% of the total reservoir inflow during the period considered, a figure almost the same as that obtained by the 1920 survey. Investigations show that 72%, or nearly three-fourths, of the silt that enters the reservoir, is deposited within an area containing not quite one-fourth of the total reservoir capacity. The total accumulation of 231 735 acre-ft. shown by the 1925 survey is only about 8.78% of the original storage capacity below the spillway crest, indicating an average yearly rate of silting of slightly less than 1% of the original storage capacity. Assuming such a silting rate to keep up indefinitely (which would be a severe assumption), the total life of the reservoir would be 114 years. Since 13 years have already passed, the remaining life would be 101 years.

William Jenner Powell,* M. Am. Soc. C. E. (by letter).—The writer has known in a general way that Lake Austin was silting rapidly, but he was not prepared for the staggering information that 95% of the water capacity had been taken up by silt in 13 years of service. The water-shed of the Colorado River for about 38 000 sq. miles spreads over what is generally known as a grassy or wooded area including, in its topographical features, flat prairie country and rugged mountainous sections.

The writer has made a survey of the silting of the White Rock Reservoir, which is about four miles east of the City Hall of Dallas, Tex. The drainage area is a wide limestone valley 114 sq. miles in extent. The reservoir was begun in 1910 and was ready for service in 1912. Practically the lowest point in the lake was 424 ft. above mean low tide. Careful surveys were not made of the original volume of water and its capacity was only estimated. The dam is of earth, and a concrete spillway with a long wide apron was constructed at the east end of Elevation 138.5, City of Dallas datum, or Elevation 457.45 above mean low tide.

Silt Surveys.—In 1923, the City Engineer made a very elaborate survey of the White Rock Reservoir, establishing bench-marks, triangulation stations, and many cross-sections. The capacity of the lake in 1923 was estimated up to Contour 140.5 and was found to be 19 525 acre-ft.; up to the spillway crest (local elevation of 138.5 ft.), the capacity was 16 896 acre-ft.

Fig. 21 (*a*) shows a map of the lake, while Fig. 21 (*b*) shows a cross-section at Section 2-4; and Fig. 21 (*c*) shows that the dry land is creeping down the lake. The notation, "136 N", indicates the new location of Contour 136. As a general proposition the silting near the dam has been almost nil. The lake originally extended north of the highway at the upper end. This part was shallow, permitting the growth of weeds and willows, which soon converted it into a swamp. The flood water spreads through these marshes before reaching the main body of the lake, and the result is that the current is retarded and a large part of the silt is deposited at the head of the lake. Immediately below the highway the water was very shallow and reached the main body of the lake under two small bridges.

Silt Survey, 1928.—The writer made a silt survey of White Rock Reservoir in July, 1928, with soundings at Sections 4-2, 1-2, 3-4, 5-6, 7-8, 9-10, 11-12,

* Cons. Engr., Dallas, Tex.

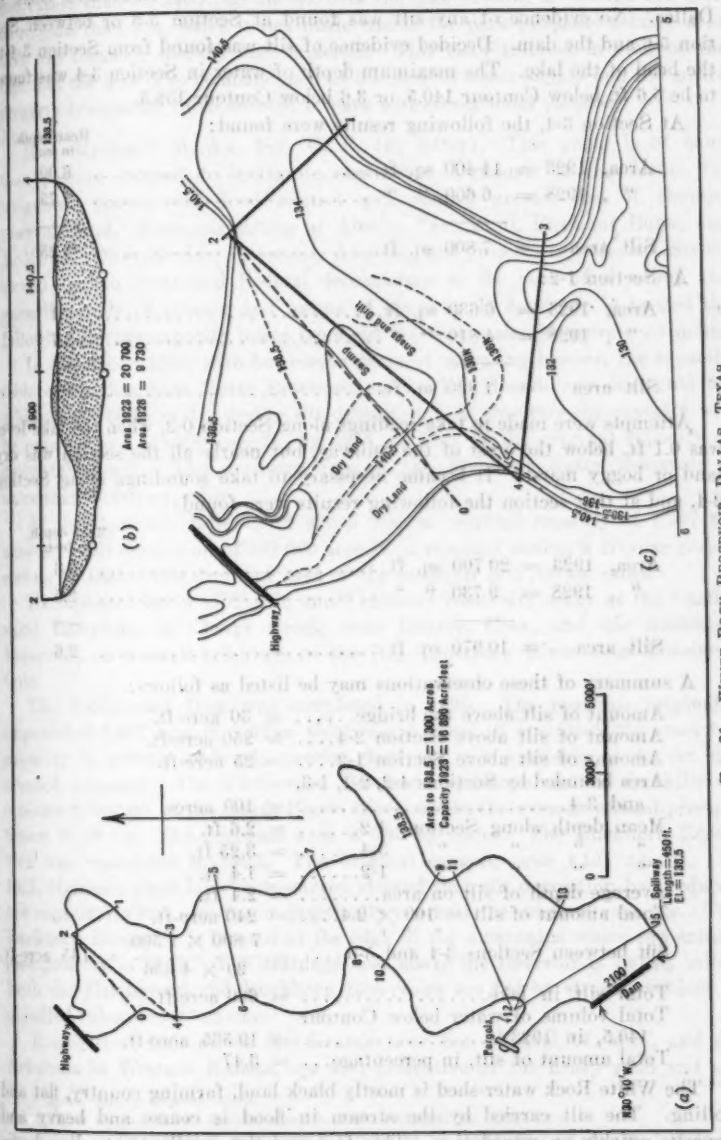

FIG. 21.—WHITE ROCK RESERVOIR, DALLAS, TEXAS.

and 12-13 (Fig. 21 (*a*)). These soundings were compared with those taken in 1924 by Messrs. McCombs and Ernest, of the City Engineer's Office of Dallas. No evidence of any silt was found at Section 5-6 or between Section 5-6 and the dam. Decided evidence of silt was found from Section 3-4 to the head of the lake. The maximum depth of water in Section 3-4 was found to be 5.6 ft. below Contour 140.5, or 3.6 below Contour 138.5.

At Section 3-4, the following results were found:

		Mean depth, in feet
Area, 1923	= 14 400 sq. ft.	6.00
" , 1928	= 6 600 " "	2.75
Silt area	= 7 800 sq. ft.	3.25

At Section 1-2:

Area, 1923	= 6 630 sq. ft.	5.1
" , 1928	= 4 810 " "	3.7
Silt area	= 1 820 sq. ft.	1.4

Attempts were made to take readings along Section 0-2, when the lake level was 0.1 ft. below the crest of the spillway, but nearly all the section was dry land or boggy marsh. It became necessary to take soundings along Section 2-4, and at that section the following results were found:

		Mean depth, in feet.
Area, 1923	= 20 700 sq. ft.	5.3
" , 1928	= 9 730 " "	2.5
Silt area	= 10 970 sq. ft.	2.6

A summary of these observations may be listed as follows:

Amount of silt above the bridge..... = 30 acre-ft.
Amount of silt above Section 2-4.... = 250 acre-ft.
Amount of silt above Section 1-2.... = 25 acre-ft.
Area bounded by Sections 4-2, 2-1, 1-3, and 3-4..... = 100 acres.
Mean depth along Sections 4-2..... = 2.6 ft.
" " " " 3-4..... = 3.25 ft.
" " " " 1-2..... = 1.4 ft.
Average depth of silt on area..... = 2.4 ft.
Total amount of silt = 100 × 2.4.... = 240 acre-ft.
Silt between Sections 3-4 and 5-6.... = $\frac{7\,800 \times 1\,500}{20 \times 4\,356}$ = 135 acre-ft.
Total silt in lake..... = 680 acre-ft.
Total volume of water below Contour 140.5, in 1923..... = 19 535 acre-ft.
Total amount of silt, in percentage... = 3.47

The White Rock water-shed is mostly black land, farming country, flat and rolling. The silt carried by the stream in flood is coarse and heavy and deposits quickly on retardation. This fact and the excellent retarding basin formed by the growth at the head of the lake have practically prevented silting

in the main body of the lake, and by making land in the shallows at the upper end rather than distributing the silt over the lake bottom, the silting has been more gain than loss, since it has made usable for park purposes a large area that was formerly marshy and valueless. This is of interest in view of the fact that the lake is to be abandoned as a source of water supply and the entire property is expected to be devoted to park and recreational purposes.

R. I. MEEKER,* M. AM. SOC. C. E. (by letter).—This paper is of more than passing interest to hydraulic engineers. Demands of the future for irrigation, power, and flood control will compel greater use of channel reservoir sites. Reservoir silting at Austin, Tex., Zuni, Elephant Butte, and McMillan,† New Mexico, Roosevelt, Arizona, and projects in adjacent States, should awaken State and Federal departments to the need of a survey and scientific study of erosion and means of control. If emphasis is needed the following storage capacity losses from silt deposition should prove convincing.

In December, 1925, with but eleven years of operating history, the capacity table of the Elephant Butte Reservoir on the Rio Grande was corrected for a loss of 220 000 acre-ft., due to silt deposition. At this rate the capacity will be reduced to 1 418 000 acre-ft., by 1975, or 54% of the original capacity of 2 638 000 acre-ft. The drainage area of the Elephant Butte Reservoir is more than 30 000 sq. miles.

At the Roosevelt Reservoir,‡ which had an original capacity of 1 367 000 acre-ft., a silt deposition of 101 000 acre-ft. is reported during a 20-year period ending in 1925. The drainage area of the reservoir is 5 760 sq. miles.

Examples of heavy silting in small channel reservoirs occur at the Castlewood Reservoir, on Cherry Creek, near Denver, Colo., and the Buckhorn Reservoir, on a small tributary of the Big Thompson River, near Loveland, Colo.

The Castlewood Dam was completed in 1890. The reservoir originally impounded 5 267 acre-ft. After thirty-eight years of operation the reservoir capacity is greatly reduced; precise data are not available as to the decreased capacity. The Castlewood Reservoir is located in the foothills on a plains tributary of the South Platte River, where the average annual precipitation is 18 in. The drainage area is 165 sq. miles. The Buckhorn Reservoir was completed in 1907. The original capacity was 1 191 acre-ft. In 1925, eighteen years later, a re-survey showed that silt deposition had reduced the capacity to 626 acre-ft., or practically one-half the original capacity. The Buckhorn Reservoir is located at the edge of the mountains where the annual precipitation is 16 in. The drainage area above the reservoir is 130 sq. miles. Both the Castlewood and Buckhorn Reservoirs are fed by streams subject to so-called "cloudburst" storms.

Rising river beds of the Rio Grande near San Marcial, N. Mex., and the Arkansas in Western Kansas, are also indicative of the heavy sand and silt

‡ "Silt in the Colorado River and Its Relation to Irrigation," by Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, Assoc. M. Am. Soc. C. E., *Technical Bulletin* 67, U. S. Dept. of Agriculture, 1928, p. 22.

burden resulting from erosion induced by settlement. The former has risen 12 ft., and the latter 5 ft., in a period of 45 years.

Considerable information is available on quantities of silt carried by streams of the Southwest and on silt deposition in reservoirs thereon. The origin of the silt question is erosion, and the writer feels that the problem should be attacked from that angle. Information is needed on its causes and control. Over-grazing by sheep and cattle has heavily depleted the grass carpet of the plains, foot-hills, and plateau areas of the Colorado, Rio Grande, Arkansas, and Platte River Basins and has contributed greatly to erosion, which is increasing in the arid Southwest. Enormous areas of public lands are affected, and public agencies cannot ignore the problem of erosion when its far-reaching effect on future water control and utilization is realized. Erosion impinges heavily on the present and future water problems of the Western United States. Experience in arid South Africa confirms the experience in the Southwestern United States, and the following statement* appears in agreement with American history:

"In course of time burning and the concentrated grazing and tramping of sheep, goats, and cattle caused progressive desiccation. To-day, the broad valleys are drained by deep and wide river channels, and the rich grass flats are dried out and eroded. Rivers only a few feet wide a generation ago are now two or three hundred feet in width. The dense bush in the valleys has disappeared, and the river channels, now ten or twenty times the size they used to be, present an unobstructed passage to flood water entering them."

TABLE 11.—Silt Deposition, Channel Reservoirs, Southwestern United States.

* Old reservoir.

† Precise data are not available at this time.

The recent *Bulletin*† on "Silt in the Colorado River", by the U. S. Department of Agriculture, could well be a forerunner of another *Bulletin* on erosion. Through the Forest Service and associated divisions, the Department of Agriculture is well qualified to study this important problem in a comprehensive and scientific way.

* "The Principles of Irrigation Engineering," by F. E. Kanthack, pp. 103–105.

† *Technical Bulletin No.* 67, U. S. Dept. of Agriculture, 1928.

The investigational studies of erosion and silt control by the Middle Rio Grande Conservancy District in New Mexico is intelligent pioneering on a subject destined to play an important part in water conservation. The States of Arizona, Colorado, New Mexico, Texas, Utah, and Wyoming cannot afford to ignore the problem of erosion and means for its control. The Colorado River Basin and the Rio Grande Basin offer excellent opportunities for a systematic survey and study of that problem. Grazing control on the Jornado Grazing Reserve north of Las Cruces, N. Mex., may develop some valuable information concerning erosion. An interesting bibliography on silt problems, prepared by the Special Committee on Irrigation Hydraulics, has been published by the Society.* Table 11 summarizes the losses in various reservoirs from silt deposition in the Southwest.

T. U. Taylor,† M. Am. Soc. C. E. (by letter).—Practically all descriptions of the measurements made, have come from the arid and semi-arid West, and these are largely confined to the Southwest. However, the results have been valuable beyond expectation. The writer, after spending more than a third of a century in studying silting of reservoirs and in making actual measurements on existing reservoirs, has had some of his cherished ideas exploded. The first of these was the assumption on his part that there was a direct connection between run-off and the amount of silt deposited in the reservoir. The data contributed by Mr. Robinson have proved that in some reservoirs there is slight connection. A very dry, parched water-shed with a sudden run-off will produce a much greater amount of silt than a much heavier rain on a wet water-shed.

It has been claimed that lakes spreading out over their banks and having widths many times that of the river channel, will not silt as rapidly as channel lakes. This is not substantiated by experience at the old or the new lakes at Austin, Tex. The width of the new lake on the average was three times that of the river channel, two-thirds of it being over the relatively flat uplands near the dam. For the stretch extending from the dam to a point 1 003 ft. up stream the channel part of the lake has silted to 84% of its capacity in 1913, while that part on the nearly flat valley which was formerly a farm, has silted to more than 114% of the original capacity. Next to the bank on the east side there has been added (in the period from 1913 to 1926) a strip of land of an average width of 327 ft. and a length along the river bank of 1 027 ft., covering an area of 14.5 acres, all outside the channel area. On the west bank, 1 mile above the dam, a more intensive silting outside the channel area has taken place. At this point, a boathouse resting on high columns, under which there was a depth of 11 ft. of water in 1913, is now "high and dry" on 16 ft. of silt at least 200 ft. from the water's edge. In all, there are three broad marginal areas on the west side of the lake, aggregating a total length of 5.2 miles and containing silt to the amount of more than 100% of the original capacity. On the east margin there are five curved strips aggregating a total length of 7.5

* *Proceedings*, Am. Soc. C. E., March, 1925, Society Affairs, pp. 151–153.
† Dean of Eng., Univ. of Texas, Austin, Tex.

miles where the lake spreads out over old farm lands. In this total length, that part outside the channel is more than 111% in every case, while that in the channel proper is less than 88% of the original capacity.

In 1913, at a point 1 000 ft. up stream from the dam, the water was 3.2 ft. deep on the east side. In 1928, the silt was 7.8 ft. above the crest of the dam, making a total silting at this section of 11.0 ft. on the east bank. In the center of the present channel there is a depth of water of 5.5 ft. where, in 1913, there was a depth of 51.42 ft., or 45.92 ft. of silt, in the middle of the old and present channel.

A study of all the reservoirs for which data can be obtained convinces the writer that silting is no respecter of channel or valley. The broad reservoirs of McMillan, Zuni, and Lake Worth, all bear out the fact that valley reservoirs, if the width of the channel is insignificant with respect to the width of the lake, will collect silt. On the other hand, the reservoirs at Austin, Lake Pennick, and the Lower Rio Grande, bear out the fact that the channel will also collect silt.

The silt cakes and cracks on the Rio Grande near San Benito are almost exact duplicates of those at Austin. The behavior of these cakes will convince any one that the "hog wallow" prairies of Texas were produced by exceedingly dry seasons during which the ground broke open and left cracks from 2 to 3 in. wide. Later, rains would soften and break the edges which would sink into the cracks and leave a hill in the center and a hollow or depression between the cakes. While the distance between "hog wallows" is about 4 ft. from crest to crest, the silt cakes and cracks are not more than one-third of this.

The most striking example of the fact that valley reservoirs collect silt is the case of Lake Worth, near Fort Worth, Tex. The original volume of Lake Worth in 1915—when the reservoir first began functioning—was 47 177 acre-ft. In July, 1928, thirteen years afterward, the writer made a complete survey from the dam to the head of the lake, which gives the total capacity as 33 340 acre-ft. The lower sections of the lake (south of "9-Mile Bridge") were kept separate for comparison; the silting is shown in Table 12.

The main channel of the river, from its entrance to the dam, because of its meanders, is 10 miles long. Its total surface area is 112 acres, or only 3% of the total area of the lake. The total amount of silting in the 15 years has been 13 837 acre-ft., and the silting in the channel proper is proportionate to that in the valley, that is, in the lake area outside the channel. Some parts of the valley have filled 100%, while in no place has the channel been filled to the brim.

The writer has come to the deliberate conclusion that the ordinary freshets or small floods have little effect on the silting, and that it is extraordinary floods, water-spouts, tornadoes, hurricanes, and cloudbursts falling on a relatively dry water-shed that contribute the larger part of the silt to impounding reservoirs. The flood in the spring of 1922 contributed more silt to the new lake at Austin in 2 weeks than had accumulated in the previous 5 years.

However, if the silt is assumed to have been deposited at a uniform rate during the 13 years of the life of Lake Worth, the capacity in 1928 was 70.67%

of the full 1915 capacity; and, at the same rate, it will be reduced by 1941 to 49.95%, or about 23 000 acre-ft.

TABLE 12.—CAPACITY OF LAKE WORTH.

Location.	WATER CAPACITY, IN ACRE-FEET.		AREA, IN ACRES.	MEAN.	DEPTH, IN FEET.
	1915.	1928.	1915.	1915.	1928.
Below 9-Mile Bridge...	38 364	29 880	2 590	14.81	11.54
Above 9-Mile Bridge...	8 813	3 460	1 180	7.47	2.93
Entire lake.....	47 177	33 340	3 770	12.51	8.84

During November, 1928, the writer visited the Lower Rio Grande Valley with a view of seeing at first hand the conditions outlined in the discussion of Mr. Welty. In 1925, the Rio Grande, true to form, cut through one of the old sags referred to by Mr. Welty, and left the pumping plants of the San Benito Company and of Harlingen, Tex.—1¼ miles up stream—more than ½ mile from the river. The river cut across a U-shaped section, Fig. 22(a), and left the two pumping plants on the old loop of the river. This forced each company to use the old section of the river from the plant to the new river course as a forebay or feed canal for the pumps.

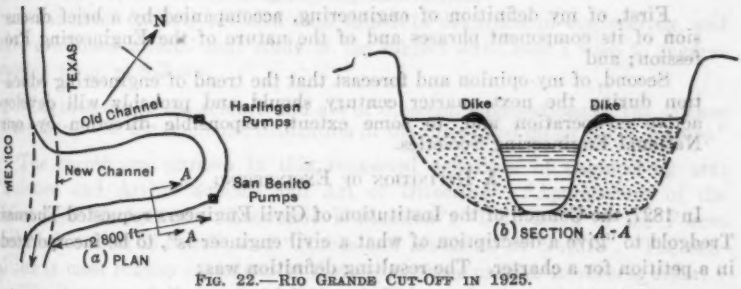

FIG. 22.—RIO GRANDE CUT-OFF IN 1925.

The silt from the Rio Grande is an ever-present menace to the San Benito Company in closing its forebay or source of supply. An 8-in. pump is kept at work in the old channel ten months of the year. The middle third of the old river is used as a channel (Fig. 22) and the "slush" is deposited on each side by the hydraulic-fill method. The pump is kept on a barge and works from it. The silt is stirred into a slush consisting of 85% water, which is pumped over a berm and is kept from flowing back into the river by a small dike on the river side of the berm. This method is used throughout the entire 2 800 ft. to the new river.

Paper No. 1721

ENGINEERING AND ENGINEERING EDUCATION

ADDRESS AT THE ANNUAL CONVENTION, AT MILWAUKEE, WIS., JULY 10, 1929

BY ANSON MARSTON,* PRESIDENT, AM. SOC. C. E.

This address will be devoted to the presentation:

First, of my definition of engineering, accompanied by a brief discussion of its component phrases and of the nature of the Engineering Profession; and

Second, of my opinion and forecast that the trend of engineering education during the next quarter century should and probably will develop active co-operation and, to some extent, responsible direction by our National Engineering Societies.

A DEFINITION OF ENGINEERING

In 1827, the Council of the Institution of Civil Engineers requested Thomas Tredgold to "give a description of what a civil engineer is", to be incorporated in a petition for a charter. The resulting definition was:

"Civil Engineering is the art of directing the great sources of power in Nature for the use and convenience of man, as the means of production and of traffic in states both for external and internal trade, as applied in the construction of roads, bridges, aqueducts, canals, river navigation and docks, for internal intercourse and exchange, * * *, and in the construction and adaptation of machinery, and in the drainage of cities and towns."

The many attempts made by engineers during the last forty years to formulate a new definition of engineering prove that this famous statement incorporated in 1827 in the charter of the (British) Institution of Civil Engineers is not satisfactory under present-day conditions.

The difficulties in the way of devising a satisfactory definition of modern engineering are very great, perhaps insuperable. Many objections, at least

* Dean of Eng., Iowa State Coll., Ames, Iowa.

some of which appear valid, have been raised to every suggested definition of which I know.

In 1927, the Mining and Metallurgical Society of America, presented an original and an amended definition of engineering,* both prepared by a committee, together with the opinions thereon of 95 members. The definitions were as follows:

Original Definition.—

"Engineering is the practical application of scientific methods to the utilization of the resources of Nature for the use of Man."

Amended Definition.—

"Engineering is the application of scientific methods to the utilization of the resources of Nature."

Only 7 members approved the original definition and only 34 the amended definition, while 44 members were not satisfied with either. Many thought the definitions basically wrong, because they would include many occupations other than engineering.

In the years 1906-1919, inclusive, I gave annually to engineering seniors a course of lectures, about half of which were printed and copyrighted in 1912, on the History of Engineering, containing some discussions on definitions of engineering. In 1913-1914, I served as Chairman of a committee which made a study of original source material and formulated definitions of mechanic arts and of engineering, which were adopted officially and published in 1914 by the Land Grant College Engineering Association.

I was never entirely satisfied with this 1914 definition of engineering, and have continued intermittent study of the subject until now I wish to suggest another form, as follows:

"Engineering is the science and art of directing applications of the science of mechanics in the economic utilization of the forces and materials of Nature."

The significant phrases in this suggested definition of engineering are: "Science and Art"; "Science and Art of Directing"; "Applications of the Science of Mechanics"; "Economic Utilization"; "Utilization of the Forces and Materials of Nature"; and "Forces and Materials of Nature". The definition is most readily explained by discussing these phrases in reverse order.

The Forces and Materials of Nature.—This phrase covers the entire physical universe and, hence, it includes the entire field of the physical sciences and applied mathematics. While engineering is founded mainly on the sciences of mathematics, physics, and chemistry, in many instances it is based on biological science.

Engineering, however, does not include all applications of the physical and mathematical sciences, but is restricted to the particular ones that are characterized by the necessary use of designs, methods, and devices which are based on the science of mechanics.

It is a common fault of suggested definitions of engineering to word them so broadly that while often they may describe engineering with much truth, they include various other occupations which are widely different.

* *Bulletin 190*, Min. and Metallurgical Soc. of America, October, 1927.

The Utilization of the Forces and Materials of Nature.—This phrase covers not only engineering, but agriculture, the handicrafts, medicine; in short, all industries, all trades, and all professions, in which any use is made of any of the organic or inorganic forces or materials of the physical universe.

Engineering, however, does not include all utilizations of the forces and materials (the resources) of Nature, but is restricted to those particular utilizations which are characterized by applications of the science of mechanics.

Economic Utilization.—Emphasis has always been given the economic side of the engineer's work, his ability "to do with one dollar what some one else could do with two". In recent years this has been made more emphatic, and it is now widely recognized that the engineer must have a working mastery of the correct principles of economics and business. Engineering is now recognized as including the work of the industrial executive.

Applications of the Science of Mechanics.—This phrase covers all mechanic arts industries. In 1914, the Land Grant College Engineering Association officially adopted the following definition:

"The mechanic arts are those arts which are characterized by applications of the science of mechanics."

It was prepared by the Executive Committee of the Association, after a careful study of original source material, some of which, arranged in chronological order, is quoted as follows:

"'The use of the term, Mechanic Arts, in standard literature dates back to Francis Bacon, 1561-1626. The term was first applied to machine devices.'" (Letter from the Lexicographer, *Literary Digest*, 1913.)

"'The Mechanick Art is a Science which contemplates about the quantities of moving forces, and the times in which the motion is made.'" ("Mechanick-Powers", Venturus Mandey and James Moxon, London, 1696.)

"'Most of what are usually called the Mechanic Arts are partly mechanical and partly chemical.'" (Webster's Dictionary, 1848; copyright date, 1847; on the title-page, 1848.)

"'Journal of the Franklin Institute of the State of Pennsylvania, for the Promotion of the Mechanic Arts, Devoted to Mechanical and Physical Science, Civil Engineering, the Arts and Manufactures, and the Recording of American and Other Patent Inventions.'" (Title of the *Journal* for 1857, Philadelphia.)

"'Mechanics, Applicate or Applied, is a term which, strictly speaking, includes all applications of the principles of abstract mechanics to human art, * * *.'" (Encyclopedia Britannica, 1857, American Reprint, Little, Brown & Co., Boston.)

"'The Mechanic Arts are those which comprehend the means of promoting and facilitating the necessities of existence.'" (The American Encyclopedia, 1859-63.)

"'Mechanical Art is most easily distinguished from fine art by the character of its products: Those of fine art represent ideas, those of mechanical art answer purposes; the former result in a gratification of the æsthetical sense, the latter are made for practical use. * * *'". (Johnson's New Universal Cyclopedia, 1877, Edited by F. A. P. Barnard, President of Columbia, and Arnold Guyot, Professor of Geology and Physical Geography, College of New Jersey.)

No permanent list of mechanic arts industries can be made, for new industries are constantly developing as civilization advances. A present-day list would include:

Ceramic Industries.
Communication Industries: Telegraph, Telephone, Wireless.
Construction Industries.
Electrical Industries.
Gas Industries.
Handicrafts: Masonry, Metal, Wood, etc.
Manufacturing Industries.
Mining Industries.
Petroleum Industries.
Power Industries: Electric, Gas, Steam, Water, Wind.
Quarry Industries.
Sanitation Industries: Sewerage, Water Supply.
Transportation Industries: Aeronautics, Highways, Navigation, Railways, Waterways.
Utilities: Bus, Electric, Gas, Heat, Railway, Water.
Various other industries not enumerated.

Agriculture is not a mechanic arts industry, although it requires the use of many mechanical devices, for agriculture is characterized by the cultivation and care of plants and animals, not by the use of tools and machines. Many other industries and occupations in which the use of mechanical contrivances is essential, are excluded for similar reasons.

Only a limited fraction of the hundreds of millions of persons who are employed in the mechanic arts industries can properly be termed engineers.

The Science and Art of Directing.—This phrase restricts engineering to the professional phases of mechanic arts work.

Tredgold was right in making the phrase, "the art of directing", one of the most prominent components of his famous definition, and the word, "directing", should be considered an essential part of any correct definition of engineering.

Engineering is a true profession, with real professional characteristics and requirements, including:

1.—A great system of engineering education.
2.—Increasingly widespread requirement of governmental professional licenses to practice engineering.
3.—A great professional engineering literature.
4.—Many local and several great National professional engineering societies in each great country.
5.—Increasingly strict enforcement of formal codes of professional engineering ethics.

Engineering differs in characteristics from the other great professions mainly in that the engineer is unique in his close and vital relation to hundreds of millions of persons engaged in pursuits closely allied to his profession. It is easy to make the distinction between the apothecary and the physician, or between the bailiff and the lawyer, but it is not so easy to draw a sharp line of separation between the highly skilled mechanic arts master workman and the professional engineer. This is because engineering is both a science and an art.

Science and Art.—Science is classified knowledge; "art is that which depends on practice and skill in performance". "In science, we know that we may know; in art, we know that we may produce."*

* See Webster's Dictionary, and Karslake as quoted therein.

From the remotest ages, engineering has originated from the union of the most advanced contemporaneous physical and applied mathematical science with the highest contemporaneous skill attained in practice in the mechanic arts. As far back as the beginning of the Christian era, the Roman architect-engineer, Vitruvius,* wrote of architecture, which then included engineering:

"Architecture is a science arising out of many other sciences, and adorned with much and varied learning; by the help of which a judgment is formed of those works which are the results of other arts. Practice and theory are its parents. * * * the mere practical architect is unable to assign sufficient reasons for the forms he adopts; and the theoretic architect also fails, grasping the shadow instead of the substance. He who is theoretic as well as practical, is therefore doubly armed; able not only to prove the propriety of his design but equally to carry it into execution."

In Tredgold's day (1827), almost all English engineers had risen from the ranks of master workmen, and it was natural for him to refer to engineering as only an "art". Since Tredgold's time, there has been a very extensive development of the scientific aspects of engineering knowledge and qualifications, which I have come to believe should be recognized by defining engineering as both a "science" and an "art". While engineering is based on certain phases of the physical and mathematical sciences, there is a body of real "engineering science," consisting of certain highly specialized developments (dealing almost wholly with engineering problems) of the physical and mathematical sciences. Engineering mechanics, the theory of structures, and the theory of machine design are good illustrations. The physicist, the chemist, the biologist, the mathematician, would have to become engineers to become qualified to develop and advance modern engineering science.

More and more universally in modern engineering, empirical methods and solutions of engineering problems are found insufficient and unsatisfactory. No engineering problem can be considered solved satisfactorily until a sound theory of its solution is discovered.

The origin of the words, "engineering" and "engineer", is such as to indicate that the engineer should be thought of as primarily a man of genius, or possessing ingenuity, and that engineering should not be considered as merely an art.

The words† "engineering" and "engineer" come from the Sanskrit, *jan*, to be born, from which came the Greek form, *γεν*, and the Latin, *gen*.

"The direct line of derivation [of the word, engineer] may be traced to *ingenium*—natural capacity, talent, capacity for invention—and is closely linked with the words *genius* and *ingenuity*."‡

The name, "engineer", came to us from the Latin through the French noun, *ingénieur*.

It is a mistake to think that the name of our profession is derived from the word, engine, or that the engineer is primarily concerned with engines. An engineer is an ingenious man, a man of genius. An engine is an ingenious machine.

* Translation by Joseph Gwilt, an English architect, 1874.

Engineering Education—Its Relation to Professional Engineering Organizations

No profession can be a true profession and keep up with the advance of science without wise, ample, and ever-improving provision for its professional educational requirements. In the United States, our engineering societies have not taken a sufficiently active part in shaping and directing engineering education. In a paper* entitled "A Comparative Study of Engineering Education in the United States and in Europe", Mr. W. E. Wickenden gives an excellent summary discussion of the development of modern engineering education in Europe and in the United States. The time has come when our engineers' clubs within the great cities, our State engineering societies within the several States, and our great National engineering societies for the Nation, ought to assume real responsibility and undertake real initiative in engineering education.

It is not sufficient for engineering practitioners to confine themselves to criticism of engineering graduates; that is too much like school boys making faces at their professors from behind their backs.

The writer agrees with Mr. Wickenden* that:

"In no other country [than the United States] have the engineering schools been so free from outside domination. They owe little to statecraft other than the provision of means for their extension and support. They owe little to the organized engineering profession except the benefits of occasional criticism of their aims and methods. They owe little to industries except an ever-widening field of employment for their graduates. To a striking degree, these schools have been left to work out their own destiny and fend for themselves. This has been the source of both weakness and strength."

It should be borne in mind that throughout all civilizations, up to the beginnings in the Eighteenth Century, in France, of the development of our modern engineering schools, the education of engineers was left almost wholly to themselves. We know by the character of their engineering constructions that the great engineers of Ancient Chaldea and Egypt must have been fully acquainted with the best scientific and mechanics arts knowledge of their times. We know that Heron, of Alexandria, whom Truesdell† has erroneously designated "the first engineer", was a great mathematician and author, as well as a great engineer. The Roman architect-engineer Vitruvius, enumerates the subjects in which an architect should be educated, as including: Good writing (we now say "English"); history; music; moral philosophy (ethics); physics (sanitation); law (business law relating to party walls, roof water, cesspools, sewers, and the like); natural philosophy (physics, as exemplified in the works of Archimedes and Ctesibus and as applied to the conduct of water); drafting; arithmetic; geometry; and astronomy.

In modern times, engineering education in England was left mainly to the Engineering Profession itself for a long time and, according to Mr. Wickenden,*

* "A Comparative Study of Engineering Education in the United States and in Europe", *Bulletin No. 16*, Soc. for the Promotion of Eng. Education, 1929.

† *Journal*, Assoc. of Eng. Societies, Vol. 19, July, 1897.

"From its foundation in 1818, the Institution of Civil Engineers has exercised a dominant influence on the professional training of engineers. British policy is to leave such matters to the organized profession rather than the law and the professional institution, by virtue of its character, acts as a quasi-legal body."

In Germany, says Mr. Wickenden,*

"The influence of the *Verein Deutscher Ingenieure* must be ranked among the major forces in the upbuilding of both the technical universities and the *realschulen*."

It is true that America is not England or Germany. The reason for our comparative failure to the present time to develop adequate systems of elementary trade schools and technical high schools is the universal freedom to choose any occupation and to aspire to any social plane which our American ideals strive to preserve for the American youth until they have passed the high school age. Our engineering schools are not to blame, as some have charged. Those engineering schools which have failed to devote their energies mainly to professional college courses have been killed or dwarfed by lack of attendance. You cannot teach without students.

The fact that the problem of developing adequate systems of technical education is vastly more difficult in America than in countries where class distinctions lead the great majority of youth to settle inevitably at comparatively early ages into defined life occupations, is not a valid excuse for American professional engineering societies to neglect their duty to assume proper responsibility and initiative in connection with engineering education. By co-operation with the Society for the Promotion of Engineering Education the American Society of Civil Engineers should proceed promptly to assume real responsibilities in shaping civil engineering education in our engineering colleges. In this, as in other engineering activities, the Society should work in co-operation with the other Founder Societies, as far as they are ready to go.

In my judgment, the Society might well at this time study with great care the feasibility and advisability of proceeding in the immediate future with active co-operation in shaping and advancing civil engineering education in America in accordance with all or a part of the following program, several features of which have already been given tentative consideration by the Board of Direction:

1.—Adopt formal requirements, materially higher than have been accepted heretofore, for the admission of engineering colleges to the accredited list of the Society. In formulating the standards, the Society should consider contents of engineering curricula, qualifications of engineering professors (which will necessarily involve their remunerations), engineering libraries and their use, housing, laboratory equipment, engineering research, and the achievements of engineering alumni.

2.—Require candidates for admission who are non-graduates of accredited engineering colleges, as a condition for acceptance, to pass actual examinations demonstrating educational and professional attainments equivalent to the completion of a standard engineering course. In such examinations (which should

* "A Comparative Study of Engineering Education in the United States and in Europe", *Bulletin No. 16*, Soc. for the Promotion of Eng. Education, 1929.

be partly written and partly oral), the candidate's professional achievements should be given due weight. Questions for the written examinations should be prepared and the papers should be graded at Society Headquarters. The examinations might be given by the Local Membership Committees.

Candidates who are graduate engineers might well be required to appear in person before the Local Membership Committees for conferences which would be somewhat of the nature of oral examinations.

3.—In my judgment, the Society might very properly and wisely proceed, in co-operation with the Society for the Promotion of Engineering Education, to formulate and secure the adoption, by accredited engineering colleges, of standard requirements for the professional engineering degree of Civil Engineer (C. E.).

Almost all our standard engineering colleges are already agreed that the professional degrees, of Civil Engineer, Mechanical Engineer (M. E.) and the like, should be awarded only after years of successful engineering practice; never for engineering college work alone, for which the standard degree is Bachelor of Science (B. S.). It is, therefore, very proper that our National Civil Engineering Society participate in deciding how much and what kind of civil engineering practice should be required before giving any person the legal right to use the title of Civil Engineer.

The present requirements for the degree of Civil Engineer vary greatly in different institutions, and I believe that the engineering colleges would, in general, welcome action by the Society which would standardize professional degrees. When so standardized, the Society might well give such degrees greater weight than at present in connection with its requirements for admission to the grade of Associate Member.

4.—The Society ought to take some active steps to aid effectively in the development of true graduate civil engineering work of high order in our engineering colleges.

It now seems settled that, at least for a considerable period in the future, the standard engineering college course will be four years, following graduation from standard secondary schools. This means that the educational attainments of the engineering graduate cannot be expected to advance markedly until that indefinite future date when the junior high school and the junior college movements develop to the point of delivering to the engineering colleges candidates for admission who have already completed one or two years of work now done in college.

The engineering colleges, however, are now actively developing one to three years of graduate engineering work, designed to serve only the best fraction of engineering graduates. The National Engineering Societies can and should do much to assist in placing such graduate work on a very high plane, and in encouraging practicing engineers to take advantage of the facilities of the graduate laboratories of our great engineering colleges.

5.—It would be well for the Society to study the feasibility and the advisability of sponsoring in the near future advanced schools, of several weeks'

duration, restricted to practitioners of experience and merit, for instruction in the most advanced developments in specialized branches of civil engineering practice.

I visualize such schools as financed by fees and endowments and as gatherings where our most aspiring and promising civil engineers of ages, say, between 27 and 40, could learn at the feet of the foremost engineers, with some of the foremost scientists interpreting the latest scientific discoveries.

I dare even to dream that the Society might obtain from Congress special legal authority to conduct such schools, to award diplomas for completion of work therein, and possibly to confer upon that fraction of the membership of the Society who meet certain specified high qualifications some legal designation which will win them, in fact if not in law, some special rights and privileges in their professional practice.

MEMOIRS OF DECEASED MEMBERS

FREDERIC VAUGHAN ABBOT, M. Am. Soc. C. E.*

DIED SEPTEMBER 26, 1928.

Frederic Vaughan Abbot was born in Cambridge, Mass., on March 4, 1858. He was a son of Henry L. and Mary Susan (Everett) Abbot, his father having been a Brigadier-General in the United States Army, and an officer of distinction both as a Civil and as a Military Engineer.

Mr. Abbot was educated at private schools until he received an appointment to the United States Military Academy at West Point, N. Y., to which institution he was admitted as a Cadet on July 1, 1875. He was graduated in 1879, at the head of his class, and was commissioned a Second Lieutenant, Corps of Engineers, U. S. Army.

He was promoted to the grade of First Lieutenant on June 17, 1881; Captain, on July 22, 1888; Major, on July 5, 1898; Lieutenant-Colonel, on September 9, 1906; Colonel, on June 24, 1909; and Brigadier-General, National Army, on August 5, 1917. He was placed on the retired list on account of physical disability incurred in the line of duty on May 10, 1920, after more than forty years of commissioned service, all of which was with the Corps of Engineers, U. S. Army.

General Abbot had a varied and extensive career of service both as a Civil and as a Military Engineer. After graduating from West Point he was assigned to duty at the United States Engineer School of Application, Fort Totten, New York Harbor. While attending this school he translated and published for the instruction of student officers, Colonel Schiednagel's book on "Submarine Mines" (Spanish), and Schlicting's "Navigable Non-Tidal Rivers" (German). From June, 1882, to August, 1884, he served as Assistant on the improvement of the Mississippi River from St. Louis, Mo., to Cairo, Ill., and on detached service, surveying a portion of the boundary line between Maryland and Virginia. In August, 1884, he became Assistant on the improvement of rivers and harbors in North Carolina and South Carolina, and on the construction of fortifications along the South Atlantic Coast. From May, 1888, to September, 1897, he was in charge of these works, completing the project for obtaining a channel of 21 ft. across the bar at the entrance to Charleston, S. C., Harbor, by means of converging jetties; constructing a battery for sixteen 12-in. mortars on a swamp foundation; and constructing emplacements for 10-in. guns operating on disappearing gun carriages.

From September, 1897, to August, 1900, General Abbot (then a Major), was in charge of the river and harbor works of Minnesota and Wisconsin, constructing two large reservoir dams at the head-waters of the Mississippi River, and a lock and dam in that river above St. Paul, Minn.

From August, 1900, to April, 1910, he served as Assistant to the Chief of Engineers, U. S. Army, with station at Washington, D. C. In April, 1910,

* Memoir prepared by C. McD. Townsend, M. Am. Soc. C. E.

he was placed in charge of the Boston, Mass., Engineer District, and from June, 1913, to October, 1917, he served as Division Engineer of the Northeast Division Engineer Department, and was in charge of river and harbor construction in portions of New York and New Jersey.

From October, 1917, until his retirement, he again served as Assistant to the Chief of Engineers, acting as Chief of the Division of Operations, Office of the Chief of Engineers, where he supervised the enlistment, organization, training, and forwarding of more than 300 000 engineer troops for service in the World War. He also acted as Chief of Engineers on numerous occasions. During this service General Abbot was a member of numerous boards convened by the War Department or the Chief of Engineers, of which the most important were the Board of Engineers for Fortifications, the Board of Engineers for Rivers and Harbors, the New York Harbor Line Board, the Boston Harbor Line Board, the Joint Artillery and Engineer Board to locate fire-control stations at all seacoast defenses in the United States, and a Board appointed to co-ordinate the work of the Corps of Engineers, Ordnance Department, and Signal Corps.

While General Abbot's services in the field as a Civil Engineer were highly creditable, he obtained his greatest reputation as a Military Engineer and as an Administrative Officer, having been awarded a Distinguished Service Medal by the War Department for his service during the World War, the citation reading as follows:

"For exceptionally meritorious and distinguished service in the organization of Engineer troops and the procurement of enlisted men for the service in the War. His zeal was untiring and the success of his efforts marked."

The closing sentence of this citation can be applied to his entire career, "His zeal was untiring and the success of his efforts marked."

He died on September 26, 1928, and is survived by his widow, *née* S. Julia Dehon, two daughters, Marion B. and Elinor R., and a son, Henry Dehon Abbot.

General Abbot was elected a Member of the American Society of Civil Engineers on December 3, 1884.

HENRY SEWALL ADAMS, M. Am. Soc. C. E.*

DIED AUGUST 21, 1927.

Henry Sewall Adams, the son of Charles Sylvester and Christiana Wyman (Jennison) Adams, was born in Cambridge, Mass., on March 16, 1864. At an early age he lost his parents, as well as his only brother and sister, and his boyhood was spent with his Grandfather Adams, in Cambridge, and at the farm of his Grandfather Jennison, in Burlington, Mass.

At the age of seventeen, Mr. Adams began his engineering career with a survey party on the sewerage system of Woburn, Mass., work which occupied four summer vacations during his course at the Woburn High School and following his college Freshman year. In 1883 he entered the Massachusetts Institute of Technology where he studied civil engineering with the Class of 1887, leaving, however, before graduation, to take a position in the office of the City Engineer of Cambridge.

Municipal engineering work in Cambridge and work as Assistant County Engineer of Middlesex County occupied Mr. Adams until 1893, when he opened his own office in Boston, Mass., for the private practice of engineering which was continued uninterruptedly until his death.

In his early years of consulting practice, Mr. Adams' professional work included water-front developments at Boston, reporting on mines in Montana, Idaho, California, and Mexico, and on other properties in different parts of the country. In 1895 was begun the construction of Boston's Subway System, the pioneer undertaking of its kind in the United States. This extensive work of underground construction presented new and unusual problems relative to the underpinning and safety of buildings. In the several years during which subways and tunnels were being built in down-town Boston, Mr. Adams, more often than any other engineer, was called upon by private clients to advise on these foundation problems and to look after the safety of more than one hundred important buildings.

Gradually, work on difficult foundations, and more particularly that in connection with the building of water-front structures, came to absorb Mr. Adams' attention. In this special field he made a reputation which was not confined to Boston. Not only did he come to be looked upon as the leading consulting engineer on the development of the Boston water-front—and no engineer has been more closely identified with private developments at that port—but his services were in demand elsewhere. He was one of two engineers commissioned by the City of Newark, N. J., in 1909, to study and report upon the layout of the port development of the Newark Meadows; he designed wharves and docks for Ponce, Porto Rico; he designed and supervised the building of the Sandy Bay improvements at Rockport, Mass.; and he was Engineer on harbor and water-front improvements at other ports.

For many years, until his death, Mr. Adams was Consulting Engineer to the Atlantic Sugar Refineries, Limited, of Montreal, Que., Canada., on its water-front plant at St. John, N. B., Canada, where his advice was sought

* Memoir prepared by Frederic H. Fay, M. Am. Soc. C. E.

not only on difficult water-front problems, but also on the general development and upkeep of the plant. Likewise, for many years he was Consulting Engineer to the Pocahontas Fuel Company, Incorporated, in connection with its coal-handling plants at Portland, Me., and at New Bedford, Mass. At both Portland and St. John, he successfully met some unusually difficult problems of water-front construction in connection with structures, previously built by others, which had failed. Many fuel companies engaged his services in connection with the building and repair of coal-handling plants. Included among his clients were railroad and steamship companies and many corporations, as well as most of the private wharf owners along the Boston water-front.

Mr. Adams showed peculiar ingenuity and resourcefulness in solving problems of unusual difficulty and complexity. Painstaking and thorough in his work, he was also a man of broad outlook and sound judgment. By his clients, many of whom he served continuously over a period of years, his advice was sought, not only on structural problems, but also on the conduct of business.

For more than thirty years, and until his death, Mr. Adams lived in Arlington, a suburb of Boston. He retained also the farm of his Grandfather Jennison in Burlington, where part of his boyhood had been spent and in which he always took a special interest. He served the Town of Arlington in many ways. During the early years of his private practice, and until the appointment of a full-time Town Engineer, he acted in that capacity and took an important part in the laying out and development of this growing community. He was elected a member of the Board of Public Works of Arlington in 1912, a position which he filled for several years, part of the time being Chairman of the Board. He was elected a member of the first Planning Board of the town in 1914.

Being deeply interested in historical and genealogical matters, he was long an active member of the Arlington Historical Society as well as of the Bostonian Society.

Mr. Adams was admitted to membership in the Boston Society of Civil Engineers on October 19, 1892, and served as a Director of that Society in 1925 and 1926. He was a life member of the International Association of Navigation Congresses; a member of the American Society for Testing Materials, and of the Association of Professional Engineers of the Province of New Brunswick, Canada. He was a member of the Engineers Club of Boston and of the Boston Chamber of Commerce, in which latter organization he took an active part in the work of the Maritime Association.

In October, 1892, Mr. Adams was married to Bessie Lockwood Tucker, of Cambridge. He is survived by his widow and four sons, Charles Jennison, Laurence Wilder, Ralph, and Henry Sewall, Jr. There are also two grandchildren, Jane and Charles Jennison, Jr.

By ability and achievement, he worthily earned a position of standing in the Engineering Profession. Ever modest, genial, and true to his own high standards, he endeared himself to a wide circle of friends and associates. Especially was he held in high regard by the clients whom he served. One of them writes:

"Mr. Adams had the happy faculty of always impressing his client with explicit confidence in his judgment, and I never knew a more careful and painstaking man than he when he had a difficult problem confronting him, and he had one of the most lovable natures that I ever knew in a man of his ability. Our Company has suffered a great loss in the death of Mr. Adams."

Another client says of him,

"The recital of Henry S. Adams' services to this company would be a long and unbroken record of valuable contributions. He possessed an engineering ability that in itself was sufficient to distinguish him, but over and above this was a pride and joy in his work and a simple devotion to an ideal which, combined with his professional ability, gave him that place and position which he occupied so well. Possessed of a delightful modesty and never superior to gaining information from whatever source it might be offered, he none the less inspired full reliance by his own quiet confidence.

"It is, however, impossible to consider Henry S. Adams except it include his own charming and lovable character. The start of our business relationship marked also the beginnings of a personal attachment which grew and deepened until it became one of life's delightful realities. It is a great privilege to have had him as a friend and to continue him in our affectionate remembrance."

An able engineer and useful citizen, Henry Adams was a lover of Nature, a devoted husband and father, and a loyal and understanding friend.

Mr. Adams was elected a Member of the American Society of Civil Engineers on June 6, 1906.

ROBERT PAUL ANDERSON, M. Am. Soc. C. E.*

DIED JANUARY 24, 1929.

Robert Paul Anderson, the eldest son of the Rev. R. E. and Alice B. Anderson, was born in Redwood Falls, Minn., on December 11, 1884.

Mr. Anderson received his preparatory education in the grade schools of Heyworth, Ill., the Chambersburg Academy, Chambersburg, Pa., and Grand Prairie Seminary, Onarga, Ill. In the fall of 1906 he entered the University of Illinois, Urbana, Ill., where he spent three years studying Civil Engineering.

After leaving the University Mr. Anderson entered the employ of the Illinois Central Railroad Company and was engaged in the construction of docks in New Orleans, La., and railroads in Mississippi. Later, he spent a year with the United States River and Harbor Commission on Mississippi River work, and from there he went to the Spokane, Portland, and Seattle Railway Company as Resident Engineer in charge of heavy construction along the Snake River.

In 1909, Mr. Anderson was appointed Locating Engineer for the Northern Pacific Railway Company, working in Montana and Washington. He then became Assistant Engineer on Construction, the youngest man to occupy this position in the entire System.

In 1912, he became Locating and Reconnaissance Engineer for the Farquhar Syndicate in South America and three times crossed the Andes in charge of survey parties on important and dangerous work. He had many adventures in little known parts of Brazil, Bolivia, and Chile.

On returning to the United States in 1914, Mr. Anderson was engaged in construction work in El Paso, Tex., and Juarez, Mexico, until the outbreak of the World War, when he enlisted and served in France as Captain of Company E, 55th Engineers, until he was mustered out in July, 1919. During his service in France he was critically ill with pneumonia. This undoubtedly weakened his constitution and contributed to his early death.

Following the war he returned to El Paso and was engaged in work for the City Engineering Department, a notable accomplishment being the construction of the Scenic Drive on Mount Franklin. In 1923, he was appointed City Engineer and served for four years, during which time he had charge of the design and construction of a high-line reservoir of 2 300 000 gal. capacity, with a reinforced concrete dome 140 ft. in diameter, reported to be the largest flat dome in the country. Important street improvements, river protection, and sewerage projects were also carried out during this term of service.

In 1927, Mr. Anderson returned to the contracting business and was Superintendent of Construction for the Ware Company of El Paso until the beginning of his last illness.

* Memoir prepared by W. E. Stockwell, Esq., El Paso, Tex.

Mr. Anderson had a winning personality and is mourned by a host of friends from among those who came in contact with him.

In 1919, he was married to Mary Emma Jackson, of Paragould, Ark. He is survived by his widow and one daughter, Mary.

Mr. Anderson was elected a Member of the American Society of Civil Engineers on January 18, 1926.

WALTER EUGENE ANGIER, M. Am. Soc. C. E.*

DIED DECEMBER 29, 1928.

Walter Eugene Angier was born at Fitzwilliam, N. H., on May 18, 1863. His father, Philip Doddridge Angier, a native of Fitzwilliam, represented his district in the State Legislature for two terms. His mother, Sarah Arabella (Reed) Angier, a sister of the mother of the poet, Eugene Field, was the "Aunt Belle" to whom Mr. Field dedicated his "Love Songs of Childhood", and it was at his request that her son was given his name.

The family moved to West Swanzey, N. H., when Mr. Angier was very young, and it was in that town that he was reared, receiving his early education in the common schools and at Mt. Caesar Academy. In 1885, he received his Bachelor of Science degree from the New Hampshire College of Agriculture and Mechanic Arts; and, in 1887, he received the degree of Civil Engineer at the Thayer School of Civil Engineering, Dartmouth College, Dartmouth, N. H.

His first professional experience, during the summer vacation of 1886, was in the office of the late John W. Ellis, M. Am. Soc. C. E., Chief Engineer of the Providence and Worcester Railroad Company, and also with Mr. Dana C. Barber, of Philadelphia, Pa., whom he assisted in surveys and plans for the sewerage system of Lakewood, N. J.

Immediately after his graduation, in April, 1887, Mr. Angier went to Fort Madison, Iowa, as Rodman and Assistant on the Mississippi River Bridge which was being built by the Atchison, Topeka and Santa Fé Railroad Company, under the late Octave Chanute, Past-President, Am. Soc. C. E., as Chief Engineer. In this position, he inspected cement, assisted in the field work, and in the sinking and sealing of, the caissons. From October, 1887, to October, 1888, and again in January and February, 1889, he was Sub-Inspector on the harbor improvement at Galveston, Tex., and Recorder on a survey of the harbor and Lower Bay at Galveston. In the interim, from October, 1888, to January, 1889, as United States Assistant Engineer, he was engaged in an examination of the Rio Grande River, from Embudo, N. Mex., to El Paso, Tex., in order to determine its facilities for navigation.

Bridge work was Mr. Angier's particular desire and he left the Federal Service in February, 1889, to go to Memphis, Tenn., as Assistant Engineer on the Mississippi River Bridge, under the late George S. Morison, Past-President, Am. Soc. C. E., as Chief Engineer, and the late Alfred Noble, Past-President, Am. Soc. C. E., as Resident Engineer. He had special charge of all masonry work and the erection of the west approach viaduct. After the completion of the bridge in the summer of 1892, Mr. Morison put him in charge of the construction of a Memorial Library at Peterborough, N. H. For a short time, also, he was engaged on sewer work at Rochester, N. Y.

In November, 1892, Mr. Angier entered the employ of the Illinois Central Railroad Company as Inspector of Bridges, on both shop and field work, and,

* Memoir prepared by a Committee of the Illinois Section, consisting of E. E. R. Tratman, Assoc. M. Am. Soc. C. E., *Chairman*, Charles L. Strobel, and Arthur L. Webster, Members, Am. Soc. C. E.

later, as Assistant Engineer of Bridges, under the late H. W. Parkhurst, M. Am. Soc. C. E., then Bridge Engineer of that Company. He remained there until January, 1902, when he was appointed Resident Engineer on the Thebes Bridge, his third Mississippi River bridge, under Mr. Noble and Ralph Modjeski, M. Am. Soc. C. E., Chief Engineers. On the completion of the Thebes Bridge, in 1907, he became associated with Mr. Modjeski as his Principal Assistant and, later, was his partner under the firm name of Modjeski and Angier. During the next twenty years he was engaged in the design and erection of several important bridges, his specialty being in connection with difficult foundation work and heavy masonry. In writing of Mr. Angier, Mr. Modjeski states:

"I had a great appreciation for his ability and conscientiousness, which I considered invaluable. His judgment was always characterized by great directness, which often simplified very complex questions. He was of an extremely unassuming nature and a man of very few words."

Mr. Angier suffered a partial paralysis from cerebral lesion in May, 1926, which caused him to retire, although he remained active and retained his interest in engineering work. He was stricken again, at his home in Wheaton, Ill., on Sunday, December 23, 1928, and died on December 29.

In December, 1889, he was married to Mary Powell, of Luling, Tex., who survives him. He leaves also a daughter, M. Estelle Angier, and two sons, Philip Powell Angier, an engineer, of Melville, La., and Robert M. Angier, of Los Angeles, Calif. He was a member of the Western Society of Engineers, and the Chicago Engineers Club.

Mr. Angier was elected an Associate Member of the American Society of Civil Engineers on September 7, 1892, and a Member on September 3, 1902.

LELAND RELLA BALCH, M. Am. Soc. C. E.*

DIED APRIL 18, 1928.

Leland Rella Balch was born in Neillsville, Wis., on March 10, 1883. He was the son of the late Rella W. Balch and Nettie B. (Whipple) Balch, and a descendant in the tenth generation of John Balch, of Somerset, England, who settled in Beverly, Mass., in 1626.

Mr. Balch spent his early life in Neillsville, where he fitted himself for college. He was graduated from the University of Wisconsin with the degree of Bachelor of Science in Civil Engineering in 1905, and received the professional degree of Civil Engineer in 1909.

He spent the summers of 1902-04 as an Assistant with the County Surveyor of Clark County, Wisconsin, and began his professional work with the United States Reclamation Service, first as Engineer's Assistant, then Instrumentman, and, later, as Chief of Party and Resident Engineer in charge of surveys on the Huntley, Sun River, Blackfeet, and Flathead Irrigation Projects in Montana.

From September, 1909, to March, 1910, he took post-graduate work at the University of Wisconsin. In April, 1910, he was appointed an Assistant Engineer with the U. S. Reclamation Service on the Shoshone Project in Wyoming. From November, 1911, to August, 1912, he was engaged as Research Assistant in Hydraulics, at the University of Wisconsin, and spent his time in experimental research and in the preparation of technical *Bulletins* for publication. He prepared several important *Bulletins*, among which may be mentioned: "Tests of Flash Wheels"; "Flow Through Submerged Orifices and Tubes"; and "Hydraulic Curve Resistances". He rendered important service in editorial work in the preparation and revision of various textbooks by D. W. Mead, M. Am. Soc. C. E., including "Water Power Engineering", "Hydrology", and "Contracts, Specifications, and Engineering Relations".

From 1912 until his death, Mr. Balch was with the firm of Daniel W. Mead and Charles V. Seastone, Members, Am. Soc. C. E., Consulting Engineers, of Madison, Wis. With this firm he had responsible charge of the design and construction of many important works, among which may be mentioned the reconstruction of the municipal pumping plants at Madison, Rockford, Ill., Dubuque, Iowa, and Harvard, Ill.; additions to the power plants of the Madison Gas and Electric Company, at Madison; the Mississippi Valley Public Service Company, at Winona, Minn.; the Peninsular Power Company, at Iron River, Mich.; the Eastern Oregon Light and Power Company, at Baker, Ore.; and of the design and construction of the Diesel electric plant of the Peninsular Power Company, at Iron River.

He also participated in investigations and preparation of reports; in the design of numerous water-works, water power, and sanitary works; in divers appraisals and valuations; and also in numerous investigations and reports on power projects and flood-protection works.

* Memoir prepared by Daniel W. Mead, M. Am. Soc. C. E.

Mr. Balch was a man of high ideals, of sterling character, of the highest integrity, and of marked ability. Throughout his career he adhered to the highest of moral and professional standards. A man of pleasing personality, he possessed a genial disposition, and a keen sense of humor, endearing himself to all who knew him.

Mr. Balch was married in Chicago, Ill., on June 15, 1918, to Margaret Elizabeth O'Reilly. Their children are Margaret O'Reilly, Dorothy Jane, James Leland, and Ruth O'Reilly.

He was a member of the American Society of Mechanical Engineers, and the Engineering Society of Wisconsin; an Associate Member of the Wisconsin Utilities Association, and a Member of the Madison Technical Club. He was also a Thirty-second Degree Mason and a member of the Blackhawk Country Club of Madison.

Mr. Balch was elected an Associate Member of the American Society of Civil Engineers on October 5, 1909, and a Member on August 12, 1920.

JOHN WESLEY BALL, M. Am. Soc. C. E.*

DIED JULY 22, 1928.

John Wesley Ball was born at Walton, Ind., on August 8, 1888. He was the elder son of Joseph Ball and Sarah Ann (Johnson) Ball. He was graduated from the Galveston, Ind., High School in 1908, and from 1908 to 1910 attended the Indiana State Normal School. In 1910, he entered the Civil Engineering Department of Purdue University at Lafayette, Ind., from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1914; he received the degree of Civil Engineer in 1917. During the summer vacations of 1911 and 1912 he worked for the R. C. Bowman Company, of Cleveland, Ohio, and, during the 1913 vacation, as Engineering Assistant for the Cleveland, Cincinnati, Chicago and St. Louis Railway.

After his graduation in June, 1914, Mr. Ball, having passed the required Civil Service examination, was appointed by the late Logan Waller Page, M. Am. Soc. C. E., as Civil Engineering Student of the (then) Office of Public Roads in the United States Department of Agriculture. He worked in the Washington Office until July and was then made Chief of Survey Party on highway location in Sequoia and Yosemite National Parks, reporting to T. Warren Allen, M. Am. Soc. C. E., now Chief of Management in the U. S. Bureau of Public Roads.

A year of this work was succeeded by a transfer, in July, 1915, to Skamania County, Washington, and a promotion to the position of Locating and Designing Engineer for the Bureau on road construction under a $210 000 bond issue in that County. Mr. Ball had sufficiently advanced this work by March, 1916, to permit his transfer to Jackson County, Oregon, to locate 70 miles of proposed highway between Medford, Ore., and Crater Lake National Park. This road survey was an outstanding job for excellence and low cost, and the present road follows closely the line run by Mr. Ball.

On the establishment in 1916 of a District Office at Portland, Ore., by the U. S. Bureau of Public Roads, Mr. Ball was attached to the Staff and during the season from March to November, 1917, he made investigations and reconnaissance surveys and prepared reports on National Forest Highway projects in Idaho, Washington, and Oregon.

On the entrance of the United States into the World War in April, 1917, Mr. Ball applied for admission to the Officers' Training Camp at American Lake, but was rejected on account of a defect in his heart action. In November of that year, however, he became Assistant Engineer for the U. S. Bureau of Public Roads on the paving work in that camp and remained there until February, 1918. During the spring and summer of 1918, he was at the Portland District Office. In October, he took charge of the construction of the Canyonville-Galesville National Forest Highway, in Oregon, which was completed in the fall of 1919. Mr. Ball then went to Lake Crescent,

* Memoir prepared by L. I. Hewes, T. Warren Allen, and J. S. Bright, Members, Am. Soc. C. E.

Washington, as Resident Engineer during the construction of the National Forest Highway there and remained until its completion in April, 1921. These two Forest Highways cost about $600 000 for 20 miles of grading.

When the U. S. Bureau of Public Roads established a Regional Office at San Francisco, Calif., Mr. Ball was selected to take administrative charge of National Forest highway construction in the eleven Western States and Alaska, reporting to L. I. Hewes, M. Am. Soc. C. E., Deputy Chief Engineer. This position he held with distinguished ability. In September, 1927, he was also placed in administrative charge of road construction by the Bureau in the National Parks in the Western States. He remained in charge of all this work in the National Forests and Parks until his death.

Mr. Ball was a man of unusual ability. In college, he was a member of both Phi Beta Kappa and Sigma Xi. His whole professional career was given to public service of a high order. He entered the U. S. Bureau of Public Roads in a minor position on graduation from college and through earnest and continuous application to his work rose step by step until he was filling the highest grade in the service. His technique was excellent and his love for perfect work outstanding. The development of modern standards of location and design in the National Forest and National Park roads owes much to the painstaking care of Mr. Ball in all details. His ability as an administrator constantly developed, and his work was characterized by a quality of humor and intelligence that drew people to him. He was a member of the Mystic Shrine and a Thirty-second Degree Mason.

In 1919, Mr. Ball was married to Ruth Stevenson, of Stevenson, Wash. He is survived by his widow and by a daughter, Elizabeth Ann, and a son, John Wesley Ball, Jr.

Mr. Ball was elected an Associate Member of the American Society of Civil Engineers on July 11, 1921, and a Member on March 15, 1926.

JOHN TONER BARR, M. Am. Soc. C. E.*

DIED JUNE 26, 1925.

John Toner Barr was born in Philadelphia, Pa., on November 25, 1876. He was the son of John C. Barr, of Blairsville, Pa., whose great-grandfather crossed the Allegheny Mountains from Baltimore, Md., long before the Revolution. His mother was Sarah Toner, of Gallipolis, Ohio. Her people came from York County, Pennsylvania, where they had settled during Colonial days.

Mr. Barr attended the public schools of Pittsburgh, Pa., until he was sixteen years of age, when he went to work as Draftsman in the City Engineer's Office. At the end of seven years, in 1898, he gave up this position and became a student in the Western University, now the University of Pittsburgh. He continued his studies at the University, working part of the time as Draftsman for the West Virginia Short Line Railroad Company, now part of the Baltimore and Ohio System, and also for the Allegheny Valley Railroad Company. He was unable, however, to finish his course at the University.

From 1899 to 1902 Mr. Barr worked, successively, as an Engineer for the Allegheny Valley Railroad Company, the Baltimore and Ohio Railroad Company, the Illinois Steel Company, and for the George S. Davison and the Mellon Interests. He designed the plant for the Pittsburgh Reduction Company at St. Louis, Mo., and was also Chief Engineer for the construction of the many miles of interurban electric railways running out of Pittsburgh.

Hard work and close application to the task in hand while fitting himself for his later undertakings began to undermine his health and he was advised to go West for recuperation. While in the West he worked in the office of the City Engineer of Salt Lake City, Utah; for a brief period as Engineer in Thunder Mountain, Idaho; later, at Pitkin, Colo., on mine surveys; and also as Machine Helper on the Oregon Short Line Railroad.

Mr. Barr returned to Pittsburgh in 1904 and became Chief Engineer for his brother, J. Carroll Barr, M. Am. Soc. C. E., and also for the Thomas McNally Company. He remained with them until 1907 when he launched out for himself under the firm name of J. Toner Barr, Civil Engineer, and from 1911 until the time of his death, practiced as J. Toner Barr, Engineer and Contractor. During this time Mr. Barr laid practically all the underground cables for the Bell Telephone Company in the Pittsburgh District.

On the evening of January 6, 1922, while at work in his office, a pistol which he had carried with him for many years for payroll protection accidentally slipped off his desk and was discharged. The bullet struck his right leg, glancing upward, necessitating, five days later, amputation in order to save his life. Mr. Barr met the situation bravely, declaring that he never had made any money with his legs anyway and proceeded to do more business following his accident than he had ever done before. He carried on until June 26, 1925, when he died after an operation for gallstones.

* Memoir prepared by Stewart C. McFarland, Esq., Pittsburgh, Pa.

In 1905, he was married to Anne M. Hogan, of Pittsburgh, who, with four children, Sarah, Rosemary, Jone, and Nellie, survives him. His brother, Mr. J. Carroll Barr, also survives him.

Mr. Barr was a popular member of the Rotary Club of Pittsburgh, holding the office of First Vice-President at the time of his death. The following memorial, delivered before the Club by Past-President and Past District Governor Stewart C. McFarland, who knew him intimately, gives a true picture of Mr. Barr and the esteem in which he was held by his fellows:

"Our friend, our First Vice-President—your friend and my friend—J. Toner Barr, has taken his place in the silent halls of cherished memories.

"Toner's going brings us once again face to face with the Great Inevitable—the final and conclusive fact that no matter how brilliantly a race the white steed of life may run, the black and inexorable steed of death is sure to win.

"When we laid Toner's tired frame in his narrow cell in Calvary last Monday morning we gave back to earth her own. His unconquerable soul and indomitable spirit, his clean life and splendid character, his sense of justice and his loyal devotion to truth, honor, and right are ours forever. This he has bequeathed to us and a richer heritage no man can bequeath to his fellows.

"Toner had a wonderfully discriminating mind and was frankness personified. He never ran away from any situation. He could detect insincerity afar off. He had a keen sense of values. He was seldom if ever misled by the false. He had the hard head of the engineer and the soft heart of the poet. At one time he remarked, 'Take sentiment out of life and all you have left is arithmetic.'

"Toner's home life was a symphony of sentiment. No man ever loved more tenderly his wife and children and no man ever lived in a richer atmosphere of love returned. The happiness of his home life was so complete that at one time he made the statement that he could be happy in Hades.

"J. Toner Barr's seat here to the right of President Jax is now vacant, but in the words of Riley:

> "'We cannot say, and we will not say,
> That he is dead—he is just away;
> With a cheery smile and a wave of the hand,
> He has wandered into an unknown land.'

"To consecrate his memory and to render him a final Rotary service, I propose that we stand for a moment and in that moment pray for the well-being of his soul, and that in our prayer we include his bereaved and broken-hearted widow and children."

At the time of his demise Mr. Barr was an active member of the Chamber of Commerce, the Americus Club (since disbanded), the Engineers Society of Western Pennsylvania, the Historical Society of Western Pennsylvania, and the Duquesne Club of Pittsburgh.

Mr. Barr was elected a Member of the American Society of Civil Engineers on March 4, 1913. He was also a Past-President of the Pittsburgh Section.

GEORGE STRONG BAXTER, M. Am. Soc. C. E.*

DIED JULY 2, 1928.

George Strong Baxter was born in New York, N. Y., on November 21, 1845, the son of George and Anna (Strong) Baxter. His childhood and school days were spent mainly in New York, after which he went to Williams College at Williamstown, Mass., from which he was graduated in 1865. Three years later, he was graduated from the Columbia University School of Engineering.

From 1868 to 1872, Mr. Baxter was employed in land surveying in various parts of the United States. In New York City, he constructed the foundations for the Second and Third Avenue Elevated Lines. He was engaged on the Fourth Avenue Improvement in 1872, became Assistant Engineer, and built the New York Central Viaduct on Park Avenue, north of 96th Street.

In 1879, he became Cashier for the Northern Pacific Railroad Company, and, in 1885, was appointed Assistant Treasurer and sent to St. Paul, Minn. In 1888, he rose to the office of Treasurer and returned to New York. Later, when the Company went into the hands of Receivers, he remained as Treasurer until it was discharged from the Receivership.

In 1895, Mr. Baxter founded the cross-tie business of G. S. Baxter and Company, of New York and Jacksonville, Fla. At first, the firm bought railroad ties in the South and shipped them to New York, but, later, the Company expanded and bought lands in Georgia where it cut its own ties; one sawmill was constructed in Fargo, Ga. In 1900, the Company handled more Southern Pine cross-ties than all other dealers combined.

Owing to some trouble with the Atlantic Coast Line Railroad Company, over shipping ties to tide-water, the Company built a short line east to connect with the Southern Railroad. Mr. Baxter then conceived the idea of a railroad line east to Jacksonville, and west to Valdosta, Ga. The Valdosta terminus made a connection with the Middle West cities and a short route from those cities to the Florida East Coast. The Atlantic, Valdosta and Western Railroad Company was then incorporated with Mr. Baxter as Chairman of the Executive Committee. The various railroad companies fought hard to prevent the admission of the Atlantic, Valdosta and Western Lines to the Union Station in Jacksonville, but they were finally defeated and the railroad was admitted to the Union Terminal rights. Later, the Atlantic, Valdosta and Western Railroad Company considered building west from Valdosta to Birmingham, Ala., and to prevent this, the Southern Railroad Company finally bought the line.

Mr. Baxter was greatly interested in the creosoting of cross-ties, and at one time considered establishing a plant for that purpose. He was also interested in the possibility of bringing tropical hard wood cross-ties into the United States. As the World War cut into the railroad tie business, G. S. Baxter and Company established a shipyard in Jacksonville, on which

* Memoir prepared by Mrs. E. Vogelsang, New York, N. Y.

Mr. Baxter was engaged until 1918 when the partnership was dissolved, and he retired.

In 1874, he was married to Emmeline Carnes Weeks, of New York, the daughter of Emmeline Carnes and Edward Augustus Weeks. She died in 1921. They had five children, of whom three survive: Wyllys Pomeroy Baxter of New York City, George Strong Baxter, Jr., of Westerly, R. I., and Mrs. Erwin Vogelsang, of New York City.

Mr. Baxter was a member of the University and the Mid-Day Clubs. After his return from St. Paul, he resided in New York, and had a summer home at Bellport, L. I. A man of simple tastes and strong affections, he was a most devoted husband and father. His was an unusual intellect and, to the time of his death, he retained his grasp of affairs and interest in life.

Mr. Baxter was elected a Junior of the American Society of Civil Engineers on May 12, 1875, and a Member on May 3, 1876.

WILLARD BEAHAN, M. Am. Soc. C. E.*

DIED FEBRUARY 5, 1928.

Willard Beahan was born in Watkins, N. Y., on January 15, 1854, the son of James and Harriet (Griswold) Beahan. His grandfather was from the north of Ireland and of Scotch-Irish ancestry; his mother was of English descent.

Mr. Beahan prepared for college at Starkey Seminary, Starkey, N. Y., and was graduated in 1873. He entered Cornell University, Ithaca, N. Y., in 1874, from which he was graduated in 1878 with the degree of Bachelor in Civil Engineering. He took a prominent part in class and college activities, playing on his class football team and in his Senior year being elected Class Historian and Chief Engineer. After graduation he was elected to Sigma XI and Tau Beta Pi, honorary fraternities. He also became Life Secretary of his Class, and at the time of his death was preparing for the 50-year re-union.

After his graduation from Cornell University in 1878 he entered the service of the United States Corps of Engineers as Assistant Instrumentman and, later, as Computer on the Mississippi River Survey. In 1880, he was employed by the Gould Lines in the Southwest as a Rodman on the Texas and Pacific Railway. He was advanced to the position of Division Engineer in 1881 and then became Division Engineer on the Fort Worth and Denver City Railway where he was in charge of location and construction.

After an interval of one year, from March, 1883, to March, 1884, during which time he was employed as a Transitman on the Lehigh Valley Railroad, Mr. Beahan returned to the Southwest as Division Engineer on the Missouri Pacific Railway, where he remained until February, 1889, engaged in location, construction, and maintenance. He then went to South America with the North and South American Construction Company as Superintendent of Construction and Bridge Engineer of the Chilean Railway. Before the end of the year a revolution interfered with the progress of this work and Mr. Beahan crossed the Andes on a mule, made his way to Buenos Aires, Argentina, and returned to the United States *viâ* Europe.

During 1891, he was Superintendent of Streets of St. Louis, Mo. In after years, Mr. Beahan was accustomed to refer to this engagement as the time when he was political "boss" of St. Louis.

From November, 1891, to December, 1896, he was with the Anderson and Barr Company in various capacities. As President of the Anderson and Barr Clay Company, he developed a large and important business in the manufacture of clay products, in Streator, Ill. In 1896 and 1897 he was Lecturer on Railroad Location at Cornell and Leland Stanford, Jr., Universities.

From August, 1897, to May, 1898, Mr. Beahan was Superintendent of Construction on the Cascade Tunnel on the Great Northern Railway. From September, 1898, to September, 1900, he was again with the Lehigh Valley Railroad Company as Engineer of Maintenance, following which, he served

* Memoir prepared by George H. Tinker, M. Am. Soc. C. E.

as Division Engineer on the Chicago and Northwestern Railway until March, 1905.

From 1905 to 1924, Mr. Beahan was First Assistant Engineer on the staff of the Chief Engineer of the New York Central Railroad Company at Cleveland, Ohio. This long engagement ended with his retirement under the age and pension rules. Immediately thereafter, he entered the service of the "Nickel Plate Road" (New York, Chicago, and St. Louis Railroad Company) as Special Engineer in charge of relocation surveys. After apparently recovering from the effects of a serious operation, he continued to do consulting work for the Erie Railroad Company, but in the latter part of 1927 his health began to fail. He died on February 5, 1928.

In 1892, he was married to Bessie B. DeWitt, who survives him. He is also survived by two brothers.

Mr. Beahan's interest in Cornell University continued throughout his life. He was a member of the Cornell Society of Civil Engineers of New York and was one of the leaders in organizing the Northeastern Ohio Cornell Association. He was elected Alumni Trustee of Cornell University in 1900, and, again, in 1909.

In addition to Cornell and Leland Stanford, Jr., Universities, he lectured before many educational and technical societies. His interest in education and the guidance of young engineers never lessened. He was a member of the Board of Managers of the Cleveland Young Men's Christian Association and, for years, served as Chairman of the Committee on Technical Education of the Cleveland Engineering Society. His many talks to young engineers and students on the subject of Human Engineering were illustrated copiously by incidents from his own long and notable career.

During his long residence in Cleveland, Mr. Beahan became identified with the civic and professional life of the community. He was a member of the Congregational Church and was especially a leader and adviser of young men. He was a member of the Cleveland Engineering Society (President, 1908), Board of Civic League of Cleveland, Cleveland Chamber of Commerce, a Director of the Bureau of Municipal Research, and a member of the American Railway Engineering Association. He was also the first President of the Cleveland Section of the Society.

He was the author of "The Field Practice of Railway Location", and was also a contributor to the publications of the Society.

Mr. Beahan was elected a Member of the American Society of Civil Engineers on April 3, 1889, and served as a Director from 1919 to 1921.

HEZEKIAH BISSELL, M. Am. Soc. C. E.*

DIED JUNE 23, 1928.

Hezekiah Bissell was born at East Windsor (Scantic), Conn., on February 7, 1835, the son of John Bissell and Elizabeth (Thompson) Bissell. He was a direct descendant of John Bissell who settled in Windsor, Conn., in 1639, and a year later removed to the east side of the Connecticut River.

Mr. Bissell attended the schools of East Windsor and Williston Academy at Easthampton, Mass., where he prepared for college. He entered Sheffield School at Yale University in 1857, but three months before his graduation in 1861 he left school and enlisted at Hartford, Conn., in Company A of the First Regiment, Connecticut Volunteers. He was one of the first to answer the call for the three months' volunteer service, enlisting on April 18, 1861, serving his term of ninety days, and being mustered out on July 31, 1861. On August 23, 1862, he re-enlisted in Company G, 25th Connecticut Volunteers, and was chosen First Lieutenant of that Company, which was largely made up of volunteers from his home town of East Windsor and the neighboring towns of South Windsor and Glastonbury, Conn.

This regiment served with General Banks in the Louisiana Campaign, and was engaged in the siege of Port Hudson and the Battle of Bayou Teche. Mr. Bissell's second service being a nine months' enlistment, he served his full time, and was mustered out on August 26, 1863, so that his complete service was for nearly sixteen months.

With the other students of Yale who left college to enter the Army in 1861, he was given the degree of Bachelor of Philosophy in 1881.

As an example of Mr. Bissell's oneness of purpose the following is taken from his personal memoirs: "When a pupil in Williston he was asked by Mr. J. M. Stoughton, an old friend of his father, what he intended to do, and his reply was, 'I am going to help build the Pacific Railroad; then go to South America to build more railroads; then for my real life work be Engineer of some first-class railroad in the United States; later, I will invent something to give me all the money I want to enjoy life'." And in his personal memoirs written after his retirement from all business, Mr. Bissell adds this statement, "I have done all but the last of these."

Soon after his discharge from the Army Mr. Bissell went to New York, N. Y., and at the office of the Union Pacific Railroad Company in that city, met the late Thomas C. Durant, F. Am. Soc. C. E., President, and Peter A. Dey, Chief Engineer, of the proposed railroad. As a result of this interview he was appointed Second Assistant Engineer by Gen. John A. Dix and, on April 1, 1864, reported at that Company's office at Omaha, Nebr. From this date until its completion on May 10, 1869, he was engaged on some part of the great undertaking.

His positions on this work were that of Second Assistant Engineer, First Assistant Engineer, Division Engineer, and Resident Engineer, but in the

* Memoir prepared by Lester W. Tucker, M. Am. Soc. C. E., and Walter H. Norris, Assoc. M. Am. Soc. C. E.

latter part of his service much of his time was spent in special assignments on various important undertakings. As Locating Engineer, Mr. Bissell located and built much of the original line from Laramie, Wyo., to west of Green River, and he was one of the party who ran the preliminary trial lines from the south end of Great Salt Lake westerly into what was then called the Great American Desert, and, with this party, endured great hardship. He was the only Engineer who stayed with the undertaking from the beginning of the work to its completion, a period of more than five and one-half years. In his own words, he had "staked out the first culvert at Omaha and was present when the gold spike was driven at Promontory Point."

In 1901, Mr. Bissell, while on a trip to the West, stopped in Omaha and met Mr. Burt, then President of the Union Pacific Railroad Company. Mr. Burt invited him to ride over the road with which he had been so intimately connected thirty-five years before, furnishing him a car and the Division Engineer as escort, and arranging for the entire trip to be made by daylight.

Again, in 1919, on the occasion of the Fiftieth Anniversary of the driving of the gold spike, Mr. Kennedy and Mr. Bissell were guests of the Railroad Company, and were the only representatives of the original engineering officials.

Mr. Bissell's work on the Union Pacific Railroad closed in June, 1869, and he returned East, but had been there only a short time when he was asked by Dr. Durant, the former President of the Union Pacific Lines, to undertake the location of the Adirondack Railroad then proposed to be run from Ogdensburg, *via* Canton, to Saratoga, N. Y. Surveys on this line were started late in August, 1869, and from that time until the fall of 1870 the work of surveying and grading was carried forward; but during 1871, money being scarce, little was done, and the work on this line was closed.

Early in February, 1872, he received an offer to go to South America on the roads then being built and projected by Mr. Henry Meiggs for the Peruvian Government. He sailed from New York on May 15, 1872, and after a very stormy passage to Colon (then called Aspinwall), and a slow trip down the West Coast, he finally landed at Mollendo, the Port of Arequipa, Peru.

His work was that of locating and building the railroad from Juliaca, northerly up the Pucara River for a distance of about 100 miles, this being on what was projected as the main line from Puno, a port on Lake Titicaca, to Cuzco, the ancient Inca Capital of Peru. This section, being northerly of Lake Titicaca, was located on the backbone of the Andes Mountains, and was from 12 000 to 14 000 ft. in elevation for its entire length.

The 100 miles were located and graded complete and ready for track and Mr. Bissell was ordered to establish his camps and get ready for the location and grading of the remainder of the line into Cuzco when he received sudden orders to stop all work and leave the country at once. A revolution of great intensity was under way in the northern districts of Peru, and all Americans had to flee.

Mr. Bissell was engaged for two years on this work, the entire period having been spent at these high altitudes with few, if any, white men, and at a time

when it was necessary to live as the natives lived; he always thought that his thin hair and beard were one of the results of his mode of living during these two years.

Returning to his home from this work early in 1875, he received an offer to go with the Cleveland, Cincinnati, Chicago and St. Louis Railway Company and for the next three years was with that road in various engineering capacities, revising locations, examining bridges, and constructing cut-offs from Cincinnati, Ohio, to the north and west.

On February 1, 1878, Mr. Bissell was appointed Master of Maintenance of Way of the Eastern Railroad Company extending from Boston, Mass., to Portland, Me., with headquarters at Salem, Mass. The Eastern then had 270 miles of road. In 1884, it was taken over by the Boston and Maine Railroad Company and Mr. Bissell was made Chief Engineer of the Boston and Maine Lines, with headquarters at Boston. In 1886, the Boston and Lowell Lines were taken over by the Boston and Maine, and, in 1900, the Fitchburg Lines came under the same management, so that Mr. Bissell became the Chief Engineer of one of the largest railroads in the East with a mileage of 2 300.

While acting as Chief Engineer of the Boston and Maine System, Mr. Bissell had charge of the rebuilding of much of the roadbed, many of the bridges, and the greater number of the railroad stations on that line. He relocated many miles of the first road, double-tracked much of the original Eastern and Boston and Maine Lines, and reduced grades and curves, eliminated grade crossings, and built many new yards, terminals, wharves, and docks.

On June 30, 1909, Mr. Bissell resigned his position as Chief Engineer after having served thirty-one years and, in his announcement, President Tuttle retired him with the title of Consulting Engineer and paid him an exceptional compliment of appreciation for his long and faithful service. The following year he went to California where he made his home in Altadena.

Mr. Bissell was a man of rare intelligence, great integrity, and oneness of purpose. He held the respect and loyalty of all those with whom he came in contact whether they were the men of his own organization or those of the contractors and builders with whom he was so closely associated. His directness of purpose, absolute honesty, and ability to see the other fellow's point of view made engineers and contractors alike respect him and his decisions. He was especially kind and helpful to the young engineers of his organization.

Mr. Bissell was twice married; his first wife was Alice Hughes, of St. Thomas, Ont., Canada, to whom he was married in 1875 and by whom he had three sons, all living. His second wife, Segrid Johansen, to whom he was married in 1910, died several years later.

Mr. Bissell was a member of the Yale Engineering Association, Boston Society of Civil Engineers, Southern California Association of Engineers, Engineers' and Architects' Association, and the Yale Alumni Association. During his long residence in Boston he was a member of many of the leading social and literary clubs of that city, but withdrew from most of these when

he went to California. In his early manhood he was a member of the Congregational Church, but after his marriage he united with the Protestant Episcopal Church.

Mr. Bissell was elected a Member of the American Society of Civil Engineers on September 15, 1869, and at the time of his death was the third oldest member of the Society, being exceeded only by the late Cady Staley, M. Am. Soc. C. E., who was elected on March 17, 1869, and by Clemens Herschel, Past-President and Hon. M. Am. Soc. C. E., who was elected on September 21, 1869. Mr. Bissell served as a Director of the Society from 1905 to 1907.

WILLIAM HERBERT BIXBY, M. Am. Soc. C. E.*

DIED SEPTEMBER 29, 1928.

William Herbert Bixby, the son of Clark Smith and Elizabeth (Clark) Bixby, was born in Charlestown, Mass., on December 27, 1849. He was descended from Colonial stock, his forebears having served in the Colonial and Revolutionary Wars. He attended the public schools of Brookline and Cambridge, Mass., and then entered the Massachusetts Institute of Technology. After one year at the latter institution he was admitted in 1869 to the United States Military Academy at West Point, N. Y., from which he was graduated in 1873, at the head of his class, and commissioned a Second Lieutenant in the Corps of Engineers, U. S. Army.

Lieutenant Bixby's first assignment was at the Engineer School of Application, Willets Point (now Fort Totten), N. Y., from 1873 to 1875. In 1875 he was assigned to duty at the United States Military Academy where he served as Instructor and Assistant Professor of Civil and Military Engineering until 1879. In 1879 he was sent on duty to Europe where he remained until 1882, attending the Ecole Nationale des Ponts et Chaussées of France, from which he was graduated with honor in 1881. During his tour of duty abroad, he also made numerous investigations of European practice in civil and military engineering. He received the decoration of Chevalier of the Legion of Honor of France for assisting at the maneuvers of the French Army in 1880.

Returning to the United States, he was placed on duty with the Engineer Battalion at Willets Point, where he remained until 1884. By this time he had reached the grade of Captain in the Corps of Engineers, and, from 1884 to 1910, he served as Captain, Major, Lieutenant-Colonel, and Colonel, on river and harbor or lighthouse duty at Wilmington, N. C., Newport, R. I., and Philadelphia, Pa.; at Cincinnati, Ohio, in charge of the Ohio River System; on the Great Lakes at Detroit, Mich., and Chicago, Ill.; and at St. Louis, Mo., as President of the Mississippi River Commission. In 1910, he was appointed Brigadier-General, Chief of Engineers, and served in this capacity until his retirement from active service in 1913.

On the entrance of the United States into the World War in 1917, General Bixby was recalled to active duty, and served until 1919 supervising the work of river and harbor improvement on the Mississippi River and its tributaries, in order to release officers on the active list for war service.

The foregoing outline of General Bixby's service gives only a general indication of the character and variety of his duties during his long and active life. In addition, he was a member of many Official Boards, which greatly extended the scope of his activities; and it is no exaggeration to state that there are few of the manifold activities of the Corps of Engineers to which he did not contribute during his active service of more than forty years. Possessed of a brilliant mind, a tireless energy, and a seemingly unlimited

* Memoir prepared by Herbert Deakyne, M. Am. Soc. C. E.

capacity for study and research, he acquired an almost inexhaustible fund of knowledge of civil engineering works, on which he drew in the consideration of the multifarious problems that presented themselves during his career.

One important board of which General Bixby was a member was appointed by the Chief of Engineers in January, 1894, pursuant to instructions of the Secretary of War, the late Hon. Daniel S. Lamont, to determine the maximum practicable span for suspension bridges. The other members were the late Gen. (then Major) Charles W. Raymond, U. S. Army, M. Am. Soc. C. E., and Col. (then First Lieutenant, Corps of Engineers) Edward Burr, U. S. Army, (*Retired*), M. Am. Soc. C. E. The appointment of the Board was due to strenuous efforts made by interested parties to secure the passage by Congress of a bill authorizing the construction of a bridge across the Hudson River at New York, N. Y., and specifically authorizing a pier about mid-channel. The proponents of the bridge maintained that it was a crying necessity and could not be built as a single span or without a channel pier. The Chief of Engineers strongly opposed the deliberate placing of any such obstruction as a bridge pier in mid-channel. Mr. Lamont directed the Chief of Engineers to convene a Board of Officers to investigate and report its conclusions as to the maximum length of span practicable for suspension bridges and consistent with an amount of traffic probably sufficient to warrant the expense of construction.

The members of the Board, as is customary in such cases, were given this work in addition to their regular duties. General (then Captain) Bixby, at this time, was on duty in charge of the U. S. Engineer Office at Newport, R. I. The Board, after a study of the task before it, assigned to each member particular lines of investigation, in addition to a general study of the problem as a whole. Among other things, the subject of wind pressures was assigned to Captain Bixby. The result of his investigations is printed as an Appendix to the Board's report and is characteristic of his efficiency, thoroughness, and almost infinite capacity for detail. Captain Bixby's compilation and discussion was unique in its field and filled a need long felt by engineers of that day, particularly in bridge design. The report of the Board was printed not only as an official document but also in the engineering press. *Engineering News*, in addition to printing the report, stated in an editorial* that it "forms one of the most valuable and instructive engineering investigations of the day".

The report set the accepted possibilities as to length of bridge spans far in advance of the practice then current, and preserved the Hudson River and doubtless many other important waterways from serious obstruction by bridge piers. The conclusions of the Board have been justified by the construction of the Fort Washington Bridge across the Hudson with a span of 3 500 ft., which is still well within the maximum given by the Board of about 4 300 ft.

In 1909, General (then Colonel) Bixby was selected as Advisory Engineer to the National Waterways Commission, a body created by the Act of Con-

* *Engineering News*, November 22, 1894.

gress of March 2, 1909, which Commission he accompanied to Europe. His detailed knowledge of works for the improvement of navigation both in Europe and the United States made him of great value to the Commission.

The wreck of the battleship *Maine* was removed from Havana Harbor while General Bixby was Chief of Engineers. He was deeply interested in this work, and gave it a great deal of personal attention, until the success of the undertaking was assured.

General Bixby was as active physically as mentally. As a young man he was an expert skater and, when on duty in France, took occasion during one winter to visit Holland in the hope of acquiring some of the refinements in the art. It developed, however, that his ability as a skater was already so great that he became a teacher rather than a student of the Hollanders. He found time while abroad for mountain climbing and ascended the Matterhorn with two guides. On another occasion he left Zermatt, Switzerland, about noon with one guide and ascended the Breithorn. Returning to the village about noon the next day he met a party starting out to make the ascent. They urged him so strongly to accompany them that he consented and re-ascended this mountain, getting back to the village about 4:00 P. M. of the following day, after more than 48 hours of continuous mountain climbing.

General Bixby was always intensely interested in new devices. As an Instructor at the United States Military Academy, during the period from 1875 to 1879, he foresaw the possibilities of the typewriter, then a crude machine compared to present-day models, and endeavored to secure its introduction to take the place of the laborious and time-consuming pen and ink method by which Army correspondence was then conducted.

He also took a great interest in the improvement and simplification of administrative procedure and was largely responsible for a number of methods now in use by the Corps of Engineers. One of these was the standard specifications for dredging, which he initiated and which are now in use throughout the Engineer Department for all dredging contracts. His interest extended to almost every field of scientific endeavor. The number of scientific publications to which he subscribed was so great that it was his custom to rent a private office to which all such periodicals were sent and where his professional library was kept in order to avoid overtaxing the facilities of the office assigned him for the transaction of public business.

General Bixby was a man of simple tastes; there was nothing of the martinet about him. He loved the discussion of matters of professional interest, and his tremendous fund of knowledge on military and civil engineering, and other scientific subjects, was a source of astonishment to those to whom it was displayed. He was one of the most generous and kind-hearted of men, always thoughtful of the feelings and comfort of others, and most considerate in his dealings with them. His character was unimpeachable, and he leaves a record of service to his country unsullied by the slightest spot of selfish interest.

He belongs to that remarkable group of engineers, now nearly all gone, whose active lives spanned the period between the close of the Civil War and

the outbreak of the World War; an era in which the advance in scientific knowledge and engineering achievement was so great, that some future historian of scientific progress may well describe it as the "Golden Age" of Science.

General Bixby's intense interest in science and engineering continued undiminished throughout his active life and to the end. In spite of advancing years, he was vigorous both in mind and body until stricken with his last illness when death stopped forever the strivings of his restless intelligence. He died in Washington, D. C., and after a simple service at his home, his ashes were placed in the Arlington National Cemetery.

He was married on December 27, 1893, to Mrs. H. M. Jones, of Philadelphia, the widow of Lieut. H. M. Jones, 4th U. S. Artillery. Mrs. Bixby survives him.

General Bixby was a member of the French Society of Civil Engineers, the British Institution of Civil Engineers, the American Society of Mechanical Engineers, the Institute of Construction Engineers, the Academy of Political and Social Science, and other societies of Political Economy, the American Association of Port Authorities, and the International Association of Navigation Congresses. He was President of the International Congress of Navigation, held at Philadelphia in 1912; Chairman of the Engineering Section of the Pan-American Scientific Congress at Washington, D. C., in 1915; President of the American Society for Testing Materials in 1917-18; and President, in 1918-19, of the American Society of Terminal Engineers.

He also held memberships in the Society of American Military Engineers, the U. S. Military Service Institution, the U. S. Infantry Association, the U. S. Cavalry Association, the U. S. Naval Institute, the American and British Associations for the Advancement of Science, the Mathematical Society of America, and the American Academy of Arts and Sciences.

General Bixby was elected a Member of the American Society of Civil Engineers on April 5, 1882.

WILLIAM TITCOMB BLUNT, M. Am. Soc. C. E.*

DIED MARCH 3, 1928.

William Titcomb Blunt, the only son of Aaron Drew and Helen Maria (Titcomb) Blunt, was born at Norridgewock, Me., on January 10, 1855. He received his early education in the Grammar School and Eaton Family School of his native town, entering the Massachusetts Institute of Technology in 1870, from which he was graduated in 1874 with the degree of Bachelor of Science in Civil Engineering.

During the summer vacations of 1872 and 1873, Mr. Blunt was employed by the City Engineer of Somerville, Mass., and by others, on topographic and hydrographic surveys. Following his graduation in 1874, he secured a position with the U. S. Coast and Geodetic Survey as Observer with a party making a survey of the mouths of the Mississippi River.

From 1875 to 1879, Mr. Blunt served as Clerk and Assistant Engineer with the Harbor Commission of Massachusetts on triangulation, topography, hydrography, and mapping. From 1879 to 1883, he was engaged, for the Mississippi River Commission, on triangulation, topography, and hydrography along the lower sections of the Mississippi River. In 1883 he became associated with Mr. John Eisenmann under the firm name of Eisenmann and Blunt, at Cleveland, Ohio, in the practice of architecture and engineering.

From 1886 to 1890, Mr. Blunt was employed under the U. S. Engineer Office at Cleveland, as Inspector on the maintenance and improvement of the harbors along the south shore of Lake Erie. During the last six months of 1890 he was Principal Assistant Engineer in Charge of Surveys for the Sanitary District of Chicago, Ill., but resigned with the Chief Engineer, the late Lyman E. Cooley, M. Am. Soc. C. E., on account of their objections to the way the work was being conducted by the Board of Trustees.

For a time Mr. Blunt was busy in the insurance business, but the work was not congenial to him, and he soon returned to engineering. From 1892 to 1906, he was continuously employed as U. S. Assistant Engineer in the maintenance and improvement of harbors and the location and construction of lighthouses along the south shore of Lake Erie. This work was under the U. S. Engineer Office at Cleveland, but in immediate charge of the Sub-Office at Toledo, Ohio, where Mr. Blunt resided during this period.

From 1906 to 1907, he served as Superintendent of construction with George H. Breymann and Brothers, Contractors, of Boston, Mass., on river and harbor work, especially on subaqueous rock excavation, and, from 1908 to 1910, he was engaged on similar work for the U. S. Government at the Pacific entrance of the Panama Canal. In connection with this work he designed a rock crusher that was said to be superior to the Lobnitz crusher, which was also in use.

During the following two years Mr. Blunt remained on his farm in Ohio, but in November, 1912, he became General Manager for the Shirley-Skeldon Dredging and Submarine Contracting Company, of Toledo, with which he remained until May, 1914.

* Memoir prepared by the following Committee of the Illinois Section: John W. Woermann, Clifford C. Muhs, and Edward J. Fucik, Members, Am. Soc. C. E.

From June, 1914, until his retirement from the Federal Civil Service, in January, 1925, on account of having reached the age limit prescribed by law, he was employed as Assistant Engineer, under the U. S. Engineer Office at Chicago on the maintenance and improvement of the harbors at the south end of Lake Michigan. This work included dredging operations in eight rivers and harbors, rubble mound and concrete caisson breakwaters at Chicago Harbor and Indiana Harbor, Ind., and the construction of a concrete superstructure on the old timber breakwater at Calumet Harbor, Ill. For a short period during the World War he was Acting District Engineer in charge of the office.

After his retirement from Government Service, Mr. Blunt was engaged by the Universal Portland Cement Company as Consulting Engineer on the construction of a new harbor at Buffington, Ind., including 1 300 ft. of rubble-mound breakwater. Following this, he was retained by the D. P. Davis Company, Realtors, as Staff Engineer in charge of extensive dredging operations at St. Augustine, Fla., on the development of a new seaside sub-division.

After the collapse of the Florida land boom in 1927 he returned to Chicago, and became affiliated with the Division of Waterways of the State of Illinois. During the summer and fall he was in charge of the repair of levees along the Mississippi River between St. Louis, Mo., and Cairo, Ill., and during the winter he was engaged in miscellaneous office work in Chicago.

Mr. Blunt was extremely thorough and careful in his work, and remained active and energetic until eight days before his death, which was due to pneumonia following a cold. He made loyal friends wherever he was located, and enjoyed nothing more than an evening at cards or story-telling. He has been characterized by one of his friends as "a rare raconteur tempered by the fire of a crusader; a *bon vivant* tempered by a fine æstheticism; a true friend, and a fair opponent."

He was twice married, first, in 1874, to Frances Sydney Gibbs, of Toledo, Ohio, who died in 1907, and then, in 1909, to Helen Elizabeth Norton, who survives him.

Mr. Blunt was a Royal Arch Mason and a Charter Member of the Royal Arcanum of Cleveland. He was a member of the American Association of Engineers and also of the Western Society of Engineers. At the monthly luncheons of the M. I. T. Club of Chicago, he was usually the oldest graduate present.

Mr. Blunt was elected a Member of the American Society of Civil Engineers on October 5, 1898.

GEORGE HERBERT BOYNTON, M. Am. Soc. C. E.*

DIED APRIL 20, 1928.

George Herbert Boynton was born at Meredith Village, N. H., on September 3, 1852, the son of Emory Warren Boynton and Mary (Cram) Boynton. His early boyhood was spent in the neighborhood of Watertown, Mass. He began his education at the age of three, in Lawrence, Mass., while accompanying his brother to the little "old red brick school house", which was still standing a few years ago. He, thus early in life, showed himself very persistent in any thing he undertook, consequently, his father found it necessary, at times, to carry him to school through stormy weather.

When Mr. Boynton was six or seven years old, he began his business life by delivering papers. About this time his mother died. After a few years his father was married to Eliza Hilton, who was an exceptionally fine woman, and no boy ever could have been a more devoted son than Mr. Boynton was to her until she died in her seventies.

In 1866 the family moved to Rock Island, Ill., where he attended the public schools. Soon thereafter he went to work on the Government Island where he served as Time-Keeper for a short period. In order to be early, so that he might set an example for the many men employed there by "Uncle Sam", he was obliged to get up before daylight, as he had to cross the Mississippi River and walk several miles to the head of the Island. At one time, owing to great damage by storms to the wagon bridge, he found it necessary to walk the railroad bridge. When one stops to consider the darkness, the snow, and the ice, one may realize, somewhat, the energy and ambition of a "young man" not yet seventeen. He was never late and never complained. His method of "carrying on" then, was typical of his whole after life.

Mr. Boynton next engaged in office work at the Rock Island Arsenal, and was shortly appointed Assistant to the Chief Draftsman, Mr. Otto Gronen. While thus occupied, Lieutenant Shaler became so much interested in him, that he gave him a liberal course in mathematics. It was largely due to the interest shown by his two superiors, that Mr. Boynton decided to make an effort to continue his education along engineering lines. With the encouragement and help from his family and a good friend or two, whom he later repaid, he succeeded in going to Germany in 1872, where he entered the Polytechnic School in Chemnitz, Saxony. He at once took up the strenuous task of beginning the study of German and his engineering course in that language, at the same time. He came out with flying colors in both studies and was graduated in 1875. Later in life he found much pleasure in German literature.

When he first entered the Polytechnic School he met a Norwegian of about his own age. They were attracted to each other in the unfamiliar land in which they met. At any rate, a friendship was formed which was still loyal and touching at the time of Mr. Boynton's death. "George" spent his vacations in Norway at the home of "Jens" Skougaard, and "Jens" afterward visited his friend's home in the United States many times.

* Memoir prepared by H. W. Zeug, Secretary, Northern Gravel Co., Muscatine, Iowa.

After three years of study, Mr. Boynton returned to Rock Island, ready and eager to go to work. For a time he carried on a private practice. In 1877, he was made City Engineer. This work, apparently governed largely by politics, was not entirely to his liking, and at the expiration of his term of office, in 1878, he went to the Chicago, Rock Island, and Pacific Railway Company, expecting temporary employment only, but evidently he was successful, as more and more important duties were given him, and he remained with that Company for twenty-nine years. During the first summer, he was appointed Assistant Engineer on a survey of the Mississippi River between Keokuk, Iowa, and Grafton, Ill. In the fall of 1879, he was appointed Assistant Engineer with headquarters in Davenport, Iowa. He was there for twenty years, being then transferred to the Chicago Office, where he remained until his resignation in 1907.

In 1908 he returned to Davenport and entered the general contracting business, being engaged in the construction of bridges and railroads, until 1914, when he organized the Northern Gravel Company, of Muscatine, Iowa, where he went to live a few years later. He was elected President of the Company, and held that office until he died on April 20, 1928.

Before the World War was declared, Mr. Boynton was made a member of the Naval Construction Board of the United States, organized for industrial preparedness, Mr. Thomas A. Edison being Chairman. Mr. Boynton gave his services to his country as one of the State Directors, as long as the Board continued to function.

In 1884, he had a prolonged and serious attack of typhoid fever. The first thing to make an impression on him when he came back to his normal conscious life was a notification that he had been elected to membership in the Society. It was dated September 3, 1884, which happened to be his thirty-second birthday. On November 30, 1918, thirty-four years later, he received another official notice from the Society stating that, "A Corporate member who has paid dues twenty-five years, and is seventy years old, is exempt from further payment of dues", and it further stated that he had been made a "Life Member of the Society". While for various good reasons he never took an active part in the Society's work, he was much interested in its activities and kept in touch with them, at the same time enjoying the friendship and acquaintance of many of his fellow members.

Mr. Boynton possessed a lovable personality and although he was rather quiet and reserved, his kindly interest in people, especially in younger men, seemed to invite and inspire confidence. With his high ideals of life and integrity, his own daily life seemed to be a helpful influence to many with whom he came in contact.

During the years he lived in Muscatine, he made warm friends, both in his social and business life. He was a dependable and valuable member of the Board of Directors of the Hershey State Bank, and was often called on for counsel and advice in the affairs of the city. He was a member of the Geneva Golf and Country Club and, when living in Davenport, was at one time President of the Outing Club. Mr. Boynton was a great home lover, and was fortunate in having a comfortable old-fashioned house on the bluff

overlooking the Mississippi River. He was never so happy as when at home with his wife and books by his side, having been an inveterate reader from childhood. While fond of music, having inherited a good voice and ear from his mother, walking and reading were his main recreations. Consequently, it was an unusually great sorrow when in September, 1927, an acute attack of glaucoma demanded an immediate operation, which allowed no more reading or writing. For years one of his favorite maxims had been, "there is no use kicking against the pricks", and there was little complaining; on the contrary, a feeling of thankfulness that he had been spared pain and that being in apparently excellent health, he could do everything as usual, except read and write.

It was a great shock to every one when, with no warning whatever, he was suddenly stricken with angina pectoris on January 13, 1928. He suffered great pain for a few days, which was followed by exhaustion. Continued rest and relaxation brought back his strength in no small degree, and for many weeks out of the fourteen in which he did not leave his room, he kept in constant touch with his business and the affairs of the Nation.

It may be of interest and appropriate to quote here an article that appeared in the *Muscatine Journal*, as it seemed to meet with the approval of many. It was written by a beloved and admired friend, a rather widely known historian and writer. The heading was:

"A Certain Man

"Men there are who, when taken from the world, leave it poor indeed. Such a man was Mr. George H. Boynton, of Muscatine. Mr. Boynton had a mind of technical bent. Technical things attracted him. A Civil Engineer, he so followed his calling as to be honored with membership in the American Society of Civil Engineers, later being made an Honorary or Life Member.

"But it is not of Mr. Boynton's practical aptitudes that the writer would speak. He had qualities far rarer. These caused him to be known as 'of the old school', a man of courtesy, of chivalry, a gentleman. Old Thomas Decker hesitated not to describe 'The best of men that e'er wore earth about him' as simply 'the first true gentleman'. Distinguished for courtesy, for kindliness, Mr. Boynton did not lack firmness; he was steadfast, he stood four-square to any winds that blew.

"A man's education, his training may or may not single him out. Mr. Boynton's training singled him out notably. In the main, he gained it in Germany. It was thorough—that was German. It was scrupulous—that was New England. Mr. Boynton's scrupulous thoroughness marked him from first to last. The particular thing that was just—this to him—was the vital thing.

"Kindliness evidenced in courtesy; courage evidenced in steadfastness; honor evidenced in scrupulous regard for what was just—such was Mr. Boynton's life."

On December 31, 1889, Mr. Boynton was married, in Davenport, to Frances E. Cutter, of Rock Island, who survives him.

The funeral service at his home in Muscatine was simple and modest—as typical of the man, and as he would have wished it to be. The concluding sentence of this service was most appropriate and covered his whole life. It was: "And so: We leave our brother—our friend—the husband who was still the lover".

Mr. Boynton was elected a Member of the American Society of Civil Engineers on September 3, 1884.

GEORGE HAMPTON BREMNER, M. Am. Soc. C. E.*

DIED APRIL 3, 1927.

George Hampton Bremner was born at Marshalltown, Iowa, on December 16, 1861. His father, William Bremner, came to America from Eastern Scotland in early childhood with his parents who settled in New England. After preparing for both law and engineering, William Bremner was actively engaged for a number of years in railway construction, chiefly in Connecticut. Joining the westward movement, he migrated to the State of Iowa and there was married to Catherine Hampton, of Iowa City, who was of English stock and a direct descendant of Governor Chittenden of Vermont. In 1856, they settled in Marshalltown, Iowa, where they reared their family. William Bremner served in the State Legislature in the early Sixties and practiced his two professions for many years, serving as City Engineer and as County Surveyor at Marshalltown until the end of his active professional life.

As a boy, George Hampton Bremner became familiar with the technique of instruments and practical methods of construction by helping his father. Railroads presented an attraction for him, however, and he spent his vacations, while attending the University of Iowa at Iowa City, Iowa, as a Rodman with Middle Western railway companies. After his graduation from the University in 1883, he worked with his father for two years, and then entered the employ of the Chicago, Burlington and Quincy Railroad Company in 1885, as a Division Engineer at Red Oak, Iowa.

From 1889 to 1890 Mr. Bremner was in charge of a locating party on the St. Louis, Keokuk, and Northwestern Railroad (a subsidiary of the Burlington), locating a line between Old Monroe and St. Louis, Mo., which section includes the crossing of the Missouri River near Bellefontaine, Mo. At the conclusion of this work he returned to the Chicago, Burlington and Quincy Railroad Company, and was placed in charge of the maintenance of lines in Northern Illinois with headquarters in Chicago. In 1898 the Burlington undertook its first track elevation (grade separation) at Chicago and Mr. Bremner was placed in charge. On this work he made an enviable record, taking special pride in the speed, economy, and quality of this pioneer construction, while handling it with a minimum of interference with train operation. In 1904, he was transferred to the Operating Department as Engineer, Maintenance of Way, of the Illinois Lines. He returned to the Engineering Department in 1908 as District Engineer in charge of engineering work on the lines in Illinois, Wisconsin, and Minnesota.

When the Bureau of Valuation was organized under the Interstate Commerce Commission in 1913, Mr. Bremner was appointed Assistant District Engineer in the Central District, with headquarters in Chicago. In 1915, he was promoted to District Engineer for this territory, and placed in charge of the administrative detail of field and office work, in connection with the preparation of inventories and reports of all the steam railway properties within

* Memoir prepared by a Joint Committee of the Society and the Western Society of Engineers, consisting of Elmer T. Howson, *Chairman*, Edwin F. Wendt, and W. D. Pence, Members, Am. Soc. C. E., and R. T. Scholes, M. W. S. E.

this District. In the course of his service with the Interstate Commerce Commission, he was also called upon to make a number of special reports on railway properties for the Commission under resolutions of Congress. He terminated this service in December, 1921, when the District Offices were closed and the forces concentrated at Washington, D. C. After engaging for a short time in consulting practice, he returned to the Chicago, Burlington and Quincy Railroad Company, with which he remained until his death.

Mr. Bremner always took a keen interest in the work of Engineering Societies. He joined the Western Society of Engineers on October 8, 1887, and participated in the organization of the American Railway Engineering Association in 1897-99. He was a member of the Special Joint Committee of the Society and the American Railway Engineering Association on Stresses in Railway Track, from its organization, in 1913, until his death. In 1906, the Western Society of Engineers awarded him the Octave Chanute Medal for the preparation and presentation of a paper of special merit on the subject of "Areas of Waterways for Culverts and Bridges." Mr. Bremner took a particularly active part in the work of the American Railway Engineering Association, serving at various times as a member of the Roadway and Track Committees, as well as Chairman of the Roadway Committee for three years. He was elected Treasurer of the Association in 1911, in which capacity he served until his death.

Gifted with strong personal initiative, Mr. Bremner was nevertheless a good soldier in carrying out the wishes of a superior authority, when the decision and plan of action were made. It was his habit when approaching new problems to form his judgment carefully, at times even slowly; with this quality of standing firmly for his beliefs, he did not hesitate to recast his views in the light of new facts, of which he was ever in search on his own account. Of his many strong personal qualities none is better remembered than his sturdy sense of business integrity, a steadfast loyalty to his friends, and, above all, his fine devotion to his family circle.

As a boy, Mr. Bremner united with the Presbyterian Church, which organization received his unfailing loyalty throughout his life.

He was married on September 5, 1888, at Red Oak, Iowa, to Louie A. Stephenson, who, with two sons, Charles W. and George H., and a daughter, Mrs. Clarence Schaeffer, of Chicago, survives him; he is also survived by a sister, Mrs. O. A. Byington, of Iowa City, Iowa, and a brother, William H. Bremner, of Minneapolis, Minn.

Mr. Bremner was elected a Member of the American Society of Civil Engineers on December 6, 1899.

WILLIAM CHARLES BURKE, M. Am. Soc. C. E.*

DIED JULY 21, 1928.

William Charles Burke was born near Montreal, Que., Canada, on February 1, 1857. He was the son of James and Mary (MacDonald) Burke. His father was of Irish ancestry and his mother of Scotch descent.

When Mr. Burke was fifteen years of age his family moved to Kansas City, Mo. where he completed his preliminary education. In 1874 and 1875, he attended Kansas University as a student of Civil Engineering, and, during summer vacations, received his first practical engineering experience, acting as Assistant to the City Engineer of Kansas City.

From 1876 to 1880, he was employed by the Union Pacific Railway Company and rose rapidly from a subordinate position to that of Locating Engineer. He made numerous location surveys for this Company in Western Kansas and Colorado during the period when Indian uprisings were not unusual, and military escorts were necessary.

During 1880 and 1881 he located and built the Missouri, Kansas, and Texas Railway from Fort Worth to Taylor, Tex., and, in 1882, was in charge of the erection of the Red River Bridge for the Cotton Belt Railway at Texarkana, Tex. This work was carried on under serious difficulties, as malarial fever was very prevalent and Mr. Burke was forced, on the completion of the railroad, to seek a more healthful climate. He went to San Marcial, N. Mex., as Division Engineer in charge of maintenance of way, of the Rio Grande Division of the Atchison, Topeka and Santa Fé Railway, in which position he remained until 1884 when he was appointed Assistant Chief Engineer of the Kansas City, Clinton, and Springfield Railway. He located and built this line from Kansas City to Springfield, Mo.

He spent the next two years, 1885 and 1886, with the Union Pacific Railway Company, locating a line from Salina to Lincoln, Kans., and relocating and constructing the line from Denver to Boulder, Colo. On the completion of this work, in 1887, Mr. Burke returned to the Atchison, Topeka and Santa Fé Railway Company, and located and built its main line from Fort Worth to Purcell, Okla. After this work was finished, he located and built the line of the Missouri Pacific Railway from Marquette to Gypsum City, Kans.

From 1888 to 1890, he was associated with two of his brothers-in-law under the firm name of Colt, Reinhart, and Burke, Contractors. They constructed the Missouri Pacific Railway from McCracken, Kans., to Pueblo, Colo., and the Fort Lyon Irrigation Canal in the Arkansas Valley, Colorado. The firm promoted, designed, and built the Rocky Ford, Colorado, Highline Canal, and numerous small projects, and was also engaged in the mercantile business, milling, and sheep raising. During the period from 1883 to 1890 Mr. Burke was also associated with his brother, Thomas Burke, in the cattle business, their ranch headquarters being thirty miles northwest of Prescott, Ariz.

* Memoir prepared by Morris C. Burke, Assoc. M. Am. Soc. C. E.

From 1890 to 1897, Mr. Burke lived at Las Animas, Colo., engaging in various activities. He made a report to the U. S. Department of the Interior as to irrigation possibilities in the Ute Indian Reservation. He was Consulting Engineer for the Great Plains Water Storage Company of Holly, Colo., and served for years as Receiver of the Fort Lyon Canal Company. He also made various reports of railroad and irrigation projects in the West and in Mexico.

In 1898 and 1899, as a member of the contracting firm of J. B. Colt and Sons Company, he built the St. Louis and North Arkansas Railway from Eureka Springs to Harrison, Ark. In 1901, Mr. Burke located the Eastern Oklahoma Branch of the Santa Fé Railway from Newkirk to Pauls Valley, Okla., and revised the location of the main line from Arkansas City, Kans., to Newkirk, Okla. During 1902 and 1903, as Division Engineer, he constructed the Missouri, Kansas, and Texas Railroad from Coffeyville, Kans., to Oklahoma City.

In 1904 Mr. Burke was appointed City Engineer of Oklahoma City, Okla., and remained in this position until 1911. During these years, the city grew very rapidly and the problem of keeping the improvements apace with the growth was tremendous.

From 1911 to the time of his death, he lived and maintained his office in Oklahoma City, and his consulting practice covered numerous projects of all descriptions, the more important of which were, as follows: Chief Engineer, Municipal Engineering and Construction Company; Consulting Engineer, State of Oklahoma, in the Two-Cent Rate Case; Chief Engineer, Cameron County Water Improvement District No. 1, Harlingen, Texas; Chief Engineer, Lee Land Company, Lower Rio Grande Valley, Texas; Chief Engineer, Rancho de Santa Maria, Texas; Chief Engineer, Municipal Excavator Company, Oklahoma City; Chief Engineer, State Conservation Commission of Oklahoma; Chief Engineer, North Canadian River Flood Control District No. 1, Oklahoma City; Consulting Engineer, Oklahoma Natural Gas Company; Consulting Engineer, Atchison, Topeka and Santa Fé Railway; Consulting Engineer, Citizens Committee of Oklahoma City on Union Railway Station controversy; and senior member of the firm of Burke Engineering Company.

Mr. Burke was married in 1887 to Daisy May Colt, of Clinton, Mo. He is survived by his widow, two sons, Morris Colt Burke, Assoc. M. Am. Soc. C. E., of Oklahoma City, and James MacDonald Burke, of La Jolla, Calif., and two daughters, Mary Frances Burke and Harriett Elizabeth Burke.

Mr. Burke's life was a splendid example of devotion to duty, to his profession, to his employers, and to his family. He was admired and loved by all who knew him and numbered his friends by the thousands throughout the Southwest. The history of his life is practically the history of the building of the West, and a personal narrative of his career would be rich with romance and adventure.

Mr. Burke was elected a Member of the American Society of Civil Engineers on April 12, 1926.

EUGENE DICKINSON BURNELL, M. Am. Soc. C. E.*

DIED FEBRUARY 20, 1928.

Eugene Dickinson Burnell was born at Steilacoom, Wash., on December 11, 1884, the son of Dr. A. T. and Mary (Frayer) Burnell.

Mr. Burnell attended Cornell University, at Ithaca, N. Y., from which he was graduated with the degree of Civil Engineer in 1906. From July, 1906, to December, 1908, he was employed on drafting and estimating by Hugh L. Cooper, M. Am. Soc. C. E., Consulting Engineer, of New York, N. Y., and, later, as Foreman on hydro-electric power plant construction, including the design of hydro-electric power plants.

He left the employ of Mr. Cooper in January, 1909, to fill an engagement as Assistant Engineer for the City of Pensacola, Fla.; he did not remain long in this work, however, because of his appointment to a position, in which greater experience could be obtained, with the Isthmian Canal Commission on the construction of the Panama Canal. He went to Panama in February, 1909, remaining there until January, 1910, as Assistant Engineer in the Department of Masonry Design, being particularly concerned with the design of the locks, gates, and valves, at Culebra.

In February, 1910, Mr. Burnell accepted a position with the J. G. White Engineering Company, of New York. At first, his duties included reporting on proposed hydro-electric developments, designs, and estimates. Later, he was appointed Assistant Superintendent of Construction on the 30 000 h.p. hydro-electric plant of the Canadian Light and Power Company, at Montreal, Que., Canada.

On the completion of this work in February, 1913, Mr. Burnell accepted a position as Construction Engineer for the Phœnix Construction Company, at Grace, Idaho, on the construction of the Utah Power and Light Hydro-Electric Development, one of the properties of the Electric Bond and Share Company. On this work he made evident his capabilities as a Cost Analysis Engineer.

Mr. Burnell's work in Idaho was completed in the spring of 1914, and he then accepted a position with the Power Construction Company of Shelburne Falls, Mass., as Construction Superintendent in charge of building ten miles of a standard-gauge railroad. He finished this work in September, 1914. In January, 1915, he was appointed Superintendent of Construction for the Aqueduct Construction Company, Winnipeg, Man., Canada, on the construction of ten miles of a concrete aqueduct, which position he retained until the work was completed in April, 1916.

When Mr. Burnell returned to New York, he was employed by the Agency of the Canadian Car and Foundry Company of New York, as Assistant Works Manager, at its large shell and shrapnel loading plant at Kingsland, N. J. It was during his engagement on this work that he showed his forcefulness as an efficient Production Manager, and it was largely through

* Memoir prepared by Joseph D. Evans, Esq., New York, N. Y.

his technical ability, energy, and painstaking efforts that the Company was able to fulfill the contract on which the production had fallen far behind. The penalties that were being enforced would have meant a great financial loss to the Company. Through Mr. Burnell's efforts, however, work under this contract with the Russian Government for loading 2 500 000 18-lb., high-explosive shells and 2 500 000 rounds of shrapnel, at an aggregate price of $83 000 000, was brought up to large quantity production and the Company's penalties were soon cancelled by very substantial bonuses, all of which were in excess of the original contract price.

In April, 1917, soon after the United States entered the World War, the Evans Engineering Corporation, of New York, which had been formed for the purpose of loading 18-lb., high-explosive shell for the United States Army, employed Mr. Burnell as Chief Engineer in charge of design and construction of the $800 000 shell-loading plant which this Company was building at Old Bridge, N. J. Later, he was placed in charge as Works Manager. Although this plant, which was a privately owned corporation, loading shells on a unit-price basis, with contracts from the United States Ordnance Department, was the smallest of the shell-loading plants in the United States, it holds the record for loading the greatest number of 18-lb. shells (75-mm. high-explosive) in any one day, month, or for the duration of the World War, and this work was carried on under the able direction of Mr. Burnell.

One of the financial interests in the Evans Engineering Corporation caused the Atlantic Loading Company to be formed, for the purpose of constructing an $18 000 000 to $25 000 000 high-explosive shell-loading plant for the United States Government. This plant was constructed later and operated at Amatol (Hammonton), N. J. In conjunction with his duties as Works Manager of the Evans Engineering Corporation plant at Old Bridge, Mr. Burnell was appointed Chief Engineer on design for the Amatol plant of the Atlantic Loading Company. When this latter Company's plant was sufficiently constructed to permit operations of loading high-explosive shell, Mr. Burnell devoted his entire time to serving as Works Manager at Amatol. Of the four plants of this type which the Government constructed, this one was reputed to have been the largest. It had a capacity of turning out more than 150 000 high-explosive shells daily, in sizes ranging from 18 lb. (75 mm.) to 80 lb. At the termination of the war, the Government selected this plant for carrying on several years' operations, scrapping the others which had been constructed under agency form of contracts. The Atlantic Loading Company terminated its work in the summer of 1919. Mr. Burnell's work during the war stands out eminently as an accomplishment second to none for its efficiency and harmonious operation.

In 1919 Mr. Burnell joined the Overman Cushion Tire Company, of New York, as Assistant to M. C. Overman, President; later, he was made a Vice-President. As is so marked in his career, he again showed himself to be of a constructive turn of mind and was instrumental in systematizing the entire operations of this Company.

In August, 1917, Mr. Burnell was married to Augusta A. Evans, who survives him. He is survived also by his father and mother and three sisters,

Elizabeth Burnell, of Los Angeles, Calif., Mrs. Bernice Maricle, of Everson, Wash., and Mrs. Esther Mills, of Longs Peak, Colo.

All those who knew Mr. Burnell soon learned to appreciate that he was an engineer and business man of ability, one whose loyalty and integrity ever could be counted upon. He was quiet, unassuming, and always had a kind word for every one with whom he came in contact.

He was a member of the Cornell University Club, New York, the Rod and Bob Club of New York, the Rockwood Hall Country Club, the Society of Automotive Engineers, and the American Society of Mechanical Engineers.

The passing of Mr. Burnell leaves a vacancy in the hearts of all his friends, and takes from the world an engineer and operating manager who, had he lived, might have accomplished still greater things in useful construction.

Mr. Burnell was elected an Associate Member of the American Society of Civil Engineers on June 4, 1913, and a Member on September 9, 1919.

HENRY JACKSON BURT, M. Am. Soc. C. E.*

DIED JULY 28, 1928.

Henry Jackson Burt, born February 6, 1873, at Urbana, Ill., was the son of H. Jackson Burt and Isabelle (Dunlap) Burt. His father died when he was six months old, which, to a great extent, necessitated his self-education.

Mr. Burt's entire education was received in the schools at Urbana. He was graduated from the University of Illinois in 1896, with the degree of Bachelor of Science, and was awarded the degree of Civil Engineer in 1914. During his school years of 1892 and 1893 he was engaged in surveying and modeling a relief map of the State of Illinois for the Columbian Exposition. During the summer of 1895 he served as Instrumentman and Inspector on sewer construction at Urbana.

After his graduation from the University of Illinois in 1896, he entered the employ of the Gillette-Herzog Manufacturing Company, of Minneapolis, Minn., in its New Orleans Office, designing and estimating steel structures of all kinds. On some of these structures Mr. Burt also acted as Inspector of Material and Superintendent of Erection. In December, 1898, he resigned his position with the Company to accept one with the Chicago and North Western Railway Company as Assistant Engineer on the construction of new lines in Iowa; and in January, 1900, he was placed in charge of surveying for track elevation in Chicago, Ill.

From September, 1900, to June, 1901, Mr. Burt was engaged as Assistant Professor of Civil Engineering at Iowa State College, Ames, Iowa, under Anson Marston, President, Am. Soc. C. E. In July, 1901, he entered the employ of the American Bridge Company as Contracting Manager, serving one year at St. Louis, Mo., three years at Salt Lake City, Utah, and six years at Denver, Colo., resigning in 1911 to accept a position as Chief Structural Engineer with Holabird and Roche (now Holabird and Root), Architects, Chicago. Among the notable large Chicago buildings designed under his supervision while he was employed in this capacity, or as Consulting Engineer, are the Sherman, Palmer, Morrison, and Stevens Hotels, the Tribune Tower, the Roanoke Tower, the Illinois Stadium, at Champaign, Ill., and the Soldiers' Field Stadium, at Chicago.

During the World War, 1917-1919, Mr. Burt was with the Construction Division of the United States Army, at Washington, D. C., in charge of plans for emergency construction, as Major in the Quartermaster Corps. Later, he was made Lieutenant-Colonel in the Officers Reserve Corps. After the war, he returned to practice as a Consultant in civil and structural engineering, specializing in heavy building construction, both foundations and superstructures.

He was the author of "Steel Construction", widely used as a text and reference book. He had an exceptionally well-grounded knowledge of engi-

* Memoir prepared by a Joint Committee of the Society and the Western Society of Engineers, consisting of Albert F. Reichmann, *Chairman*, August Ziesing, and F. E. Brown, Members, Am. Soc. C. E., and A. N. Talbot, Past-President, Am. Soc. C. E.

neering principles, with a thorough understanding of their practical application, and was a capable organizer and executive. With these attainments he combined good business reasoning and fair play which accounted for his cordial relations with all with whom he came in contact. His modest and unassuming manner of guidance, which was never dictatorial, endeared him to his many friends and associates. He was modern and progressive, but never radical nor over-confident, and with his keen analytical mind he would attack a problem in a manner which seemed to sense a solution by instinct.

Mr. Burt was a loyal and alert citizen, always interested in public questions, and gave much of his time, whenever he could be of service, to the community in which he lived. His work as Chairman of the Legislative Committee of the Western Society of Engineers during 1914 and 1915 is especially commendable, because it resulted in the Engineers' License Law of the State of Illinois. To the time of his last illness, he was a member of the Wheaton Sanitary District Board. He also served as Chairman of the Board of Trustees of the First Presbyterian Church. His high ideals and genial personality were an inspiration, not only to his friends, but especially to his family; and his beautiful home life reflected these influences.

In 1900, Mr. Burt was married to Edith Fleming, at Champaign, Ill. He is survived by his widow and five children, Henry Jackson, Luella, Jesse Fleming, Morris Nathan, and Helen Edith.

He was a member of the Western Society of Engineers (Past-President, 1917), American Society for Testing Materials, American Society for Heating and Ventilation, American Concrete Institute, and the Society for the Promotion of Engineering Education. He was also a member of the University Club and the Illini Club of Chicago, the Chicago Engineers Club, and the Masonic Fraternity.

Mr. Burt was elected a Member of the American Society of Civil Engineers on March 1, 1905.

DAVID SYLVANUS CARLL, M. Am. Soc. C. E.*

DIED NOVEMBER 5, 1928.

David Sylvanus Carll was born in Huntington, N. Y., on March 21, 1855, the son of David and Mariette (Parsons) Carll. He was graduated from the Huntington Union School in 1875.

Mr. Carll's professional work began immediately after his graduation, his early experience consisting of surveying in the vicinity of his home. From 1877 to 1881, he was Surveyor to various commissioners of highways. Subsequently, he was Transitman and Assistant Engineer for the Long Island Railroad Company, Assistant Engineer for the New York, West Shore, and Buffalo Railway Company, and he was also engaged in practice as a Civil Engineer and Surveyor in Saugerties, N. Y.

From 1884 to 1888, Mr. Carll was with the Department of Public Works of New York City, in connection with the construction of the new aqueduct and reservoirs. In March, 1887, he went to Kansas City, Mo., where he was engaged on the construction of the cable railway lines, his first employment being with the Grand Avenue Railway Company, and, later, as Assistant Engineer with Knight and Bontecou, Consulting Engineers. From October, 1889, to 1890, he was Superintendent of Grading and Construction in the City Engineer's Office in Kansas City.

In November, 1890, Mr. Carll began his career as Engineer Executive for the Washington and Georgetown Railroad Company, now The Capital Traction Company, of Washington, D. C. His first work in Washington was in charge of installing the cable system on the lines of that Company. On the completion of the work in 1892, he was made Chief Engineer and continued in that position, in charge of engineering work, until 1908. Subsequent to 1895, he became the Superintendent of the Company, retaining his position as Chief Engineer, and was responsible for all the Company's Operating as well as its Engineering Departments. During the construction of the cable road his duties included not only the construction of the cable lines themselves, but of a cable power station and office buildings on Pennsylvania Avenue, on the site of the present District Building. He was also engaged on the construction of several car barns and other structures.

After the destruction of the Cable Power Station by fire in September, 1897, the lines of the Company were electrically equipped; this was the first instance of the conversion of cable lines to the underground conduit system. Mr. Carll was in charge of all this work as Chief Engineer, including, in addition to the reconstruction of track, the building and equipment of a direct-current power station, the rebuilding of numerous car barns, and the design and purchase of rolling equipment. This work was done principally during 1897 and 1898, and at this time Mr. Carll's responsibilities also included the operation of all the Company's street railway lines, which for a time included operation by horse cars, cable, over-head trolley, and underground conduit. In

* Memoir prepared by J. H. Hanna, M. Am. Soc. C. E.

February, 1908, Mr. Carll was made a Director of The Capital Traction Company and elected to the office of Vice-President and General Manager. He remained a Director and Vice-President until his death, having given up his more active duties with the Company in 1916.

During Mr. Carll's long residence in Washington he showed great interest in the development of the Capital City by active association with many civic organizations. He had been a prominent member of the Board of Trade for many years and was Vice-Chairman of its Committee on Law and Order. He was a Charter Member, and served on the first Board of Directors, of the Washington Society of Engineers; he also served as Vice-President in 1908 and as President in 1909. He had been prominently active in the District of Columbia Section of the American Society of Civil Engineers since its organization and served as Chairman in 1920. He was a member of the Cosmos Club, of Washington, and many other civic and welfare organizations.

The Mt. Pleasant Congregational Church of Washington was, next to Mr. Carll's business and profession, his greatest interest. A member of the church since 1894, he was a Trustee for more than twenty years and Chairman of its Building Committee during the erection of its present structure.

Mr. Carll was married on February 22, 1883, to Maria B. Dawes, who died in 1922, leaving one daughter, Mrs. Ernest D. Roberts, of Washington. In 1925, he was married to Eliza R. Davis, of Auburn, N. Y.

To those who were fortunate enough to be associated with David S. Carll and to have his friendship, his outstanding characteristic was his humanity and love for his fellow man. An able engineer, a forceful, energetic executive, always carrying heavy responsibilities, he never failed to find time for a word of encouragement or more substantial help for any who came to him. The love of the thousands of men and women who had the privilege of working under his direction is the outstanding feature of his successful career—his bequest to them, the memory of a Christian gentleman.

Mr. Carll was elected a Junior of the American Society of Civil Engineers on March 7, 1888; an Associate Member on July 1, 1891; and a Member on October 7, 1896.

JOHN CHARLES CHURCHILL, M. Am. Soc. C. E.*

DIED APRIL 19, 1928.

John Charles Churchill was born at Oswego, N. Y., on September 20, 1856, the second son of Judge John C. and Kathleen Sprague Churchill. His father was one of Oswego's leading citizens, having been a Representative in Congress and also a Justice of the Supreme Court. He received his preparatory education in the public schools of Oswego, and was graduated, in 1878, from Lafayette College, Easton, Pa., with the degree of Mining Engineer.

From March, 1879, to July, 1881, Mr. Churchill was Surveyor and Draftsman for the Federal Government on harbor improvement work on Lake Erie. During the remainder of 1881, and until the end of 1884, he was Assistant Engineer for the Oregon Railway and Navigation Company, for two years in charge of the construction of bridges and trestles, and of tracklaying on the Baker City Branch. He returned to New York State in 1885, and from May to October was in charge of harbor improvement work at Ogdensburg, N. Y. From October, 1885, to October 1886, he was Assistant Engineer on the Rome, Watertown and Ogdensburg Railroad, in charge of the construction of a ferry slip at Ogdensburg, and of construction work on the branch from Norwood to Massena, N. Y. From October, 1886, to August, 1887, he was Assistant Engineer for the Federal Government on various surveys for harbor improvements in Northern New York and Vermont. In August, 1887, he resigned from the Government service to enter the contracting business, continuing in this work until July, 1889.

From July, 1889, to January, 1891, Mr. Churchill was Engineer and Assistant to the Building Superintendent on the construction of the St. Lawrence State Hospital, at Ogdensburg. In 1892, he acted as City Engineer of Ogdensburg, during which service he designed and constructed the South Street main sewer, and rebuilt the sea wall in the Oswegatchie River.

In 1892, he returned to the Federal Government Service in charge of harbor improvement work at Ogdensburg, continuing until August, 1895, when he was made Assistant Engineer in charge of the St. Lawrence River improvement. From January, 1896, to July, 1898, he was in charge of examination and surveys on Lake Champlain, the St. Lawrence River, and Lake Ontario, having been also from January to May, 1898, in charge of the U. S. Engineer Office at Oswego, N. Y., during the absence of the District Engineer. In July, 1898, the Oswego District was combined with the Buffalo, N. Y., District, and Mr. Churchill was given charge of the Oswego Branch Office, in which position he continued until it was again separated from the Buffalo District in August, 1909. When the Oswego District Office was re-established in August, 1909, he became Principal Assistant to the District Engineer, the District including all harbors on the south

* Memoir prepared by Lynn L. Davis, M. Am. Soc. C. E.

shore of Lake Ontario and the St. Lawrence River. In May, 1913, the Oswego District was again combined with the Buffalo District, and Mr. Churchill for the second time was made Assistant Engineer in charge of the Oswego Sub-Office, in which capacity he continued to serve until his death.

In addition to this regular service he was employed in a consulting capacity as follows: By the State of New York as Consulting Engineer and Expert Witness in matters pertaining to water power on the Oswego River; and for a time as Chairman of the Water Commission of the City of Oswego. He also served as Fuel Administrator of the City of Oswego during the World War. He had applied for a commission in the Corps of Engineers during the war, but his request was refused on account of his age. All the members of his family were engaged in some capacity in war work, his three sons having been in active service.

Mr. Churchill served the Federal Government on harbor improvement work for more than thirty-eight years, on Lakes Erie, Ontario, and Champlain, and on the St. Lawrence River. He designed and built many of the breakwaters and piers on Lake Ontario and the St. Lawrence River. His knowledge regarding the needs of commerce on these lakes and of the character and condition of all the structures in the former Oswego U. S. Engineer District was very valuable, and his advice was sought on all projects for improvement or maintenance.

He died at his home in Oswego, on April 19, 1928, and is survived by his widow, formerly Mary Beekman Westbrook, three sons, John W. Churchill, of Washington, D. C., Maj. Lawrence S. Churchill, Air Corps, U. S. A., Langley Field, Va., and Walter A. Churchill, of Salem, Mass.; one brother, Lawrence W. Churchill, of White Plains, N. Y., and St. Petersburg, Fla.; and one sister, Mrs. R. R. Fisher, of Oswego.

Mr. Churchill was one of God's noblemen. His kind and genial disposition and splendid upright character won for him the highest respect of all who were privileged to know him. In his business and professional relations he was held in the highest regard by all who were associated with him. His City will miss his wise and judicial counsel and the Federal Government will feel the loss of a valued and able servant whose wisdom was always sought in all matters of policy and details of Federal work in his District.

Mr. Churchill was elected a Member of the American Society of Civil Engineers on February 1, 1899.

WALTER WOODBRIDGE CLIFFORD, M. Am. Soc. C. E.*

DIED JANUARY 19, 1927.

Walter Woodbridge Clifford was born on February 15, 1888, at Wiscasset, Me. His parents died when he was a small boy, and he went to Hyde Park, Mass., to live with his uncle and aunt, who raised him. He attended the public schools of that city and was graduated from the Hyde Park High School in 1905. He then entered the Massachusetts Institute of Technology, receiving his degree of Bachelor of Science in the Department of Civil Engineering in 1909. While in attendance at the Institute he was a member of the Civil Engineering Society, and took an active interest in student military affairs.

In the summer of 1909, following his graduation, Mr. Clifford was in the service of the old Harbor and Land Commission of Massachusetts, as Surveyor in connection with the proposed dredging of harbors along the Massachusetts Coast. In the fall of that year he returned to the Massachusetts Institute of Technology as an Assistant in the Department of Civil Engineering, where he remained for two years. During the summer of 1910 he was employed as Resident Engineer by the Aberthaw Construction Company, which was building a concrete stand-pipe for the Town of Westerly, R. I.

After two years of teaching, he entered the employ of the United States Forestry Service as a Hydraulic Engineer, but he remained in the Service only a few months. From May to September, 1912, he was employed by Metcalf and Eddy as Resident Engineer in charge of the water supply and sewage disposal of the new Technology summer surveying camp, which was then being built at East Machias, Me. On the completion of this work he was employed for a few months by the U. S. Navy Department, at the Charlestown Navy Yard, as a Designing Engineer.

In 1913, Mr. Clifford entered the Engineering Department of Stone and Webster, Incorporated, and was assigned to the staff selected for the engineering design of the new Technology buildings at Cambridge. He did some valuable work in the solution of many difficult problems which arose in connection with the foundations and superstructure of these buildings. In 1915 he was employed as a Structural Engineer by Densmore and LeClear, and remained with this architectural firm for about two years. From 1917 to 1921, he was with the Harry M. Hope Engineering Company, first, as Chief Draftsman, and, later, as Designing Engineer on many important structures, among which was the large plant of the United Drug Company, at St. Louis, Mo.

From 1921 until his death, which occurred suddenly from heart failure at his office in Boston, Mass., he had been associated with Mr. S. G. Roeblad, under the firm name of Clifford and Roeblad, Consulting Engineers. The principal work of this organization consisted in designing industrial plants and garages, and acting in the consulting capacity of structural engineers for architectural firms. Mr. Clifford was engaged personally as an expert in Court proceedings, and also as arbitrator in connection with the interpretation of building contracts.

* Memoir prepared by Charles R. Berry, Assoc. M. Am. Soc. C. E.

He was a member of the Boston Society of Civil Engineers and the American Concrete Institute. He was the recipient from the Society of the Collingwood Prize for Juniors, for his paper, "A Reinforced Concrete Standpipe."* He took an active part in the Boston Society of Civil Engineers, having served on many of its committees. He was Chairman of the Designers Section in 1923 and 1924. At the time of his death he was Chairman of the Welfare Committee and was a candidate for Director of the Society.

Mr. Clifford was the author of many articles on engineering subjects appearing in periodicals, and was one of the Associate Editors of Hool and Johnson's Handbook of Building Construction, and of Hool and Kinne's Structural Engineers' Handbook Library. With C. Hale Sutherland, M. Am. Soc. C. E., he had recently published a textbook entitled, "Reinforced Concrete Design," which was very favorably received.

Not only was Mr. Clifford active in the affairs of his profession, but he also gave generously of his time to Hyde Park Lodge, A. F. and A. M., and Christ (Protestant Episcopal) Church, of Hyde Park, of which he was a member. At the time of his death he held the office of Junior Warden in each of these bodies. He was also a member of the Aleppo Temple Shrine of Boston. He was a Director in the Hyde Park Young Men's Christian Association.

In 1912, he was married to Helen Edelmer Mooar, by whom he is survived. He also leaves two children, James and Deborah, as well as an only brother living in California.

Although of an unassuming disposition, Mr. Clifford took an active part in the various organizations with which he was connected, and was sought out by them for office on account of his fine executive ability. A man of accomplishments, and a true Christian gentleman, Walter Clifford will be missed by a host of friends.

Mr. Clifford was elected a Junior of the American Society of Civil Engineers on November 8, 1909; an Associate Member on January 15, 1917; and a Member on March 16, 1925.

---

* *Transactions*, Am. Soc. C. E., Vol. LXXIV (December, 1911), p. 375.

WILLIAM GODLEY COUGHLIN, M. Am. Soc. C. E.*

DIED OCTOBER 12, 1927.

William Godley Coughlin, the son of Samuel Britton and Anna Margaret (Weber) Coughlin, was born on February 15, 1862, in Florence, N. J. His father was of English and Irish ancestry, whereas his mother's family came to the United States from Germany in 1833. The boy received his education in the public and private schools of Florence and, later, attended the Farnum School, at Beverly, N. J., preparatory to entering Lehigh University, at Bethlehem, Pa.

During this period, his father decided to join the Collins Expedition of 1878, with the purpose of engaging in railroad construction in Brazil. As the prospect of such an adventurous trip to South America appealed strongly to the lad's imagination, he went with the Expedition and obtained the position of Rodman on the Madeira and Mamore Railway around the Falls of the Upper Madeira in Brazil. The Expedition seems to have been ill-fated, for those of the party sailing on the second ship, the *Metropolis*, were lost at sea, Mr. Coughlin having escaped that fate by his persistent petitions to be allowed to accompany his father.

On his return to the United States, after a year and a half of service in South America, Mr. Coughlin became engaged in preliminary surveys for a railway from Pittston to Hawley, Pa. He then entered the service of the Pennsylvania Railroad Company, which was the beginning of a life service in the Engineering, Maintenance of Way and Structures, and Transportation Departments of that System. He was employed, successively, as Rodman, Levelman, and Transitman on the following work: Preliminary surveys and location for a branch line from Baltimore, to Catonsville, Md.; survey for a proposed pleasure railway through Fairmount Park; re-location and grade revision of the Western Pennsylvania Railroad; preliminary surveys and location of the Cornwall and Lebanon Railroad; revision of alignment on the main line of the Pennsylvania Railroad; location and construction of the Philadelphia and Long Branch Railway from Whitings to Bay Head, N. J.; fourth track work on the Western Division of the Pennsylvania Railroad; and location and construction of a connecting line between Dauphin and Rockville, Pa.

In March, 1883, Mr. Coughlin entered the Maintenance of Way Department of the Northern Central Railway (Pennsylvania Railroad) as Assistant Supervisor in the office of the Engineer of the Baltimore Division and, in May, 1886, he was appointed Supervisor of the West Jersey and Seashore Railroad (Pennsylvania Railroad) in charge of maintenance-of-way work, which position he held until March, 1893.

The following include some of the positions which Mr. Coughlin held during the period extending from March, 1893, to April 1, 1907: Assistant Engineer on the Baltimore Division of the Northern Central Railway, in full

* Memoir prepared by W. C. Cushing, M. Am. Soc. C. E.

charge of engineering work; Principal Assistant Engineer on maintenance-of-way work on the Erie Division of the Pennsylvania Railroad, including that territory extending from Erie, Pa., to Baltimore, Md., and numerous lateral branches; and Superintendent in charge of operations of the Elmira Division of the Northern Central Railway, with headquarters at Elmira, N. Y.

In April, 1907, Mr. Coughlin was appointed Superintendent of the Erie Division and, in March, 1909, of the Renovo Division, of the Pennsylvania Railroad Company, in which positions he had charge of operations, including engineering work, maintenance of way, bridges, buildings, construction of piers, and dredging.

From November, 1913, until his retirement in October, 1927, Mr. Coughlin held the positions of Engineer and Chief Engineer of Maintenance of Way for the Pennsylvania Railroad Company, having his office at Philadelphia, Pa. Just prior to his retirement, he was occupying the position of Special Agent with this Company.

Mr. Coughlin's faithful and loyal performance of duty appeared everywhere in his work. Gifted with an especially analytical mind, he was constantly active in inventions for the improvement of railroad structures and appliances, with a view to economy and improved elements in the management of his territorial range. He was granted several patents by the United States Patent Office, the last being received a few months before his death. These patents were closely allied to railroad construction and demonstrated the possible achievement of an active imagination coupled with a skillfully managed pencil. His work along this line made evident his earnest efforts to improve the track structure under his official jurisdiction and his vigorous activity in these conceptions during his life time.

Mr. Coughlin was of a modest and retiring disposition, possessing withal a very pleasing personality. Many anecdotes are told by his associates to illustrate his ready wit and humorous outlook. His was a bright, cheery, and sympathetic nature.

He was a member of the Engineers Club of Philadelphia and of the Madeira and Mamore Association, and a communicant of the Protestant Episcopal Church.

As Mr. Coughlin was not married, he lived during the last fourteen years of his life, with his family, at the "old home" in Burlington, N. J.

Mr. Coughlin was elected a Member of the American Society of Civil Engineers on March 4, 1913.

CLARENCE AUSTIN CRANE, M. Am. Soc. C. E.*

DIED DECEMBER 5, 1927.

Clarence Austin Crane was born in New York, N. Y., on October 18, 1874. He was the son of Warren Cady and Caroline (Cleveland) Crane, and was descended from a long line of English ancestors, both great-great-grandfathers having served in the War of the Revolution.

After his preliminary education had been completed in the preparatory schools of New York, Mr. Crane attended the School of Mines, Columbia University, during 1891 and 1892. From October, 1893, to April, 1894, he was a student at Lehigh University, South Bethlehem, Pa., taking special courses in Mechanics.

Previous to this time, Mr. Crane had been connected with the Engineering Department of the New York, Susquehanna, and Western Railroad Company, but after leaving college he resigned this position to become Assistant Engineer with the Department of Parks of the City of New York. In this capacity, he was engaged in many important plans and improvements which included the Harlem River Driveway, the Zoological Gardens of Bronx Park, and the Spuyten Duyvil Parkway.

From 1900 to 1903, he served as Assistant Engineer with the New York Aqueduct Commission, on the construction of Jerome Park Reservoir. In 1903, he resigned from the city service and entered private practice as a Consulting Engineer. As such, he was engaged in surveying in the Boroughs of Manhattan and The Bronx, and elsewhere, and had charge of numerous grading, paving, and sewer contracts, etc. He also served as a City Surveyor in the Borough of Manhattan and was engaged in street grading, etc., on the upper part of New York City.

In 1909, Mr. Crane founded the General Contractors Association, which through his efforts developed into the present influential organization. As Secretary of this Association, he was active in encouraging the enactment of statutes infinitely beneficial to contracting interests as well as to the State in general.

Although unfailing in his devotion to the Association, Mr. Crane's activities were by no means limited to this one undertaking. He was a student of and possessed an intimate knowledge of public affairs. He was a civil engineer with practical experience in engineering problems of design and construction. His advice and counsel were sought by his friends generally, as well as by public officials and members of the Association, to all of whom he was equally helpful in solving difficult civic, economic, and engineering problems.

He had a magnetism and charm of personality that won for him a loyal affection and respect, and made people seek to be with him. He was a devoted husband and father, constantly interested and eager for the welfare and

* Memoir prepared from information on file at Society Headquarters.

happiness of his family. He is survived by his widow, Edna Montgomery Crane, two daughters, Caroline Cleveland and Edna, and one son, Warren Cady, 2d; as well as his father, Mr. Warren Cady Crane, two sisters, Miss Sally B. Crane and Mrs. J. Harvey Birch, and one brother, Mr. Frank W. Crane.

Mr. Crane was a member of Mayor Walker's City Plan Committee, the Horatio Seymour Democratic Club, and the Sheriff's Jury, Third Panel. He was also a member of the Engineers Club, the Sons of the Revolution, St. John's Lodge No. 1, A. F. and A. M., and the Chapel of the Intercession of Trinity Protestant Episcopal Church.

Mr. Crane was elected an Associate Member of the American Society of Civil Engineers on March 5, 1902, and a Member on May 4, 1909. He was also a member of the New York Section.

ELMORE DAVID CUMMINGS, M. Am. Soc. C. E.*

DIED NOVEMBER 17, 1927.

Elmore David Cummings was born on November 14, 1861, in Indiana, Pa. His parents, Joseph and Margaret Shields Cummings, were farmers, and the early life of their only son was spent entirely on the farm. A natural aptitude for study and ambitions along other than farming pursuits brought about on the part of the youth an early determination for a college education along engineering lines. Aided and assisted in his studies by his parents, Mr. Cummings accomplished practically his entire preparation for college at home, save for a part of a year, at the age of 20, which he spent at Washington and Jefferson College.

Mr. Cummings entered Cornell University at Ithaca, N. Y., in 1885 and was graduated as a Civil Engineer four years later with honorable mention for his graduating thesis. He immediately entered the employ of G. W. G. Ferris and Company, of Pittsburgh, Pa., as Inspector of Materials at mills, shop construction of railway bridges, and structural work. The early and thorough insight thus gained in structural steel shop processes, together with the fact that he kept abreast of improvements in shop machinery and methods of fabrication, was of inestimable worth in his life work, which was, for the most part, that of a designer in steel. As he designed, he visualized with rare insight the various shop processes necessary to produce in tangible form the creation of his mind, and the value of his work was greatly enhanced thereby.

From 1891 to 1893, Mr. Cummings was Draftsman and Assistant Designer for the Columbus, Ohio, Bridge Company, and for the late E. L. Corthell, Past-President, Am. Soc. C. E., Consulting Engineer, on large railway bridges. Following these engagements he was an Instructor in Civil Engineering at Washington University, St. Louis, Mo.; an Assistant Engineer to the late J. B. Johnson, M. Am. Soc. C. E., in the laboratory work of the United States Timber Physics Investigations at this same Institution, and after the completion of these investigations, he was again engaged in instructional work, this time as Assistant Professor of Civil Engineering at the University of Maine, Orono, Me. His natural predilection for designing, however, led to his return to that field of endeavor, and from 1896 to 1899 he was Office Engineer and Assistant Designer for the Pittsburgh Bridge Company in charge of contractual relations and design pertaining largely to intricate roof construction and the design of mill buildings.

In 1899, the United States Engineer Office at St. Paul, Minn., engaged Mr. Cummings as Designer and Principal Draftsman under the general supervision of the Engineer Officer for special work of design in connection with the reconstruction of the reservoir dams at the head-waters of the Mississippi River, and the construction of locks and dams between Minneapolis, Minn., and St. Paul. This work demanded many detailed investigations of governing considerations, and was characterized by the most painstaking thoroughness and the exercise of a high degree of originality in design. He was pos-

* Memoir prepared by W. C. Weeks, M. Am. Soc. C. E.

sessed of an unusual ability to convince others that the devices and structures he proposed would function properly when they were fabricated and installed. The signal success of Mr. Cummings' work at this time was an accomplishment which his surviving associates of that period still remember.

From 1901 to 1903, Mr. Cummings was Designing Engineer in the Bridge and Building Department of the Chicago, Milwaukee and St. Paul Railway Company, where his work ranged from the design of culverts, shops, and chimneys, to that of bridges spanning the Mississippi River. In November, 1903, he became Junior Engineer and, later, U. S. Assistant Engineer under the immediate direction of the Chief of Engineers, at Washington, D. C.

Mr. Cummings' work in the office of the Chief of Engineers was particularly concerned with the design, construction, installation, and testing of ammunition hoists and disappearing searchlight towers for sea-coast fortifications. His work demanded special qualifications and an exercise of originality far beyond the capabilities of most designers. His accomplishments in this difficult work were of outstanding merit. He not only made many original studies of highly technical character, but he also developed a considerable number of machines and mechanical structures, and incidentally made numerous inventions on which the Government took out patents in his name. It is noteworthy that without exception the creations of his genius have proved to be eminently successful for the purpose for which they were designed. Save for one instance, descriptions of these devices, although well meriting publication in the technical press, have never appeared, due to their confidential character. By special permission of the Chief of Engineers, a descriptive paper on disappearing searchlight towers prepared by Mr. Cummings was published in February, 1924, by one of the leading engineering weeklies.

During the World War, Mr. Cummings handled the technical features pertaining to fabricated materials valued at many millions of dollars. This material was sent to France and consisted for the most part of framed structural steel for large warehouses designed for ready erection in the field.

Mr. Cummings' active life was devoted to engineering, largely in the field of engineering design in which he particularly excelled. All his work was characterized by thoroughness, simplicity, and adaptability to the purpose for which it was intended. His creations were the result of the most careful and painstaking effort, and they were notable for pronounced simplicity and practicability.

Mr. Cummings, by nature a deeply religious man, was a life long member of the Presbyterian Church. He was married on August 7, 1895, to Jessie Williams, of Cleveland, Ohio, who, with a son, Carl Elmore Cummings, survives him.

He was a member of the Washington Society of Engineers, the Society of American Military Engineers, and the Cornell Clubs of New York, N. Y., and Washington, D. C.

Mr. Cummings was elected an Associate Member of the American Society of Civil Engineers on November 4, 1903, and a Member on June 30, 1911.

WILLIAM SANBORN DAWLEY, M. Am. Soc. C. E.*

DIED MAY 18, 1927.

William Sanborn Dawley, son of John T. and Lemoille (Sanborn) Dawley, was born November 27, 1856, at Stockton, Wis.

He was graduated in 1879 from the University of Minnesota with the degree of Bachelor of Civil Engineering and immediately joined the ranks of those pioneers who were so busily engaged at that time in locating and building railroads.

Mr. Dawley's earlier apprenticeship, like that of most engineers of his time, consisted of a rapid succession of moves from one scene of activity to another. During the ten years immediately following his graduation, he was successively Rodman, Levelman, Transitman, Locating Engineer, Resident Engineer, and Division Engineer on various railroad location and construction projects for the Minneapolis and St. Louis Railroad, the Great Northern Railway, the Minneapolis, St. Paul and Sault Ste. Marie Railway, the Chicago and Indiana Coal Railway, and the St. Paul and Kansas City Railroad Companies. His activities during this period covered the greater part of Minnesota, Wisconsin, Iowa, North Dakota, South Dakota, and Indiana, but there were in addition three outstanding accomplishments.

The location of the Minneapolis and St. Louis Railroad, in 1884, which extended as far west as Watertown, S. Dak., was Mr. Dawley's first work in charge of location. This line ran through the Dakota Hills and necessitated some heavy grading and bridge work. He also located and platted fourteen town sites along this line.

In 1885 and 1886, Mr. Dawley first located and then constructed 65 miles of the Chicago and Indiana Coal Railway, which later became the Indiana Division of the Chicago and Eastern Illinois Railway. The following year he was in charge of construction of 30 miles of line southwesterly from Des Moines, Iowa; this line later was incorporated as one of the component parts of the Chicago Great Western Railroad.

In 1888, Mr. Dawley became Special Assistant Engineer to the Vice-President of the Chicago and Eastern Illinois Railway Company, with which road he remained until 1906, having been made Principal Assistant Engineer in 1890 and Chief Engineer and Engineer of Maintenance of Way in 1894. In many respects, this was the most active period of his life and the one of greatest responsibilities. Railroad mileage was being extended at a rapid pace, and Mr. Dawley had by this time a reputation as a railroad builder which made his counsel much sought. In addition to being in full charge of all engineering work, both construction and maintenance, for the Chicago and Eastern Illinois Railway Company, he located and, subsequently, built the extension from Tuscola to Shelbyville, Ill. Later, he extended the line in Illinois to Thebes on the Mississippi River and to Joppa on the Ohio River. During this 18-year period, he located and constructed more than 500 miles of railroad. In addi-

* Memoir prepared by Baxter L. Brown, M. Am. Soc. C. E., and Milton M. Kinsey, Assoc. M. Am. Soc. C. E.

tion, Mr. Dawley re-designed and rebuilt the yard at Danville, Ill., and the Terminal Yard at Dolton, Ill.

In 1906, Mr. Dawley left the Chicago and Eastern Illinois Railway Company to become Chief Engineer of the Missouri and North Arkansas Railway Company. In the following three years he located 210 miles of new line in Missouri and Arkansas, about one-half of which was in the Ozark Mountains, and required heavy grading and a large number of steel bridges, including a 300-ft. draw-span over the White River. He purchased the right of way for this line and completed its construction, having expended in three years more than $5 000 000.

In 1909, at the earnest solicitation of Onward Bates, Past-President and Hon. M. Am. Soc. C. E., Mr. Dawley signed a contract as Chief Engineer of the newly formed Yunnan, Szechuan and Teng Yueh Railway Company of China. Mr. Bates had just returned from a trip to China and had been asked to assist in the selection of an engineer for the railway. On his arrival at Yunnan Fu in Southwest China, Mr. Dawley found it necessary to train twenty young Chinese in the art of surveying before he was able to commence the work of location. His success at this unusual engineering task is evidenced by the fact that in the next four years he had completed the exploration and reconnaissance surveys for more than 1 400 miles of railway and the preliminary and final location surveys and estimates for 600 miles of additional track. All this work was in the extremely mountainous district of Southwestern China.

The unsettled condition of the country and the Revolution which resulted in the formation of the Chinese Republic produced long periods of inactivity, however, and the railroad was never constructed. After a number of rather hazardous experiences, Mr. Dawley returned home in 1913.

On his return, he entered private practice as Consulting Engineer and assisted Bion J. Arnold, M. Am. Soc. C. E., in a study and report on the railroad terminals of Chicago. He made similar studies with Mr. Arnold at Flint, Mich., in 1915, and at Baltimore, Md., in 1917. In 1918, he became associated with C. E. Smith and Company, Consulting Engineers, of St. Louis, Mo., and was in charge of many problems of river freight-handling facilities as well as railroad, industrial, and civic problems.

Although more than 60 years old at the time of the World War, Mr. Dawley made application to enlist in the Army and was commissioned a Major only to have the commission rescinded immediately due to his age. He was employed by the Government, however, as Consulting Expert on the Army Base at New Orleans, La., and, later, was assigned to the United States Railroad Administration to assist in settling claims arising from the Government operation of the railroads.

Following the war, he became greatly interested in the Federal valuation of railroads. His personal connection with the original construction of many miles of railroad, coupled with his intimate and well retained knowledge of the cost, made him much in demand to present expert opinion before the Interstate Commerce Commission. It was while on an inspection trip, preparing for a

railroad valuation case, that Mr. Dawley suddenly became ill on the train, and died shortly thereafter.

Mr. Dawley was particularly fond of young engineers, and many of them have been made better engineers and better men by the kindly and unassuming way he had of explaining to them the problems that he had faced, as well as by the way in which he always could make clear the ethics of a situation.

That equals and superiors as well as subordinates loved him and trusted him cannot better be told than in that which has been written already by a Railroad President with whom he was associated for years:

"With his ability there is coupled a kindliness of heart and temperament that makes him particularly useful in meeting strangers and adapting himself to changing conditions, and he has ability without a display of vanity and will never offend even the poorest laborer, nor be a party to corruption no matter from what source it may arise."

Mr. Dawley was a member of the Western Society of Engineers, the St. Louis Engineers' Club, the St. Louis Railway Club, the Circle Club, and the City Club of St. Louis. He was active in the founding, and was a Charter Member, of the American Railway Engineering Association and served as the first Treasurer of that Association, holding the position from 1899 to 1909.

In 1890, Mr. Dawley was married to Angie Louise Havens. Mrs. Dawley and a daughter, Helen Louise, survive him.

Mr. Dawley was elected a Member of the American Society of Civil Engineers on October 4, 1905.

JAMES HOPKINS DOUSMAN, M. Am. Soc. C. E.*

DIED JANUARY 5, 1925.

James Hopkins Dousman was born at Milwaukee, Wis., on September 24, 1863. After completing the courses in the public schools at Milwaukee, he entered the University of Wisconsin, at Madison, Wis., from which he was graduated with the Class of 1884. Even in early life he displayed an energy which was always one of his most prominent attributes. By utilizing all his vacations and other spare time, he managed to acquire the equivalent of one and one-half years of actual experience. During this period he worked for the County Engineering Department at Milwaukee, the Chicago, Milwaukee, and St. Paul Railroad Company, and for the late C. B. Davis, M. Am. Soc. C. E., a Consulting Engineer, at Chicago, Ill.

After graduation, his first position was that of Transitman with the United States Engineer Corps; subsequently, for three years he acted as Deputy County Surveyor of Edwards County, Texas; and then from 1888 to 1892 as Engineer for the Land and Station Department of the Galveston, Harrisburg, and San Antonio Railroad Company.

In 1893, Mr. Dousman organized the firm of Dousman and Sheldon, Engineers, of Milwaukee, which firm was succeeded in 1895 by that of Dousman and Austin, Consulting Engineers, also of Milwaukee. During this period of private practice, Mr. Dousman was connected with a number of important projects, including work for the Chicago, Milwaukee and St. Paul Railroad Company and water-works and sewage design for the Cities of South Milwaukee and Delevan, Wis., and others. Also, during this period he invented an automatic pressure regulating valve for stand-pipes and other hydraulic work. These valves were used in a number of cities, and a special installation was made for the Cataract Construction Company, at Niagara Falls, N. Y. Mr. Dousman also invented the "Dousman hangers" for carrying falsework on steel construction when concrete or terra cotta is used for fireproofing. In 1898, he became associated with the Milwaukee Engineering Company and held the office of Secretary of that Company until 1902. From 1902 until 1906, he was again engaged in private practice in Wisconsin, specializing in water-works and reinforced concrete design.

In 1906, he took charge as City Engineer of an important water-works improvement at Trinidad, Colo., which work he finished in a highly creditable manner. He then went to Kansas City, Mo., as Representative of the American Well Works of Aurora, Ill., in Kansas, Oklahoma, Western Missouri, and Southern Nebraska, and continued this connection until his death.

There were few, if any, who could equal Mr. Dousman in the energetic way in which he not only sought and obtained contracts, but also in the way these contracts were completed. In addition to serving his firm well, he rendered a great service to the purchaser and the public in expert and trustworthy counsel and advice. He was successful, and universally liked and

* Memoir prepared by N. T. Veatch, Jr., and Bert C. Wells, Members, Am. Soc. C. E.

respected, and his passing is deeply mourned by all who knew him. He not only had the respect and friendship of those to whom he was selling, but also that of his competitors. Until his last sickness, Mr. Dousman's entire life as an engineer had been spent in an active and earnest effort to discharge each task undertaken with credit, and in this he succeeded to an unusual degree. During his experience as Machinery Salesman a competitor once said: "I have never heard any one, anywhere, question Jim Dousman's honesty, and for energy he has anybody beaten I have ever seen."

Mr. Dousman died at his home in Kansas City on January 5, 1925. He is survived by his widow, Ina M. Dousman, two sons, Donald J., of Kansas City, and Albert H., of Long Island, New York.

Mr. Dousman was elected a Member of the American Society of Civil Engineers on April 3, 1922.

JOHN STANTON ELY, M. Am. Soc. C. E.*

DIED MARCH 30, 1928.

John Stanton Ely, the son of the Rev. John Hugh and Mary (Stanton) Ely, was born March 12, 1874, at Hillsboro, Ohio. He was the grandnephew of Edward M. Stanton, Abraham Lincoln's Secretary of War.

Mr. Ely was educated at Kenyon College and the Ohio Military Institute, from which he was graduated in 1892. From 1892 to 1895 he was engaged in private practice with a civil engineer in Cincinnati, Ohio, after which he was employed by the Cleveland, Cincinnati, Chicago and St. Louis Railway Company ("Big Four") as Assistant Engineer, Maintenance of Way.

During the Spanish-American War Mr. Ely served five months in Cuba with the 2d Regiment, U. S. Engineers. Directly following his return from Cuba he was engaged with the Baltimore and Ohio Railway Company in charge of a field party. He then spent a short time with the Niagara Falls Power and Light Company on construction work.

In 1901, he entered the employ of Westinghouse, Church, Kerr, and Company, Pittsburgh, Pa., and was engaged on the construction of a high-speed electric line between Scranton and Wilkes-Barre, Pa. The following year he entered the service of the Bureau of Filtration of the City of Philadelphia, Pa., which was later combined with the Bureau of Water. He remained in this position until 1918, when he was granted a leave of absence to join the New York Shipbuilding Corporation.

During this period Mr. Ely was engaged in detail construction work on the Torresdale Filters and large distribution pipe lines, serving also as Resident Engineer in charge of construction of the Torresdale preliminary filters and the design and construction of the Queen Lane Filter Plant. For the New York Shipbuilding Corporation he was Estimating, Distributing, and Construction Engineer. His duties consisted principally of estimating the progress on ships, designing buildings, as well as computing the cost of the new $11 000 000 shipyard.

In August, 1920, he returned to the Bureau of Water of Philadelphia as Engineer of Design and Construction. The most important parts of this work were the studies in relation to the water supply of Philadelphia and the proposed new sources; the construction of a 48-in. pipe line under the Girard Avenue Bridge; and the design and construction of the New Fairmount Dam, a concrete ogee dam, 1 120 ft. long, across the Schuylkill River just below the old wooden Fairmount Dam.

In August, 1926, Mr. Ely resigned to become Division Engineer of the Water Department of Newark, N. J., which position he held until February, 1928, when he was appointed Chief of the Bureau of Water of Philadelphia. His death occurred on March 30, 1928, before he actually assumed the duties of this position.

In November, 1927, he was injured in an automobile accident while on an inspection trip for the Newark water supply in the hills of Northern New

* Memoir prepared by Lyle L. Jenne, Assoc. M. Am. Soc. C. E.

Jersey. A car turning sharply across the road forced his driver to skirt the ditch, throwing Mr. Ely from the seat, striking his spine. For a time it was thought his back was broken, but he recovered from the injury. It is believed, however, that the shock seriously affected his health. In February, 1928, he went to Florida, hoping the change would benefit him. He went to the Halifax Hospital near Daytona, but became gradually worse. After a month he came north to the University Hospital in Philadelphia. In his weakened condition pneumonia developed, and he lived only five days.

Mr. Ely was of a quiet nature and possessed the quality of inspiring the respect and affection of his associates and friends by whom he is sincerely missed. He was fond of sports and was an enthusiastic and able golfer.

On October 17, 1900, he was married to Mary Elizabeth Johnson, of Louisville, Ky., who survives him.

Mr. Ely was elected an Associate Member of the American Society of Civil Engineers on March 2, 1904, and a Member on October 1, 1913.

CHARLES FREDERICK WILSON FELT, M. Am. Soc. C. E.*

DIED FEBRUARY 4, 1928.

Charles Frederick Wilson Felt was born on April 29, 1864, at Salem, Mass. He was a descendant of George Felt, who, with John Endicott, came to Salem in September, 1628, and founded, on June 24, 1629, the Town of Charlestown (now a part of Boston), Mass., named in honor of Charles the First.

The history of New England records the activities of this family and its branches in the settlement and development of the region centering around Casco Bay and Boston. One of Mr. Felt's antecedents was Captain John Felt, who bore an honorable part in the War of Independence against the British, particularly against the latter's aggression at North River Bridge, Salem, wherein they demanded the store of cannon held by the Colonists, on February 26, 1775, culminating in a melee, "which may be justly recorded the first blood of the Revolution."

Charles Wilson Felt, the father, following his graduation from Bridgewater Normal School in 1859, spent many years on the invention of a typesetting machine. Later, he became an author and publisher in Worcester, Mass. He married Martha Seeth Ropes and three children were born to this union.

The early years of Charles Frederick Wilson Felt were spent with relatives at Salem, and at Elizabeth, N. J., because of the death of his mother. Later, he resided at Danvers, Wakefield, Harvard, and Northborough, Mass., with his father, who had re-married. As a young man he worked on farms near Southborough and Bolton, Mass., attending neighboring schools, supplementing family funds with his own efforts, and helping to pay his way through college. He was graduated with the degree of Bachelor of Science from the Massachusetts College of Agriculture at Amherst in 1886.

Work was then his desire and necessity. In September, 1886, he turned to the West where an era of railway construction beckoned. He found his first position as an Axeman on the Atchison, Topeka and Santa Fé Railway, which at that time had an active program of expansion under way in the States of Kansas and Colorado. In this connection, and, subsequently, while with the Denver and Rio Grande, Arizona and Eastern, and the, then, Santa Fé line from Nogales to Guaymas, Mexico, he held the various positions that fell to a young engineer engaged in pioneer railway location and construction.

In May, 1890, he returned to the Santa Fé Company as Resident Engineer at Galveston, Tex., where he remained until July, 1892. Following a brief service on the Rio Grande Southern Railway in Colorado as Office Engineer, he again returned to the Gulf Lines in February, 1893, as Division Engineer, and in May, 1893, he was appointed Resident Engineer of the same line at Galveston. While thus employed, the Texas Railroad Commission, under the so-called Stock and Bond Law, made a valuation of the Gulf Lines of the Santa Fé Railway in which his work, on behalf of the Railway Company, was a conspicuous part.

* Memoir prepared by a Joint Committee of the Society and the Western Society of Engineers, consisting of G. W. Harris and C. A. Morse, Members, Am. Soc. C. E., and J. de N. Macomb, Assoc. M. Am. Soc. C. E.

In September, 1896, Mr. Felt was appointed Chief Engineer of the Gulf, Colorado, and Santa Fé Railway, with headquarters at Galveston. Shortly thereafter, the Company undertook an extensive program of reconstruction and improvement work, which was planned and executed under his direction. Also, under his supervision, several hundred miles of extensions were constructed in the States of Texas, Oklahoma, and Louisiana. During this time, he also directed the preparation of several important valuations, the need for which arose in connection with the demands of the Railway Commissions of the States of Texas and Oklahoma, as well as the needs of the Company, in connection with rate-case litigation.

In November, 1909, Mr. Felt was appointed Chief Engineer of the Atchison, Topeka and Santa Fé Railway, with headquarters at Topeka, Kans. This placed him in charge of directing the engineering features in connection with maintenance and improvement work on the Eastern and Western Lines of the Santa Fé System. The mileage of second track was extended; terminals and shops were enlarged; bridges were strengthened; and the physical plant of the road was generally improved. He also directed and participated in the work of preparing several important rate-case valuations.

In April, 1913, he was appointed Chief Engineer of the entire Santa Fé System, with headquarters at Chicago, Ill. He brought to this last assignment an ability enriched with experience and a high degree of engineering skill. In this position he had charge of all engineering, construction, and valuation work. This embraced the standardization of methods and plans, the use and service of materials and appliances, the development of timber treatment, the location and construction of extensions to existing lines, and the general supervision of engineering matters on the entire system. The extensions and new lines added to the System amounted to more than 800 miles.

During this time, also, there was initiated and completed the inventory, pricing, conferences, and hearings arising out of the Federal Valuation Act. Mr. Felt's special qualifications and zeal peculiarly fitted him to co-ordinate and direct this work. It is worthy of recital that when he first entered its employ, the Santa Fé operated 5 348 miles of road, which, by the close of his service, had increased to 12 349 miles of main line and branch lines and 1 724 miles of second track, to which increase he had given his best efforts—his all.

Mr. Felt was a Member and a Past Vice-President of the Western Society of Engineers. He was a Charter Member and Past-President of the American Railway Engineering Association, in the work of which he took an active part. He was also a member of the American Railway Association, American Railway Guild, and Past-President of the Chicago Engineers' Club.

He was affiliated with, and was Past-President of the Trustees of, the Hyde Park Presbyterian Church, in Chicago, at the same time retaining his membership in the First Presbyterian Church, which he joined in December, 1893, at Galveston, where the funeral and interment were held.

The following is quoted from a resolution of the Board of Directors of the Atchison, Topeka and Santa Fé Railway Company, passed at its meeting on February 7, 1928:

"*Resolved*, That the Directors express their great sorrow in the death on February 4, 1928, of C. F. W. Felt, System Chief Engineer. * * * Mr. Felt's engineering experience included surveys, location, construction, maintenance, and all engineering problems involved in operation. His ability and his thorough knowledge of engineering, and broad experience, his kindliness to his associates and his fairness in dealing with public authorities, won for him the highest respect and consideration of all. Every one who knew Mr. Felt loved him and feels in his death a personal loss."

He was married on April 6, 1904, to Clara C. Root, of Galveston, who survives him. He is also survived by one brother, Dr. E. Porter Felt, of Nassau, N. Y., two half-brothers, George H. Felt, of Northborough, Mass., and Benjamin F. Felt, of Melrose, Mass., and a half-sister, Elizabeth Ann Felt, of Boston, Mass.

Mr. Felt was elected a Member of the American Society of Civil Engineers on March 3, 1897.

JOSIAH FOSTER FLAGG, M. Am. Soc. C. E.*

DIED APRIL 13, 1928.

Josiah Foster Flagg was born in Dedham, Mass., on September 4, 1835, the son of Josiah Foster and Mary (Wait) Flagg.

From the Boston Latin School he entered Harvard University, at Cambridge, Mass., from which he was graduated in 1854 with the degree of Bachelor of Science, *Summa cum laude*. Immediately following his graduation he was employed as Rodman and Draftsman on the Cleveland, Columbus and Cincinnati Railroad.

In the spring of 1855, Mr. Flagg returned to Boston, Mass., where he was employed as Assistant Observer and Computer at the Harvard Observatory, having prepared himself for such work before graduating from college. While engaged in astronomical observations he went on one of the expeditions to England, in charge of fifty-two chronometers, for the purpose of checking the difference in longitude between Greenwich and Washington. This engagement led to his appointment as Assistant to Lieutenant Gisliss, at the Washington Observatory, in reducing the astronomical observations which the latter had previously made in Chile.

In the spring of 1857 Mr. Flagg resigned from the Observatory Staff to become Assistant Engineer under General (then Captain) M. C. Meigs, in charge of the United States Capitol and General Post Office extensions, and also of the Washington Aqueduct. He continued in this position until the close of 1859 when deficient appropriations necessitated a general reduction of the staff.

In the spring of 1860 he became Assistant Engineer to the late James B. Francis, Past-President and Hon. M. Am. Soc. C. E., in charge of the locks and canals at Lowell, Mass. This work, however, terminated toward the close of the year.

When the Civil War commenced Mr. Flagg offered his services to the nation in a civil engineering capacity. Not being successful in his patriotic efforts in Massachusetts, he went to Washington to further his claim for service. While he was there, the Battle of Bull Run occurred and in the tense situation that followed, further effort seemed hopeless.

In August, 1861, he accepted a position as Draftsman with Bement and Dougherty in Philadelphia, Pa. At that time this firm was second in importance to that of William Sellers and Company as manufacturers of machine tools. Later in the same year he was sent by this firm to the Springfield Armory to study the methods of making muskets, machine tools for quantity production of small arms being in great demand at that time.

In March, 1862, Mr. Flagg resigned this position to join the Atlantic and Great Western Railroad Company, subsequently the New York, Pennsylvania and Ohio Railroad, at Meadville, Pa. For ten years he served this Company in an engineering capacity as well as Land and Tax Agent and sometimes as Paymaster.

* Memoir prepared by James R. Chapman, M. Am. Soc. C. E.

In March, 1872, he resigned this position to take charge of the erection of machinery for an extensive nitrate plant at Iquique, Peru. This work required two years for completion. In 1874, Mr. Flagg assisted in the examination of the Magdalena River in Venezuela in connection with a project to improve it for navigation.

Following his return to the United States in 1875, he was one of three mechanical experts engaged to test steam engines and other machines entered in competition at the Cincinnati Exposition. The tests and compilation of the reports took several months.

In January, 1876, Mr. Flagg returned to Meadville, Pa., as City Engineer, taking up the private practice in his profession at the same time. He occupied this position for five years, resigning in 1881 to take charge of the construction of the Pacific end of the Mexican National Railway, with headquarters at Colima, Mexico. During the following three years he located, constructed, and operated 130 miles of line mostly in a very rough and difficult country. The fact that the office of the General Manager was in New York and that of the Chief Engineer in the City of Mexico—a ten-day journey—left Mr. Flagg in a position of great responsibility. All construction material and rolling stock were received by vessel. Right-of-way details and the disbursement of all funds were in his charge. Due to financial difficulties which caused a suspension of construction, he resigned in 1884.

After some months spent in travel, Mr. Flagg went to Cuba in the fall of 1885, to report on proposed plans for water supplies for the Cities of Santiago and Guantanamo. After returning from Cuba he was placed in charge of the up-town works of the New York Steam Company, in New York, N. Y.

Subsequently, Mr. Flagg was employed by the Engineering Commission appointed to formulate plans for sewage disposal at Washington, D. C. He was in charge of the investigations and computations necessary for the prosecution of the undertaking.

At the conclusion of this service he traveled extensively in Europe and North Africa, making many investigations relative to sewage disposal as developed in England and on the Continent. The latter years of his life were spent in retirement in Santa Barbara, Calif., where he died.

Mr. Flagg was married on April 13, 1858, to Emma A. Wiggin who died in May, 1888. One daughter was born to them, Helen B. Flagg, who died in 1902. On December 3, 1903, he was married to Florence N. Dukes, of Brooklyn, N. Y., who survives him.

Mr. Flagg was elected a Member of the American Society of Civil Engineers on October 7, 1874.

AUSTIN BRADSTREET FLETCHER, M. Am. Soc. C. E.*

DIED MARCH 8, 1928.

Austin Bradstreet Fletcher was born at Cambridge, Mass., on January 19, 1872. His father, Ruel H. Fletcher was, during a long and active life, a teacher in the public schools of Cambridge. His mother was Rebecca C. (Wyman) Fletcher. They were descendants of English stock, whose ancestors came to Massachusetts in early Colonial times.

Mr. Fletcher prepared for Harvard University at the Cambridge High School, and entered the Lawrence Scientific School in the fall of 1889. After two years of work in the general Science Course, he took courses in Civil Engineering, and was graduated in 1893, receiving the degree of Bachelor of Science.

Immediately after his graduation from college, he took a position as Secretary with the newly organized State Highway Commission of Massachusetts, and remained in the employ of this Commission until 1910. He had not been long in active work before he gave evidence of that exceptional executive and administrative ability for which he became noted. At the time he left the Massachusetts Highway Commission he was performing the duties of Executive Officer and Chief Engineer of the Commission.

The State Highway work in Massachusetts was pioneer work in this field, and attracted nation-wide attention, both for the actual work accomplished, as well as for the organization developed. Great credit was given Mr. Fletcher for the smooth-running, efficient organization that he perfected, the personnel of which was maintained for more than twenty years. This alone presents a great contrast to the many changes which have so often characterized public works enterprises.

During the time he served the Massachusetts Highway Commission, this organization was given supervision over the long-distance telephone lines along the public highways, which in consequence greatly broadened the scope of his duties.

At this period the character of highway traffic was undergoing a great change. It was evident that the past methods of construction would be insufficient to withstand motor traffic. The great problem presented was how most economically to treat the roads already built in which large sums had been invested, and also how best to build the new roads. No one foresaw these changes and the new demands better, or felt the responsibility more keenly, than did Mr. Fletcher. The many experiments and methods of treating road surfaces that were carried on by the Massachusetts Highway Commission attracted the widest attention. At the time Mr. Fletcher severed his connection with the Commission he was established as the foremost engineer in the highway field.

In 1910 he was induced to accept the position of Chief Engineer of the Highway Commission of San Diego County, California, where a construction

* Memoir prepared by A. N. Johnson, M. Am. Soc. C. E.

program involving millions of dollars was planned. He was engaged in this work scarcely a year when he was appointed the first State Highway Engineer of California. Here, he was destined to accomplish the greatest and most comprehensive program that has fallen to the lot of any highway engineer. One of Mr. Fletcher's colleagues in this work pays the following well-deserved tribute:

"So well did he install system in California that few changes have been made, or perhaps can be made, in the engineering principles and standards devised by this far-seeing pioneer of highway development. His ideas and ideals will ever remain foundation stones of the organization structure of the State Highway Department of California".

While engaged as State Highway Engineer of California, Mr. Fletcher was called in consultation, on several occasions, by the United States Bureau of Public Roads. During the summer of 1916, he assisted in drafting the rules and regulations to carry into effect the Federal Aid Road Law, which had just been passed by Congress.

Following the death, in 1918, of Logan Waller Page, M. Am. Soc. C. E., Chief of the United States Bureau of Public Roads, Secretary Houston, of the Department of Agriculture, tendered this position to Mr. Fletcher, who declined it, preferring to carry on the great road program in California, in which he was engaged.

From 1917 to 1923, in addition to his highway duties, he was President of the California State Reclamation Board, and from 1921 to 1923, he was Director of Public Works of California. In January, 1923, he was called East to act as Consulting Engineer for the New England Rail Committee. This Committee was made up of representatives of six New England States to study the whole transportation system in New England. Mr. Fletcher made a study and submitted a report on the motor-truck transportation phase of this investigation.

From September 1, 1923, until his death, Mr. Fletcher was connected with the United States Bureau of Public Roads as Consulting Highway Engineer.

In 1908, he was sent, as delegate from Massachusetts, to the First International Road Congress, held in Paris, France. He attended the Third International Road Congress held in London, England, in 1913, as delegate from California. In 1914 he was chosen President of the American Road Congress, which was held at Atlanta, Ga., in November of that year. During the World War he was a member of the Executive Committee of the California Council of Defense.

He was the author of a *Bulletin* on Macadam Roads issued by the United States Department of Agriculture in 1906. He contributed the chapter on "Drainage" in the American Highway Engineer's Handbook, and published many papers in various technical journals.

Mr. Fletcher was a member of the American Society for Testing Materials, the American Association of Engineers, the American Concrete Institute, the Boston Society of Civil Engineers, the Massachusetts Highway Association, the American Road Builders' Association, the American Association of State

Highway Officials, the Permanent International Association of Road Congresses, and a Fellow of the American Geographic Society.

He took a great interest in and was a member of a number of historical and patriotic societies, among which were the New England Historic-Genealogical Society, the Massachusetts Society of Sons of the American Revolution, and the Society of the Colonial Wars of California. He was a member of the Cosmos Club, of Washington, D. C., of the Harvard Club, of San Francisco, Calif., and of the Harvard Engineers Club, of New York, N. Y.

Mr. Fletcher died on March 8, 1928, at his home in Chevy Chase, Md. He had just returned from a business trip to Cleveland, Ohio, where he contracted a severe cold that developed into pneumonia.

On March 1, 1894, he was married to Ethel Hovey, of Cambridge. There were two children, Dorothy, now Mrs. Laurence H. Chapman of Sacramento, Calif., and Norman, who died when but seven years of age.

Although Mr. Fletcher was shy, sensitive, and modest to a fault, he was, nevertheless, an exacting and firm administrator. He wasted little time on what he considered useless argument and speculation; he was not to be stampeded. He had that essential quality of all great executives, the ability to select a capable personnel, and to inspire and maintain in his organization that spirit of loyalty and enthusiasm aptly called *esprit de corps*. While he was severely just in his dealings with subordinates, his disciplinary measures were always tempered with a kindliness that left no heart-burnings.

Those of the organization which he perfected in California speak of him with the greatest respect and loyalty. In the April, 1928, number of the Official Journal of the Department of Public Works of California, dedicated to him, there is paid this testimonial to his all too short, but useful, life:

"Mr. Fletcher lived to see the tree of his life mature and fruit in an added happiness and an enlarged usefulness given to the whole people of California. What greater monument could any one build? What greater reward could any one ask?"

Mr. Fletcher was elected a Member of the American Society of Civil Engineers on June 1, 1909.

GEORGE WASHINGTON GOETHALS, M. Am. Soc. C. E.*

DIED JANUARY 21, 1928.

George Washington Goethals was born on June 29, 1858, in Brooklyn, N. Y., the son of John Louis Goethals. His family was of Dutch extraction. He entered the College of the City of New York at the age of fourteen, and remained there for three years. He was then selected for a cadetship at the United States Military Academy by the Hon. S. S. Cox, Representative in Congress of the 6th District of New York. At West Point, Mr. Goethals was much liked by his classmates and other cadets, and maintained a prominent standing in his studies and his military duties. He was a Cadet Captain in his first-class year, and was elected President of his Class. Upon graduation in 1880, he was one of two to receive commissions in the Corps of Engineers of the United States Army.

After serving for two years at the Engineer School and with the Battalion of Engineers at Willets Point, N. Y. he was appointed Engineer Officer of the Department of the Columbia, with station at Vancouver Barracks, Vancouver, Wash. He then served for a year as Assistant to the late Col. W. E. Merrill, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., on the works of improvement of the Ohio and tributary rivers. From 1885 to 1889 he was Instructor and Assistant Professor of Civil and Military Engineering at the United States Military Academy, and from 1889 to 1891, Assistant to the late Col. J. W. Barlow, Corps of Engineers, U. S. Army, on the work of improvement of the Tennessee and Cumberland Rivers.

During the next three years Captain Goethals was in charge of the Tennessee River improvement and the completion of the Muscle Shoals Canal, including the design and construction of the Colbert Shoals Lock. There, he added to his previous insight into problems of canal construction and of administration and direction of work executed by the Government without intermediary contractor.

From 1894 to 1898 he was Assistant in the office of the Chief of Engineers, U. S. Army, in Washington, D. C. At the outbreak of the Spanish-American War he was appointed Lieutenant Colonel of Engineers in the Volunteer Service and assigned as Chief Engineer of the First Army Corps. As such, he organized and constructed the water supply system of the camp at Chickamauga, Ga., and directed the engineering operations of the Corps in the Porto Rican Expedition.

At the conclusion of the war he reverted to his regular rank of Captain and was appointed Instructor of Practical Military Engineering at West Point, being also in charge of completing the water supply system of the Post and the reconstruction of the Library Building. He was promoted to a Majority in February, 1900, and served in charge of works of river and harbor improvement and fortification in Rhode Island and Southeastern Massa-

* Memoir prepared by H. F. Hodges, M. Am. Soc. C. E.

chusetts, until the creation of the General Staff of the Army under President Roosevelt and Secretary of War Root, in 1903. Major Goethals' outstanding qualifications prompted his selection on the first list of this body of picked men. His tour of duty with the General Staff had almost reached the statutory limit of four years when, as a Lieutenant-Colonel, he was selected by President Roosevelt to be Chairman and Chief Engineer of the Isthmian Canal Commission, succeeding John F. Stevens, Past-President and Hon. M. Am. Soc. C. E., who had tendered his resignation. At the same time radical changes were made in the remaining personnel of the Commission, and all the members were required to live on the Isthmus of Panama in immediate touch with the field work.

The year ended December 1, 1906, was stated by the then existing Commission in its last Annual Report to have virtually closed the stage of preparation. In that stage, plant for excavating and other work had been purchased or ordered on liberal lines, commensurate with the extent of the project. A railroad transportation system had been organized which was ample and well suited to dispose of the spoil from Culebra Cut. A good plan of recruitment of labor had been put into operation and an adequate supply assured. In matters of sanitation, quarters, and subsistence, a great deal had been accomplished, and wholesome living conditions had been created for the large and increasing forces. Good progress had been made with the preliminary work upon which the final designs for the canal structures, as then planned, could be based.

By the time the new Commission, with Colonel Goethals at its head, took charge, on April 1, 1907, the excavation was well started and a considerable volume had been removed from the canal prism in Culebra Cut and from the site of the Gatun Locks. Nevertheless, serious and difficult problems of plan, organization, and execution, vital to the success of the work, remained to be solved. The designs for the locks, dams, and accessories had to be adopted definitely and pushed to rapid completion; the manner of carrying out the work, whether by contract or hired labor, a question which was still open, had to be decided; the plant to mix and lay millions of yards of concrete had to be designed and built; certain matters which were considered as settled, such as the width of the Culebra Cut, the position of the locks and dams near the Pacific Terminal, the width of the locks, the location of the new Panama Railroad, and the position of the Atlantic breakwaters, had to be re-opened and the original decisions changed. The great terminal piers, the Pacific dry dock, the coaling plants, and the permanent shops, were so far in the future that they had not even been included in the plan; the actual work of excavation and construction had to be carried on and completed; the constructing organization changed from time to time to suit the advancing work; and, finally, an organization had to be developed for operating the canal and its subsidiary activities after completion.

Whereas the chief credit for the construction of the Panama Canal rightly belongs to the man who was for seven years its Chief Engineer and under

whom the greater part of the work was done, the Canal itself will always be a monument to the genius and ability of the American engineer. Many members of the Society, and many others whose names do not appear on its rolls, contributed to the successful result and have a share in the honor.

By Executive Order of January 6, 1908, President Roosevelt restated the duties of the Commission, placing an increased measure of authority and responsibility in the hands of the Chairman individually; and from that time forward no one doubted who was in control of the work, and no one in the Canal force doubted its ultimate success.

The achievements of the next seven years are already well-known to those who will read this memoir, and require no extended recounting here. The Canal was finished within the estimate of cost made in 1908, and was opened to traffic before the date then set. Operation, however, was interrupted later for some months by slides in the Culebra Cut, but the Canal has since been serving a heavy traffic which threatens to tax its capacity.

Toward the conclusion of the construction period, when the organization for operation was developed, Colonel Goethals was made the first Governor of The Panama Canal. On March 4, 1915, he was made a Major General of the Line of the Army and received the thanks of Congress for his services. On November 1, 1916, he was retired from active service at his own request.

In 1917 he was appointed State Engineer of New Jersey by Governor Edge. After a few months spent in laying out a new highway system for New Jersey and in practice as Consulting Engineer, he was appointed by President Wilson to be General Manager of the Emergency Fleet Corporation, United States Shipping Board. He was pronounced in his opposition to the plans for extensive construction of wooden ships, and resigned from the Fleet Corporation in July, 1917, to resume his consulting practice.

In December, 1917, General Goethals was recalled to active service and made Acting Quartermaster General, United States Army. In this capacity and as Assistant Chief of Staff and Director of Purchase, Storage, and Traffic, he served through the remainder of the World War, and until March 4, 1919, when he was relieved at his own request from further active duty. He then again took up his practice as Consulting Engineer in New York City, a practice in which he continued until his death. During its course he was associated for a time with the firm of Jamieson, Houston, Graham, and Jay, subsequently absorbed by George W. Goethals, Inc., of which Company he was President. He was also President of Goethals, Wilford, and Boyd, Inc., and of the American Ship and Commerce Corporation.

General Goethals and his associates were consultants on many important works, such as the Inner Harbor Navigation Canal at New Orleans, La.; the Columbia Basin Irrigation Project; the East Bay Municipal Utility District, of Oakland, Calif. and the Lake Worth Inlet District, in Florida. The New York-New Jersey Port and Harbor Development Commission, created by Acts of the State Legislatures in 1917, selected him as its Chief Consulting Engineer, and he continued as such with The Port of New York Authority created by the same Legislatures in 1921 to carry into effect the compre-

hensive plan prepared by the earlier Commission for re-organizing the facilities for, and modernizing the methods of, handling the commerce of the Port of New York. His connection with this great work continued until his death. In January, 1923, he was appointed Fuel Administrator of the State of New York, and served as such for a few months.

General Goethals possessed in a marked degree the technical qualifications, the good professional judgment, and the administrative and organizing ability which characterize the great engineer; but perhaps the most effective weapon in his armament was his tremendous driving power. This was not shown in arbitrary pressure or nagging criticism. Indeed, it would not be far wrong to state that it acted as much by inspiring as by spurring his subordinates; for he spared himself no more than he did them.

He succeeded in winning the confidence, respect, and even affection of the working force on the Isthmus, to a remarkable extent. Every one among them felt sure of fair treatment at his hands. His spirit rose especially against anything which savored of oppression of the lower by the higher; this characteristic was so well-known that all felt free to lay any case of real or fancied injustice before him in person, without fear of unpleasant after effects. His Sunday mornings were spent in such personal interviews. While they thus absorbed much of his scanty leisure time, and even more of his nervous energy and, perhaps, his patience, they were more than worth while, because of the intimate relation which they built up with the men in the ranks, and the consequent abiding trust in him which was the certain result.

General Goethals was a warm and steadfast friend to those to whom he gave his confidence; but this was not given readily, nor until he had proved to his satisfaction that it could be based upon esteem as well as personal regard. Once given, it was rarely withdrawn. Those who possessed it would have gone to any lengths for him.

He was a man of strong opinions, but open to argument and tolerant of difference from his own views, even of opposition to them, as long as a plan might be still under consideration. Once the matter had been decided and directions given, he expected loyal compliance, and did not welcome any attempt to revive the issue. To take such a step one had to have a very good reason and be sure of his ground.

For his service during the World War General Goethals received the Distinguished Service Medal from the President of the United States; the Cross of Commander of the Legion of Honor from the President of the French Republic; and was made Honorary Knight Commander of the Order of St. Michael and St. George by the King of England. He received also the Grand Cordon of the Order of the Striped Tiger, 2d Class, from the Chinese Government. He was the holder of numerous medals, among them the John Fritz Medal "for achievement as builder of the Panama Canal"; the medal of the National Geographic Society; the Cullum Medal of the American Geographic Society of New York; the President's Medal of the Architectural League; and the medal of the National Academy of Sciences. He received Honorary Degrees of Doctor of Laws from Harvard, Yale, and Princeton

Universities, the University of Pennsylvania, Johns Hopkins University, and Dartmouth College; of Doctor of Philosophy from the Chicago Polytechnic Institute; of Doctor of Science from Columbia and Rutgers Universities; and of Bachelor of Science from the College of the City of New York, which he attended before going to West Point. He was a member, regular or honorary, of many clubs and societies, social and technical, including the Institution of Civil Engineers of Great Britain and the Royal Engineering Society of Holland.

General Goethals' death was the occasion of many tributes to the high regard in which he was held. The President of the United States wrote that,

"General Goethals will be remembered most widely for his great achievement in the construction of the Panama Canal, as Chief Engineer, and in placing its operation and the administration of the Canal Zone on the extraordinary basis of efficiency which has made it so successful. But his skill and genius were no less marked in other work. Particularly, were they invaluable to the Government during the World War when, coming back from well-earned retirement, he displayed his great ability in a variety of activities. His name was known throughout the world and will remain for all time on the roster of those who have done big things for our country."

The Governor of the State of New York wrote that in his passing,

"The State of New York, as well as the nation, lost a notable public servant. He brought to his duties as Chief Consulting Engineer of The Port of New York Authority that same expert wisdom which made him the genius of the Panama Canal.

"At great personal sacrifice he responded to my request to become Fuel Administrator of the State at a time when we were suffering a serious fuel emergency * * *. Here again, with his great executive talent, his power of decision and of direction, he gave to the State a useful and successful service.

"He has left behind a permanent memory of great personality and a splendid record of achievement."

Many other expressions from those who had been associated with him show how deeply they were impressed by his exceptional ability and by the strength of his character, the purity of his ideals, and the integrity of his motives. In the words of one of them, "He was at all times found equal to the important and responsible positions in which he was placed."

General Goethals was married in 1884 to Effie Rodman, of New Bedford, Mass. His widow and two sons, George R. Goethals, M. Am. Soc. C. E., and Dr. Thomas R. Goethals, of Brookline, Mass., survive him.

General Goethals was elected a Member of the American Society of Civil Engineers on March 1, 1910, and served as Director in 1918.

ALVAH SEYMOUR GOING, M. Am. Soc. C. E.*

DIED MARCH 21, 1927.

Alvah Seymour Going was born at Portland, Ore., on April 7, 1860, the son of James Wallace and Isabella (Eads) Going. His father's family settled at Shirley, Mass., early in the Eighteenth Century, the family name then being Gowing. Mr. Going was educated in the public schools of his native city and for a time attended the Oregon State College.

In 1881 he began his railroad career as Levelman on location for the Oregon Railway and Navigation Company. From 1882 until 1883 he was employed as Transitman on construction of the Clark's Fork Division of the Northern Pacific Railway, and from March to October, 1883, he was in charge of exploration and location surveys for the Astoria and Forest Grove Railroad.

At this time the West was rapidly developing; many railroad projects were under way and this character of work fascinated Mr. Going. He was engaged on many of these projects in Oregon, Washington, Idaho, and in British Columbia, Canada, from 1881 to 1890, when he formed a partnership with Mr. A. W. Miller and entered the general practice of engineering at Port Townsend, Wash. During his association with Mr. Miller he served as Engineer of several small railroads then under construction and also for the Victoria, Port Crescent and Chehalis Railroad, a line about 150 miles in length.

In 1891 Mr. Going moved to Victoria, B. C., Canada, where he engaged in general engineering practice but specialized in the exploration and location of railroads. This practice included work on many small mining railroads and for a time he was engaged on collieries on Vancouver Island.

In 1903 Mr. Going was employed as Reconnaissance Engineer for the projected Grand Trunk Pacific Railway, to explore various routes through the Rocky Mountains, in advance of location survey parties. On these expeditions he was obliged to travel alone, except for Indian guides whom he employed from time to time. This exploration work was started late in 1903, making it necessary for him to spend most of a severe winter alone in a hostile, uninhabited country. He started this expedition with two horses, but was obliged to abandon them and complete the work on foot, arriving at Fort George, B. C., Canada, after many hardships, but in possession of much invaluable information regarding the passes through the Continental Divide. Few engineers could have endured the hardships of this work. It was in this class of occupation that he found the greatest interest. He was at his best when confronted with the problem of finding a location for a railroad through new territory.

In October, 1905, Mr. Going was engaged by the Minneapolis and St. Louis Railroad Company in South Dakota, where he located and built 130 miles of line from Conde to LeBeau on the Missouri River.

During 1907 he became associated with the Grand Trunk Railway Company of Canada as Locating Engineer, with headquarters at Montreal, Que.

* Memoir prepared by R. D. Garner, Esq., Providence, R. I.

As such, he supervised all the location work under way at that time, notably the 85-mile extension of the Central Vermont Railway to Providence, R. I. When the Grand Trunk Railway and the Canadian Northern Railway were merged into the Canadian National Railways, Mr. Going was retained in the Bureau of Economics as Terminal Engineer. He held this position until his death.

Mr. Going is best remembered by those who were fortunate enough to be associated with him for his unfailing energy in helping younger engineers. He was never too busy or too tired to lay aside the work in hand to aid and counsel others. He possessed a remarkable memory which was combined with an almost uncanny ability to know exactly where to look for the engineering information that might be wanted. He was an omnivorous reader. No technical publication escaped him and from these he made innumerable notes and references for future use. In disposition, he was the personification of modesty, and ever tolerant of the defects in the characters of others.

Mr. Going was a member of the Masonic fraternity. He was also a member of the American Railway Engineering Association and served on its Committee on the Economics of Location for many years, having devoted a great deal of study to this work.

While in the South, in December, 1927, Mr. Going was taken seriously ill. He returned to Montreal, where after a lingering illness he died at the Royal Victoria Hospital on March 21, 1927. He is survived by his widow, Harriett Jackson Going, and one daughter, Mrs. Chase Going Woodhouse, of Washington, D. C.

Mr. Going was elected an Associate Member of the American Society of Civil Engineers on May 4, 1892, and a Member on June 7, 1899.

SILAS MAXWELL HAIGHT, M. Am. Soc. C. E.*

DIED SEPTEMBER 29, 1928.

Silas Maxwell Haight was born in Elmira, N. Y., on May 5, 1883. His father, Maxwell Haight, one of those high-minded, great-hearted, jovial men who endear themselves to all, enjoyed a wide popularity in his community. His mother was a woman of beautiful character and great courage whose maiden name was Frances Hendy. She was a direct descendant of John Hendy who held a commission as Colonel in General Washington's Army during the Revolutionary War, himself a surveyor and engineer. He was the first white settler in the Chemung Valley and his descendants have always lived in or near the present City of Elmira.

Mr. Haight's early education was acquired in the public schools and High School in Elmira. He afterward entered Lafayette College, at Easton, Pa., from which he was graduated in June, 1908, with the degree of Civil Engineer.

His first professional engagement was with the City of Elmira as Transitman in the Engineering Department, where he soon assumed responsible charge of much municipal work. He remained with the City of Elmira as Construction Engineer until the outbreak of the World War. In August, 1917, he entered the Officers Training Camp, at Fort Niagara, New York, where he was commissioned a First Lieutenant. He was assigned to duty overseas and attached to the 475th Aero Squadron, American Expeditionary Force. After service in France, he was ordered to Lopcombe Corner, England, where he was placed in full charge of the design and construction of airdrome buildings and pertinent works.

On his return after the war, Mr. Haight resigned his municipal position to take up private engineering work in which he was very successful. He constructed many miles of brick and concrete pavements, and was Resident Engineer during the building of the beautiful reinforced concrete bridge in Elmira which spans the Chemung River at Main Street. After many other private engineering accomplishments, Mr. Haight accepted an important position as Engineer with the Highway Products and Manufacturing Company, manufacturers of Armco corrugated iron pipe. He assumed complete charge of the design and installation on many large drainage projects, flumes, sewers, etc., and his work in iron-pipe promotion was so pronounced and successful that he soon attracted the attention of several other manufacturers who accordingly bid for his services. Just a few months before his death, he had accepted a responsible position with the Sweet Steel Company, of Williamsport, Pa., and he was taking a business trip for this Company when he was instantly killed in a motor car accident, in the prime of his busy life.

"Si" Haight, as he was familiarly called, had friends by the thousands. He was sociable and kind, with a great mind and memory. Blessed as he was with a keen sense of humor and happy disposition, he won warm friends wherever he traveled. He was a gentleman at all times, big-hearted, noble, and brave, and ever loyal to his legion of friends who mourn his loss.

* Memoir prepared by M. W. Wipfler, M. Am. Soc. C. E.

Immediately following Mr. Haight's funeral, which was largely attended, several of his more intimate friends met at the City Club in Elmira and perfected a permanent organization known as the "Si Haight Club". The members of this Club intend to meet once each year on the anniversary of Mr. Haight's death and hold a banquet in his honor, at which time fitting tributes will be extended to his memory.

Mr. Haight was a member of Union Lodge No. 95, F. and A. M., Elmira; the Corning Consistory; Kalurah Temple, A. A. O. N. M. S.; the Southern Tier Shrine Association; Elmira Lodge of Elks No. 62; Phi Delta Theta Fraternity, and various other organizations.

He was unmarried and was always devoted to his mother and to his sister, Mrs. Grace Haight Parker, who is his sole survivor.

Mr. Haight was elected a Member of the American Society of Civil Engineers on June 6, 1927.

WILLIAM BURR HARRISON, M. Am. Soc. C. E.*

DIED OCTOBER 20, 1926.

William Burr Harrison, the son of William Elsey Harrison and Elizabeth (Edwards) Harrison, was born at Leesburg, Va., on February 27, 1871. After attending High School at Leesburg, he entered the Virginia Military Institute at Lexington, Va., from which he was graduated in 1892 near the head of his class, with a Civil Engineer's degree.

After his graduation, Mr. Harrison lost no time in taking up active practice. He immediately accepted a position as Engineer in charge of construction of a three-span highway bridge across Goose Creek, at Evergreen Mills, Va. When this work was completed in March, 1893, he was employed by the Lake Shore and Michigan Southern Railway Company until June.

From June, 1893, to January, 1899, he was with the United States Engineer Office at St. Louis, Mo., in responsible charge of surveys, triangulation, precise leveling, design, and construction of river and harbor work. From January, 1899, to 1902, Mr. Harrison was with the United States Engineer Office in Washington, D. C., in responsible charge of surveying, triangulation, leveling, the laying out and the receiving of bids for contract work, and the design and making of computations for various classes of river and harbor work. With the same Department from 1902 to 1908 he was in responsible charge of most of the field work and the preparation of designs, computations, and estimates on which contractors were paid. From 1908 to 1917, he was Principal Assistant Engineer in responsible charge of all office and field work, as well as the supervision and direction of all river and harbor work under the same Office.

Mr. Harrison entered the military service of the United States in February, 1917. He was appointed a Major, Engineer Section, Reserve Corps, and as such was on active duty during the World War, in the Office of the Chief of Engineers in Washington, D. C., with the Engineer Replacement Troops at Camp Humphreys, Virginia, and, later, with the 153d Engineers at Camp Shelby, Mississippi.

In July, 1920, he was commissioned in the Regular Army and after a short period of duty in Washington and at Headquarters, 11th Corps Area, he was sent to the Canal Zone, where he remained until March, 1924. After his return to the United States, Major Harrison was on duty at Fort Hayes, Ohio, until his retirement on September 21, 1926, on account of physical disability.

By his death at Walter Reed Hospital, on October 20, 1926, his country lost a loyal soldier, an untiring and conscientious worker, and a citizen of the highest type.

* Memoir prepared by B. Powell Harrison, M. Am. Soc. C. E.

Major-General Hines, Chief of Staff, U. S. A., writing of him, stated,

"Although Major Harrison had been a member of the military establishment but a few years, his ability, earnestness, and the conscientious performance of the duties assigned him won the commendation of those with whom he was associated."

He was a member of the Protestant Episcopal Church. In December, 1906, Major Harrison was married to Lelia Virginia Wheeler who, with one daughter, survives him.

Major Harrison was elected a Member of the American Society of Civil Engineers on April 30, 1912.

HANS HELLAND, M. Am. Soc. C. E.*

DIED MARCH 9, 1928.

Hans Helland, the son of Hans and Marie Helland, was born at Bergen, Norway, on August 10, 1854. He received his early education at the Primary and High Schools of Bergen and Christiania. He then attended the Technical Institute at Trondhjem, and, still later (1879), was graduated from the Royal Saxon Polytechnicum, of Dresden, Saxony, Germany, with the degree of Ingenieur Civil.

Prior to his graduation in 1879, however, Mr. Helland had served his apprenticeship in the Laxevoag Machinery Factory, and had been an Assistant Engineer on the Royal Norwegian Railways. The year following his graduation he became Statistician for the Royal Railways and the Department of Highways of Norway.

In 1881, he emigrated to America, settling in Texas, where he became imbued with the "spirit of the West", and henceforth remained to devote a useful life to transforming a frontier State to its present highly industrialized civilization. The crying need of that day was the construction of railroads, and naturally Mr. Helland assumed his share of this duty. On his arrival in Texas in 1881, he immediately became a Construction Engineer on the Texas Central Railroad and remained with that Company until 1889, when he became Vice-President and General Manager of the Central Texas and Northwestern, and the Fort Worth and New Orleans Railroad Companies. When these two lines were consolidated with the Houston and Texas Central Railroad in 1902, he became Maintenance-of-Way Engineer for the entire System (now a part of the Southern Pacific System). He remained in this capacity until 1906, when he resigned to locate and construct the Panhandle Short Line. In 1908, he became Maintenance-of-Way Engineer for the San Antonio and Aransas Pass Railroad Company, with which he remained until 1913.

From 1913 to 1921, during its first struggle toward greater improvements, the City of San Antonio, Tex., employed him as its City Engineer. It is noteworthy that, after approximately thirty-two years of active building and improvement of railways in Texas, Mr. Helland should then take up the work of enlarging a pioneer city to one of metropolitan proportions.

After 1921 he was engaged in the private practice of engineering in San Antonio, until his death, when his son Hans Helland, III, assumed the direction of the office.

Mr. Helland was a member of the American Society for Municipal Improvements and the San Antonio Scientific Society; he was also a member of the Polyteknisk Forening of Norway, and of the Ingenieur Verein of Dresden, Saxony.

Mr. Helland was elected a Member of the American Society of Civil Engineers on June 3, 1915.

* Memoir prepared by Rufus C. Thaxton, Assoc. M. Am. Soc. C. E.

KEARNEY EVERETT HENDRICKS, M. Am. Soc. C. E.*

DIED MAY 14, 1927.

Kearney Everett Hendricks, the son of George and Priscilla (Spoon) Hendricks, was born near Asheboro, N. C., on January 9, 1878. He was graduated from Guilford College, Guilford, N. C., in 1900, and from Haverford College, Haverford, Pa., in 1902. In 1903, he attended Johns Hopkins University as a graduate student in mathematics and physics.

From July, 1902, to March, 1903, Mr. Hendricks was engaged as Leveler on railroad location, and from March to October, 1903, as Transitman for the Norfolk and Western Railroad Company. From August, 1904, to April, 1905, he served as Transitman for the Carolina and Northwestern Railway Company, in North Carolina, and from April, 1905, to March, 1907, was Resident Engineer on heavy mountain construction, building a tunnel, ½ mile long, for the Clinchfield, Carolina, and Ohio Railroad Company. For a few months in 1907, he was Assistant Engineer on a small railroad in North Carolina. In September, 1908, he accepted a position as Instructor in Civil Engineering at Lehigh University, Bethlehem, Pa., where he remained for eight years.

In September, 1916, Mr. Hendricks was engaged as Assistant Engineer in charge of construction of a large earth and concrete dam for the Southern Power Company, at Bridgewater, N. C. He remained with this Company until February, 1920.

For a few months in 1920, Mr. Hendricks served as Draftsman for the Arizona State Highway Department, as well as Estimator on Federal Aid Projects, and the designer of two reinforced concrete arch bridges. From July, 1920, to January, 1921, he acted as Chief Draftsman for the Salt River Valley Water Users Association, and from that time to July, 1923, he was Assistant Engineer of the Southern Power Company. In July, 1923, he accepted a position as Engineer for the Lakeview Park, Incorporated, at Asheville, N. C., which position he held until his death on May 14, 1927.

On August 17, 1918, he was married to Ethel M. McGill, of Natural Bridge, Va., who, with one daughter, Priscilla, survives him.

Mr. Hendricks was an engineer of unusual ability and wide experience. He impressed all with whom he came in contact as being dependable, honorable, and unassuming, and he was faithful to every trust that he ever undertook.

As a child, he was affiliated with the Methodist Episcopal Church, but, later, favored the Quaker faith. He was a member of the American Association of Engineers and of the Kiwanis Club.

Mr. Hendricks was elected an Associate Member of the American Society of Civil Engineers on October 4, 1910, and a Member on June 6, 1921.

* Memoir prepared by F. H. Cothran, M. Am. Soc. C. E.

JAMES ORMEROD HEYWORTH, M. Am. Soc. C. E.*

DIED MARCH 15, 1928.

James Ormerod Heyworth was born in Chicago, Ill., on June 12, 1866, the son of James O. and Julia F. (Dimon) Heyworth. He was educated in the public schools of Chicago and was graduated from Yale University, New Haven, Conn., in 1888.

Mr. Heyworth was both an Engineer and a Contractor, a great amount of the work carried out by him as Contractor having been designed under his personal direction as well. He became interested in concrete construction early in his career and was the Contractor on some of the earlier undertakings in which reinforced concrete was used in the United States. Among other work, he designed and built the first concrete building in Chicago, in 1904.

He was always interested in efficient construction and accordingly underwent a rigorous training in the field, spending considerable time on the work, in order to keep in close personal contact with it. He was a member of the firm of Christie, Lowe, and Heyworth from 1897 to 1903, after which he operated under his own name. During the last few years his activities were carried on under the name of James O. Heyworth, Inc.

Mr. Heyworth was particularly interested in difficult and hazardous engineering undertakings, or in those in which speed of construction was one of the essential factors. Heavy excavation and difficult foundation and concrete work, railroad track elevation, bridges, hydro-electric plants, locks, dams, piers, wharves, docks, canals, tunnels, and caissons, both in the United States and in Canada, constituted the bulk of his work.

In the course of his career, Mr. Heyworth was called upon to restore and rebuild eight dams which had failed. In every case the work was carried out safely and successfully under his direction.

His desire to be engaged in difficult enterprises was displayed in the building of the concrete arch bridge over the Mississippi River between St. Paul and Minneapolis, Minn. In North Carolina, he achieved a record, not only for speed in concrete road mileage built during one season, but also for the uniform excellence of the work.

Mr. Heyworth had many inventions to his credit, among others being that of the modern dragline excavator, which was developed by him.

He was a great believer in team work and during his years of activity was assisted by a loyal organization working under his direction. He was an indefatigable worker, personally laying out details of plant and equipment on his contract work and always eager to apply new methods of merit in its prosecution. He was one of the first to use a central flexible electric power plant on large construction work and was a great believer in the use of Diesel engines for this purpose.

Mr. Heyworth's activities, however, extended beyond engineering and contracting lines. He was deeply interested in civic and philanthropic

* Memoir prepared by the following Committee of the Illinois Section: I. F. Stern, *Chairman*, A. J. Hammond, and O. E. Strehlow, Members, Am. Soc. C. E.

affairs, full of human sympathy, an enthusiastic yachtsman and fisherman, and a lover of the great outdoors. Some years ago he was President of the Local Branch of the Izaac Walton League of America and also Commodore of the Chicago Yacht Club.

He was instrumental in securing the present quarters of the Chicago Engineers Club. When the opportunity offered itself, he took an option on the property in his own name, without consulting the members of the Board, and called a meeting of the prominent members of the Club. By the time the Club membership voted to secure quarters of its own, the value of this property had risen very considerably. Mr. Heyworth then turned his option over to the Club and, as a result of the increased value of the property, there was no difficulty in floating a bond issue. During these trying times, Mr. Heyworth was induced to take the Presidency, which he held for three consecutive years at a great personal sacrifice to himself. To him, more than to any other man, credit should be given for enabling the Engineers Club to acquire its own quarters.

Mr. Heyworth was always enthusiastic in regard to every enterprise with which he was connected. He was intensely loyal to his Alma Mater, Yale University, from the day of his graduation to that of his death, and always a "prime mover" in anything pertaining to her interests. He was a member of the Executive Committee of the Yale Advisory Board; Chairman of the North Central Division of the Yale Endowment Fund; and a member of the Yale Clubs of Chicago and New York, as well as of other college organizations and clubs.

In 1917, he heeded the call to assist in war activities and accepted the position of Manager of the Division of Wood Ship Construction of the Emergency Fleet Corporation, United States Shipping Board, which he held until after the end of the World War. During this period he turned his own contracting business over to his subordinates and devoted himself entirely to the work of his Department of the Shipping Board, which, under his direction, showed a great record for efficiency. For some time, before the end of the war, fifty ships completely equipped, ready for service, were being turned out each month.

In 1902, Mr. Heyworth was married to Martica Gookin Waterman. They had two children, Francis Dimon and James O., Jr.

He was in the prime of his powers at the time of his death. He was taken ill in August, 1927, and was ordered by his doctors to Arizona with the hope that the dry climate would restore him to health. For a time he made progress toward recovery, but later complications set in and he grew steadily worse. He asked to be taken home to Chicago where he passed away a few hours after his arrival.

His death is deeply mourned, not only by his family and friends, but by a host of younger engineers and contractors who came to him for advice and help in their troubles and to whom he gave an unstinting measure of his broad training and ripe experience.

Mr. Heyworth was elected a Member of the American Society of Civil Engineers on May 6, 1914.

JOHN BYERS HOLBROOK, M. Am. Soc. C. E.*

DIED AUGUST 20, 1928.

John Byers Holbrook was born in New York, N. Y., on July 12, 1872. He was the son of Edwin W. and Fanny Chick Holbrook, both parents being descendants of families prominently identified with the early history of Manhattan. His father was engaged in commercial banking for many years, and at the time of his death was the oldest living member of the Union League Club. His son became associated with this Club on attaining his majority.

On completing his academic schooling in New York, Mr. Holbrook entered the Pennsylvania Military College, at Chester, Pa., from which he was graduated in 1892 with the degree of Civil Engineer. In 1893, he entered Cornell University, graduating in 1896 with the degree of Mechanical Engineer. At Cornell, he joined the Delta Kappa Epsilon Fraternity, with which, during his life, he maintained an active connection. He held the office of President of the Alumni Association of his Chapter and was diligent in his efforts to influence the young students in making the most of their college life.

Upon leaving college, Mr. Holbrook spent five or six years in perfecting himself in steam power plant design and operation, by employment with various companies, notably the E. W. Bliss Company, Brooklyn, N. Y., and the New York Edison Company and the American Blower Company of New York City. In 1901, he began private practice as Consulting Engineer, specializing in steam power plants and heating and ventilating. He designed and supervised the installation of the power plants in many of the earlier skycrapers of downtown New York, among which the Trinity Building, City Investing Building, and Commercial Cable Building are of importance. Later, his work extended throughout the United States and was marked by a thoroughness and conscientious attention to detail that resulted in very successful installations.

Mr. Holbrook served an enlistment of five years in Squadron A, New York National Guard. He always maintained his interest in the Veteran Organization and, in 1916, returned to active service for the duration of the World War.

His personality was characterized by a rare cheerfulness and geniality which drew to him, and held continuously, an unusual number of loyal friends.

He was married on October 3, 1903, to Blanche V. Meehan, of New York, who survives him.

Mr. Holbrook was elected a Member of the American Society of Civil Engineers on April 6, 1909.

* Memoir prepared by W. W. Ricker, Esq., New York, N. Y.

HAROLD WELLINGTON HORNE, M. Am. Soc. C. E.*

DIED MAY 23, 1928.

Harold Wellington Horne, the son of George and Mary (Barnard) Horne, was born at Belmont, Mass., on October 12, 1873. He was graduated from Harvard University with the degree of Bachelor of Arts in 1894 and from the Lawrence Scientific School, *Magna cum laude*, with the degree of Bachelor of Science in Civil Engineering in 1896.

Mr. Horne's first employment was as Rodman with the Metropolitan Water Board of Massachusetts, in September, 1896. Later, he was advanced to the position of Transitman and remained on this work until March, 1906, having been engaged on various structures for the distribution of water to Boston, Mass., and surrounding municipalities.

From March, 1906, to January, 1912, he served as an Assistant Engineer with the Board of Water Supply of the City of New York, first, on location surveys for the Catskill Aqueduct within the Hudson River Division and, later, in charge of the construction of a section of the Aqueduct which included the Bull Hill Tunnel and the Foundry Brook Pipe Siphon.

In January, 1912, Mr. Horne became associated with the Board of Water Commissioners of Hartford, Conn., in the capacity of Division Engineer on the work then being undertaken for an additional water supply. At first, he was occupied with the extensive topographical and subsoil surveys for reservoir and dam locations and title search of large areas of land takings. After this he took charge of the construction of the various structures comprised in the Nepaug Reservoir, including the large earth dam at Philips Brook, several miles of relocated highway, tunnel, and grade conduit, together with 8 miles of 42-in. pipe and the main dam, which was a high concrete structure. Later, he undertook the construction of the long earth dam at New Hartford, Conn., for the compensating reservoir. This work was concluded in March, 1918.

From March, 1918, to December, 1921, he was Assistant Division Engineer with the Miami Conservancy District of Ohio in charge of the construction of the Englewood Dam for flood control of the Miami River.

There followed an interval of about five years devoted to private affairs and certain business enterprises in which engineering played no large part. Mr. Horne, however, became convinced that permanent retirement was not wise. His education, his experience, and his native talent all combined to make engineering the most useful as well as the most congenial field for his effort. Consequently, he resumed his professional work.

In October, 1926, he was called to the Metropolitan District Water Supply Commission of Massachusetts, as Assistant District Engineer. On June 1, 1927, he was promoted to the position of District Engineer in which capacity he continued until the time of his death. He was given general charge of the preliminary surveys and sub-surface explorations for the aqueduct tunnel

* Memoir prepared by Samuel D. Dodge, Esq., Suffern, N. Y.

from the Swift River Reservoir to the Wachusett Reservoir and, subsequently, of the construction of a part of this tunnel. He lived to complete only the shafts.

To his friends and associates is left the memory of a kindly spirit, a wide culture, especially in the arts of music and literature, and a soundly educated mind. They recall, moreover, the singular fidelity and painstaking devotion to whatever task was in hand, tedious and uninspiring though it sometimes was, which were the true expression of his ingenuous and honorable nature.

Mr. Horne was married in 1915, to Anna Garfield Davis who, with two children, Richard and Mary Barnard, survives him.

He was a member of the New England Water Works Association and of the Harvard Club of New York.

Mr. Horne was elected an Associate Member of the American Society of Civil Engineers on October 2, 1907, and a Member on December 3, 1913.

DAVID JANNEY HOWELL, M. Am. Soc. C. E.*

DIED AUGUST 28, 1928.

David Janney Howell was born in Charlestown, W. Va., on September 8, 1863, the son of Samuel and Adele (LaFitte) Howell. His father was of Scotch ancestry, while his mother was of French descent.

Mr. Howell received his early education in the Charlestown Academy, Charlestown, and afterward attended Washington and Lee University, at Lexington, Va.

His early experience—starting as Rodman and afterward being promoted to Instrumentman and Topographer on railroad surveys in Virginia—was followed by his Civil Service appointment in 1884 in the United States Geological Survey as Assistant Topographer. This position he held until his resignation in 1887 to enter private practice in civil engineering in Washington, D. C.

From 1890 to 1897 Mr. Howell's practice embraced the planning, surveys for, and superintendence of, the improvements of various suburban properties within the District of Columbia and the adjoining States. He was also engaged on surveys for and superintendence of the construction of the walks, roads, lake, and bridge in the National Zoological Park; municipal improvements in Alexandria, Va., as City Engineer; surveys, construction, and superintendence of electric railways in Washington, D. C.; an 80-ft. iron span bridge and 50-ft. short-span bridge over Great Hunting Creek in Fairfax County, Virginia; and engineering work and superintendence on drainage canals in North Carolina. In addition, he acted as Chief Engineer for the Washington, Alexandria, and Mount Vernon Railway Company between Washington and Alexandria, exclusive of electrical equipment.

From 1897 to 1910 his work embraced the following positions: Assistant Engineer under the United States Board of Engineers on Deep Waterways in charge of surveys, investigations, and report of the Oswego Route, Eastern Division, from Albany to Herkimer, N. Y., about 90 miles for the ship canal from the Great Lakes to the Atlantic Ocean; Engineer to the New York State Canal Advisory Committee (appointed by President Roosevelt, then Governor of New York State), making estimates of cost and report on the enlarged Erie Canal, from Troy to Buffalo, N. Y.; Consulting Engineer to the New York State Engineer and Surveyor, Edward A. Bond, M. Am. Soc. C. E., in charge of surveys, plans, estimates, and printed report to the New York State Legislature on the enlargement of the canals of the State known as the Barge Canal, the estimated cost of which was about $100 000 000; surveys, plans, and specifications for the water-works system, at Fultonville, N. Y., and surveys and plans for the development of water power on the Shenandoah River above Harpers Ferry, W. Va., for the Shenandoah Electric Light and Power Company; Engineer to the late F. W. Hodgdon, M. Am. Soc. C. E.

* Memoir prepared by Beaudric L. Howell, Assoc. M. Am. Soc. C. E.

Mr. Howell also served as Engineer of the Massachusetts River and Harbor Commission, on plans and estimates of cost of locks on the Taunton River, Boston Ship Canal; report on improvements to water-works system at Frostburg, Md.; electric railway surveys and report, Canandaigua, N. Y., to Lake Ontario, 30 miles; the planning and construction, as part owner, under franchise of the water system and electric plant at Welch, W. Va., and the direction of its operation until it was sold in 1911; the investigation and report on additional water supply for Bristol, Va., and the preparation of plans for, and the superintendence of the construction of, a spring supply and 4 000 000-gal. reservoir; plans and report on the new distributing reservoir, Alexandria Water Company, Alexandria, Va.; railroad surveys from Cherry Run to Cumberland, Md.; investigation and full report with estimates of cost for a dam and large storage reservoir and 5½ miles of pipe line, and the purchase of land and water rights for the same, for the Alexandria Water Company, known as Barcroft Dam and Reservoir; plans for and the general supervision of the new reservoir, at Warrenton, Va.; report on improvements for the water-works system, Washington County Water Company, Hagerstown, Md.; general report and appraisal of plant, Alexandria Water Company; surveys and plans for a new dam and storage reservoir and pipe line, Charlottesville, Va.; surveys and reports on the sewerage system, Laurel, Md.; and consultation and report on an additional water supply and about 7 miles of pipe line in Bristol, Va.-Tenn.

From 1910 until 1918 Mr. Howell was engaged in the following work: Surveys for the planning of and superintendence of the construction of surface and underground improvements for the development of numerous suburban properties in the District of Columbia, Maryland, and Virginia; all engineering work and superintendence of construction of the Barcroft Dam and Reservoir for the Alexandria Water Company, the dam being 500 ft. long, with a maximum height of 70 ft., and the reservoir storage being about 600 000 000 gal.; and the investigation and report on a proposed storage dam for electric power in Virginia and various valuations and reports on water-works properties and sewerage systems.

Mr. Howell was made Manager of the Alexandria Water Company, of Alexandria, and acted as such for a period of about two years. His work with this Company embraced plans for and superintendence of its filtration plant. He was also engaged on complete surveys, plans, and superintendence for a separate sewerage system for the Town of Potomac, Va.; and a complete report, with estimates of cost, for a water supply and sewerage system for Arlington County, Virginia, embracing about 30 sq. miles.

During 1918 and 1919, Mr. Howell served as Supervising Engineer in the United States Quartermaster Department, in charge of surveys, plans, and the construction of surface and underground improvements at the Enlisted Men's Barracks, South Potomac Park, Washington.

From the opening of his private offices in 1887 to the time of his death, he acted as Engineer for the larger real estate operators of Washington, and in adjoining States, and had full charge of planning and developing many beautiful subdivisions in and around Washington.

On August 25, 1928, he was appointed by Governor Byrd, of Virginia, a member of the Commission to confer with a similar Commission of the State of Maryland for the purpose of settling a dispute which had arisen between the two States.

In 1910, he organized, with his son, Beaudric L. Howell, Assoc. M. Am. Soc. C. E., as Junior Member, the present firm of David J. Howell and Son, of Washington. He continued as an active member of this engineering firm until his death. Mr. Howell died suddenly of heart failure while engaged in an inspection of construction work on August 28, 1928.

Mr. Howell was a member of the New England Water Works Association, the American Water Works Association, and the Washington Society of Civil Engineers, and was a Certified Professional Engineer of the State of Virginia.

In 1887, he was married to Mary M. Gibson, who, with one son, survives him.

Mr. Howell was elected a Member of the American Society of Civil Engineers on September 5, 1900.

JULIUS MERRIAM HOWELLS, M. Am. Soc. C. E.*

DIED APRIL 22, 1927.

Julius Merriam Howells was born in Bowling Green, Ohio, on March 26, 1859, the son of Joseph and Ruth Merriam Howells. His childhood was spent on a farm in what he termed, "the Black Swamp", near Toledo, Ohio. His father, Joseph Howells, was progressive in thought, adopting the new school of medicine in his practice as a physician, and the new teachings of the Swedenborgian Church in his religion in place of the old orthodox beliefs. Remuneration from his medical practise among the farmers being inadequate for his large family, he moved to Richmond, Ind., where he entered the drug business. Joseph Howells' idea of justice was so unique that upon arriving at a degree of success, his conscience forbade him to enjoy such an easy life, so he again took up his more moderate practice as a physician. This quality of mind was inherited to some extent by his son, Julius, who loved his profession as an engineer, but had little regard for the money it brought him.

Julius Merriam Howells received his education at Earlham College, Indiana, and, later, from the late James E. Mills, M. Am. Soc. C. E., Geologist, of California. Like many others of the older engineers, Mr. Howells had his first practical experience in railroad location and construction for the Monarch Pass, Gunnison and Dolores Railroad, in Colorado (never built), and the Denver and Rio Grande Railroad in Marshall Pass and on the Rio Grande River, in Colorado. During 1881 and 1882 he was with the Maintenance of Way Department of the Pennsylvania Railroad Company, at Pittsburgh, Pa. From 1882 to 1884, he made studies of the tertiary history of the Sierra Nevadas, and mineral surveys under Mr. Mills, with Agassiz and Shaw, Geologists, his headquarters being at Quincy, Calif. From 1884 to 1888, he was Assistant City Engineer, and then City Engineer, of Richmond, Ind., at which time he became a Member of the Western Society of Engineers. From 1888 to 1892 he practised as Consulting Engineer in Chicago, Ill. His practice included work for the Municipal Investment Company, a Chicago firm, and he also served as Chief Engineer for Fostoria, Ohio, where he designed and built the entire system of water-works.

From 1892 to 1894, Mr. Howells was Chief Engineer of the Santa Fé, N. Mex., Water Company, at which time he did his first work in hydraulic-fill dam construction. He built the Santa Fé Canyon Dam, on which he experimented with the hydraulic-fill process. He then spent a year as Chief Engineer of the Tyler, Tex., Water Company, where he designed and constructed the Tyler Dam, the first hydraulic-fill dam ever built.† He also represented the Municipal Investment Company, of Chicago, as Engineer-Inspector of properties scattered over half the United States. In 1895, he became Chief Engineer of the Santa Fé Gas and Electric Company, for the Municipal Investment Company. From 1895 to 1898, he was Chief Engineer of the San Diego Flume

* Memoir prepared by Philip Schuyler, M. Am. Soc. C. E., and Hamilton R. Howells, Assoc. M. Am. Soc. C. E.

† "Reservoirs for Irrigation, Water Power, and Domestic Water Supply," by James Dix Schuyler, M. Am. Soc. C. E.

Company, and built the La Mesa Dam. In 1898, he designed the Pine Valley Dam, which was never completed. From 1899 to 1901 he was Consulting Engineer for the San Joaquin Electric Company, for which Company he built the Crane Valley Dam (hydraulic-fill and rock-fill).

In 1901 Mr. Howells became associated with the late James Dix Schuyler, M. Am. Soc. C. E., of Los Angeles, Calif., which association and friendship continued until the death of the latter. In 1903, he built the Lake Francis Dam (hydraulic-fill), for the Bay Counties Power Company, now the Pacific Gas and Electric Company. It was in 1901 that Mr. Howells conceived the Big Meadows and Feather River hydro-electric development; and from 1903 to 1905 he worked at interesting capital, promoting the Feather River project, obtaining early water rights, and commencing planning and construction.

From 1905 to 1909 he was employed by the Kobe Syndicate in the development of the Anglo-Japanese hydro-electric project, in Japan, following which he spent nearly a year in Switzerland. During 1910 to 1912 he was in Porto Rico as Chief Engineer of an irrigation system near Barceloneta, for which Mr. Schuyler was Consulting Engineer.

From 1912 to 1927 Mr. Howells carried on a general private consulting engineering practice in San Francisco, Calif., his clientele including the East Bay Water Company; the Western Canal Company; the Ocheco Irrigation District; the Reclamation District No. 784; the Montague and Granada Irrigation Districts; the Anglo and London Paris Bank; the Anglo California Trust Company; the James D. Phelan Estate; the Dodge Land Company; Girvin and Miller (bonds); Stephenson and Company (bonds); the Farm Land Investment Company of Fleishackers; the James Irvine Water Development, etc.

For this same period—1912 to 1927—he was Consulting Engineer for the Great Western Power Company for which he designed and built the Big Meadows Dam (hydraulic-fill) in 1913, and the Butte Valley Dam in 1923. In 1926, he engaged in the enlargement of the Big Meadows Dam.

Mr. Howells had an unusual imagination and the faculty of accurately visualizing structures in their completed state, long before their construction. His natural ability to estimate quantities and costs of engineering works amounted to genius. His associates would laboriously prepare an estimate only to find that they verified his simple estimate given weeks before without any apparent effort. He had a natural knowledge of proportion and logic, viewing all problems in their entirety without being confused by details. He was an idealist in his profession as he was in his private life. He had a rigid code of business ethics, and a very fair but strict idea of justice.

He readily grasped the economic and political aspects of problems and, due to this trait, found himself useful as an engineering diplomat and arbitrator in controversies among reclamation districts in co-operating with the State plan of reclamation. Loyalty to his friends and associates was probably his strongest trait. He took great pleasure in his work and keenly enjoyed the engineering profession. He was an exceedingly hard worker and preferred to work rather than to pursue the usual diversions of business men.

One of Mr. Howells striking characteristics was his unusual engineering economies. He constantly indicated to his associates where savings of money and effort could be made by using original and unique processes—many so simple that others overlooked them. To illustrate this, when the consolidation of an earth dam was being contemplated and intricate methods of compacting were being discussed, Mr. Howells accomplished a superior and cheap consolidation of the fill by arranging with a near-by goat farm to borrow a band of goats to drive to and fro across the fill. This ingenuity was also exhibited in his rather inventive turn of mind.

He was a member of the Institution of Civil Engineers of Great Britain and Chairman of the Economic Committee of the Immigration Section of the Commonwealth Club of California.

In his private life Mr. Howells was also the idealist. He stood for the very highest code of morals and might have given the impression of being intolerant of violators of his strict code. He was devoted to his home and family. He was a great lover of music and provided a musical training for each of his children. He was extremely interested in plant and animal life as well as in the geologic structure of the earth. He possessed a great familiarity with these subjects and made frequent allusions to them when in the field on business.

His other interests were: The Commonwealth Club and the League of Nations Non-Partisan Association. He stood for the Republican Party in politics. He was a member of the Swedenborgian Church, but during his last few years he was affiliated with the Unitarian Church, being interested in its educational lecture form of sermons.

He is survived by his widow, two sons, Hamilton R. Howells, Assoc. M. Am. Soc. C. E., and Merriam J. Howells, and two daughters, Mrs. George F. Buckingham and Mrs. Southall R. Pfund.

Mr. Howells was elected a Member of the American Society of Civil Engineers on June 4, 1902.

FRANK JAMES HUBBARD, M. Am. Soc. C. E.*

DIED FEBRUARY 23, 1927.

Frank James Hubbard was born on February 24, 1868, in Plainfield, N. J. He was the son of Joseph A. and Charlotte Elizabeth (Robertson) Hubbard. He was graduated from the Plainfield High School in the Class of 1887 and after his graduation spent nearly three years on a ranch in Wyoming for the benefit of his health.

From 1889 to 1893, Mr. Hubbard was employed in the office of the County Engineer of Union County, New Jersey, on highway construction, surveys for the mapping of Lapeer County, Michigan, and also in charge of street paving in Olean, N. Y. The following year he was a Special Student at the Massachusetts Institute of Technology, after which he entered the employ of the City of Plainfield as Assistant Engineer on the construction of its sewer system, serving in that capacity until 1896.

At the conclusion of his engagement with the City of Plainfield, Mr. Hubbard entered private practice, in which he was engaged until the time of his death. During this period he designed a sewer system for the Village of Sea Cliff, Long Island, served as Borough Engineer of North Plainfield, N. J., from 1897 to 1912 and from 1920 to 1926, and as County Engineer of Union County, from 1897 to 1911, designing and supervising the construction of bridges and paving. In 1903, he designed and installed a waterworks system for Alfred, N. Y., and, from 1915 to 1927, held the office of Borough Engineer of Dunellen, N. J. Just prior to his death he completed the work of designing a viaduct over a stream dividing the municipalities of Plainfield and North Plainfield.

Mr. Hubbard was a member of the Union County Chapter of the New Jersey Society of Professional Engineers, the Engineers' Club of Plainfield, and the Rotary Club of Plainfield, of which he was a Charter Member.

He served the community in which he lived in many positions of responsibility and trust and will ever be remembered for his interest and services in civic affairs. He had been a member of the Board of Education since 1915 and served as its President from 1923 until his death. During this period, he superintended the erection of a number of the finest school buildings in the city for which work he was eminently fitted by his engineering training and experience. In recognition of his work as a member of this Board, the City honored his memory by giving his name to its most recently constructed school building.

During his life Mr. Hubbard gave much time and attention to Muhlenberg Hospital; he was a member of its Board of Governors for nearly a quarter of a century and its President for four years. He also took an active interest in the building of the newer and larger fireproof structures of this institution, which construction he personally superintended.

* Memoir prepared by A. W. Vars, M. Am. Soc. C. E.

He was a member of the Seventh Day Baptist Church and was actively connected with several of its denominational interests. He was Treasurer of the Board of Trustees of the Seventh Day Baptist Memorial Fund which administers the endowment funds of that denomination.

In 1897, Mr. Hubbard was married to Bessie Evelyn Titsworth who survives him.

Mr. Hubbard was elected a Member of the American Society of Civil Engineers on April 12, 1926.

RICHARD LEWIS HUMPHREY, M. Am. Soc. C. E.*

DIED NOVEMBER 2, 1928.

Richard Lewis Humphrey was born in Marblehead, Mass., on October 19, 1869, the son of Richard Hales and Caroline (Curtis) Humphrey and a descendant of Benjamin Hales Humphreys, who came from Wales early in 1600 and settled in Marblehead. His father, who dropped the final "s" from his name, was a manufacturer of shoes in Marblehead and, later, in Philadelphia, Pa., and lived to be nearly ninety years of age. The son was graduated from the Central High School of Philadelphia with the degree of Bachelor of Arts in 1888 and Master of Arts in 1893, and from the University of Pennsylvania in 1891. He later received the degree of Civil Engineer from this institution, and subsequently took a special course in chemistry there.

Mr. Humphrey began his professional career in 1890, during the summer vacation of his Senior year, as Assistant and Topographer to the Division Engineer, on the Cumberland Gap Extension of the Louisville and Nashville Railroad Company. After his graduation, in 1891, he accepted a position as Draftsman in the service of the Philadelphia and Reading Railway Company, resigning in 1892 to become Draftsman and, later, Engineer in the Bureau of Surveys, Philadelphia. He was assigned, successively, to work on plans for the Cresheim Arch of the Wissahickon Creek high-level sewer, main and branch sewers, Front Street plate girder bridge (100-ft. span), and the drainage of the meadow lands in South Philadelphia. He was Designer and Engineer in charge of the Philadelphia Municipal Testing Laboratory. This laboratory grew in importance and in it much valuable research work was carried on, particularly in the development of the use of cement, concrete, and reinforced concrete as materials of construction, and Mr. Humphrey was considered a pioneer in work of this character.

In 1899, he became Engineer and General Manager of the Buckhorn Portland Cement Company, and during the ensuing four years he designed, built, and operated this Company's Portland cement plant at Manheim, W. Va. In 1903 he became a Consulting Engineer and Expert, serving the Pennsylvania Railroad Company, and other large corporations. He was Engineer in charge of the construction of the reinforced concrete Exhibition Building and of the assembling and erection of the collective American Portland cement exhibit and model testing laboratory of the American Portland Cement Manufacturers, which exhibit received the Grand Prize at the Louisiana Purchase Exposition, at St. Louis, Mo., in 1904. He served as Cement Expert of the United States Reclamation Service and Cement and Concrete Expert of the United States Geological Survey, and was Engineer in charge of the Government Structural Materials Testing Laboratories in St. Louis, Pittsburgh and Northampton, Pa., and Atlantic City, N. J., from 1905 to 1910, which laboratories he planned. He was Chairman of the Committee appointed by the Government to investigate the effects of alkali on concrete and rein-

* Memoir prepared by a Committee consisting of George S. Webster, Past-President, Am. Soc. C. E., and Samuel T. Wagner and S. M. Swaab, Members, Am. Soc. C. E.

forced concrete used in the construction of United States Reclamation Projects.

Mr. Humphrey also made, in 1906, an investigation for the Government of the effect of the San Francisco earthquake and fire on structures and structural materials, the results of which were published as a Government *Bulletin*. He established and designed the laboratory at Northampton, Pa., for the testing of the Portland cement used in the construction of the Panama Canal and was in charge of it until 1910. From 1910 until 1920 he was Consulting Engineer to the United States Bureau of Mines. During a part of 1910 he was also Consulting Engineer to the United States Bureau of Standards. He was the Expert retained in connection with the revision of the New York City Building Code in 1908 to 1909.

During the World War Mr. Humphrey was appointed (on October 7, 1917, as a "dollar a year" man) an Expert on the Raw Materials Committee, Council of National Defense, 1917-18. He was also appointed Director of Building Materials and of the Building Materials Division of the War Industries Board, which was created during the summer of 1918, and handled all matters relating to the conservation and distribution of building materials and supplies. He further served on the United States Highway Council, representing the War Industries Board in 1918. After the dissolution of the Board at the close of 1918 he continued to act for the Government in planning for the disposal of surplus building materials in such a way as to give the maximum price return to the Government and, at the same time, not unduly disturb the building materials market.

He was deeply interested in the welfare of the University of Pennsylvania. As President of the Engineering Alumni Society and as a Director of the General Alumni Society, he gave of his time and ability without stint. His duties were discharged with courage and fidelity, and he has left his impress on the affairs of this great educational institution.

Mr. Humphrey was an outstanding character. His activities were numerous, his energy great. He achieved much in the field of engineering, especially in such organizations as the American Society of Civil Engineers, the American Society for Testing Materials, and the American Concrete Institute.

In the American Society of Civil Engineers he was a leader in the movement to establish Local Sections and in having them take an important part in Society activities. The developments which followed created a new era in Society affairs and resulted in greater service being rendered to the membership throughout the country.

He was deeply interested in the registration of engineers and served as Chairman of a Committee of the Society to draft a uniform law on this subject to be adopted in all parts of the United States. Such a law having been enacted in Pennsylvania, Mr. Humphrey was appointed by the Governor of the State, as Chairman of the Board to administer the law, which position he held from the institution of this Board in 1921 until his death. He was largely instrumental in establishing the highest ideals for the Engineering Profession in the operations of the Board.

The high regard with which the members of the Board held Mr. Humphrey may be best expressed by the words which they addressed to him on December 19, 1924, as follows:

"For a leading and distinguished engineer to have made the sacrifice of time and energy in the service of the State, that you have made, affords a notable example to the members of the Engineering Profession of how one of their number can lay aside personal interests, and forego large private gain, to give to the State high service for the promotion of the public good and the elevation of the profession of engineering."

In January, 1928, Mr. Humphrey was appointed a member of the Special Committee of the Board of Direction of the Society on Technical Expansion. On this Committee, as well as on all committees on which he served, he always gave unselfishly of his best thought in advancing the interests of the Society.

In the American Society for Testing Materials and in the American Concrete Institute, he had a most important part in the development of cement and concrete specifications and was recognized as an authority on these subjects.

Mr. Humphrey received a Gold Medal as collaborator at the Louisiana Purchase Exposition, St. Louis, Mo., in 1904, and the Medal of the British Concrete Institute in 1911. He was United States Delegate and Honorary President of the International Congress for Testing Materials at Copenhagen, Denmark, in 1909. He was appointed by President Roosevelt as a Member of the National Advisory Board on Fuel and Structural Materials and was its Secretary from 1905 to 1910.

He was a member of the Institution of Civil Engineers (Great Britain); Société des Ingénieurs Civils de France (Vice-President, American Section); British Fire Prevention Committee; National Fire Prevention Association; a Fellow of the American Association for the Advancement of Science; a member of the National Geographic Society; American Chemical Society; Society of Chemical Industry (British); Société Industrielle Chimie; International Association for Testing Materials (Chairman of the International Committee on Constancy of Volume of Cement); American Society for Testing Materials (organized it and was its first Secretary, 1898-1900); American Railway Engineering Association; National Association of Cement Users (First President, 1905-13); American Concrete Institute (First President, 1913-15; First Honorary Member, 1926); awarded the Wason Medal in 1925 for two papers, "Twenty Years of Concrete" and "The Promise of Future Development"; Oesterreichischer Béton Verein; American Concrete Pipe Association; Secretary of the Joint Committee on Concrete and Reinforced Concrete, the constituent organizations of which were the National Societies of Civil Engineers, Testing Materials, American Railway Engineering Association, the American Concrete Institute, and the Portland Cement Association; Chairman of the Joint Committee on Specifications for Concrete and Reinforced Concrete (since 1920); Secretary of the Committee on Uniform Tests for Cement; Secretary of the Committee on Concrete of the American Society for Testing Materials; and a member of the Executive Committee of the Joint Conference Committee on Uniform Methods of Tests and Standard Specifications for Cement, consisting

of representatives of the American Society of Civil Engineers, American Society for Testing Materials, and the United States Government. He was also Chairman of the governing body of American Engineering Council and Chairman of the Committee on Procedure, representing those National Engineering Societies which created the Federated American Engineering Society.

Mr. Humphrey was a man of remarkable ability and of comprehensive good judgment and rendered many useful services in the engineering world. He was especially helpful in his contacts with young men entering the profession and was active in organizing Student Chapters in the Society.

He was an indefatigable worker, thorough and painstaking in every thing he undertook, always an earnest and forceful advocate of the measures which he believed to be for the best interest of the Engineering Profession.

He was a staunch friend, a charming and lovable companion, and it was a privilege and an inspiration to be associated with him. The loss of his influence and counsel will be keenly felt at future meetings of the technical societies of which he was a member.

He is survived by his widow, Anna Kay Humphrey, and two sons.

Mr. Humphrey was elected an Associate Member of the American Society of Civil Engineers on May 5, 1897, and a Member on May 3, 1904. He served as Director from 1921 to 1923 and as Vice-President in 1925 and 1926.

FRED ATWOOD JONES, M. Am. Soc. C. E.*

DIED MAY 22, 1928.

Fred Atwood Jones was born in Dallas, Tex., on August 23, 1875, the son of Frank Jones and Nannie E. (Hunt) Jones, natives of Missouri, his father having gone to Texas as a lumberman with the William Cameron Interests.

When the boy was three years of age the family moved to Bonham, Tex., where he was educated, having been graduated from Fannin College, at the age of fifteen. He then attended and was graduated from Richmond College, at Richmond, Va., receiving his Bachelor of Arts Degree from that institution in 1894. He then enrolled in Cornell University, at Ithaca, N. Y., to take professional courses and, in 1898, he received the degree of Electrical and Mechanical Engineer.

After his graduation from Cornell, Mr. Jones began the practice of miscellaneous engineering and surveying in Northern Texas. Later, he took the Student's Course with the General Electric Company, at Schenectady, N. Y., and for two years he was engaged in the Testing and Railway Engineering Departments of that Company.

In January, 1902, Mr. Jones opened an engineering office in Houston, Tex. He served as Consulting Engineer during the building of the power station of the Southern Pacific Terminal Company, at Galveston, Tex., as well as that of the Corsicana Gas and Electric Company, and many other such plants, at the same time submitting a great number of engineering reports. By 1908, he had gathered about him other highly efficient engineers and builders. To list his chief works would be to review the great building operations of many large centers of Texas, from the older cities to the new-born oil centers. Among other structures at Dallas that may be credited to his organization, are the Dallas Country Club; the Sumpter (now the Central Bank) Building; the Southern Methodist University Administration Building; the City Hall, which is a lasting monument of beauty and stability, comparing well with the foremost municipal buildings of the largest cities; the Southland Life Building; the eight-story addition to the Interurban Building; the White Rock Reservoir; the Dallas Filtration Plant; the Texas "Farm & Ranch" Building; the Palace Theatre, which ranks with the leading theatre buildings of America; and the interurban lines leading from Dallas to Sherman, from Dallas to Corsicana, and from Dallas to Waco.

At Houston, the Rossonian Apartments, the Sunset Hospital, the Bender Hotel, and the Levy Brothers Department Store are some of his work in that city, as well as the Telephone Exchange, which is also to his credit. There is also the American National Insurance Building, at Galveston, Tex.; the Nueces Hotel, at Corpus Christi, Tex.; the Paso Del Norte Hotel, at El Paso, Tex.; Trinity University Dormitory, at Waxahachie, Tex.; the National Supply Building and the Republic Supply Building, at Ranger, Tex.; the Atlas Supply Company Building, at Eastland, Tex.; and the County Hospital, the Moulton Hotel, and the American Trust and Savings Bank Building, a twenty-story structure, all at Birmingham, Ala.

* Memoir prepared from information on file at the Headquarters of the Society.

In addition, Mr. Jones prepared the cost review report on the Roosevelt Dam, Salt River Valley Project, which brought into usefulness land valued at $10 000 000. He also made the survey and report for the proposed Dallas-Wichita Falls Interurban Line, and his organization handled the construction of Camp McArthur Cantonment, Rich Field (an aviation camp), and a large hospital for the Government, at Waco.

During the World War, he was Chairman of the Military Training Camps Association, and conducted examinations of civilians for Officers' Training Camps. He also represented the Secretary of War in visiting training camps and aviation fields in Texas and conferring with officers on various matters.

On September 5, 1910, Mr. Jones was married to Gussie Holland, the daughter of the late Col. Frank P. Holland, a former Mayor of Dallas, and the owner of *Farm & Ranch*, and *Holland's Magazine*. They had three children, Fred A. Jr., Robert Holland, and Latham Fletcher Jones. He is also survived by his brothers, the Hon. Frank C. Jones, of Houston, and C. A. Jones, of Greenville, Tex.

Although quiet and unassuming, Mr. Jones was one of the most prominent engineers and builders of the Southwest. He allied himself with the social and civic life as well as with the commercial affairs in each city in which he resided. He was a Shriner, a member of Hella Temple, Dallas, and a member of the City Club, the Dallas Country Club, and the Brook Hollow Golf Club. He was one of the oldest members of the American Institute of Electrical Engineers.

Mr. Jones was elected a Member of the American Society of Civil Engineers on December 6, 1915.

HAROLD VINCENT JOSLIN, M. Am. Soc. C. E.*

DIED NOVEMBER 3, 1928.

Harold Vincent Joslin, the son of William C. and Elizabeth Florine (Freeman) Joslin, was born on June 22, 1883, at Belleville, N. Y. He was educated at Clinton Liberal Institute, Fort Plain, N. Y., and at Brown University, Providence, R. I., having been graduated with the degree of Bachelor of Arts in 1904.

After graduation, Mr. Joslin's first work was with the White Mountain Lumber Company, of Conway, N. H., where he was engaged in land surveys and in the location of narrow-gauge railways. From there, he went to Newark, N. J., where he served for a short time as Draftsman with the New York and New Jersey Telephone Company. He then became associated with Betts Academy, at Stamford, Conn., as Instructor in Mathematics.

In October, 1905, he entered the service of the Norfolk-Southern Railway, in Norfolk, Va., where he won rapid promotion. He served, successively, in the positions of Draftsman, Levelman, Transitman, Resident Engineer, Assistant Engineer of Maintenance of Way, and First Assistant to the Chief Engineer, until March, 1910. He then accepted a position with the City of Norfolk, and was in charge of surveys for water supply until June, 1911.

From June, 1911, until March, 1912, Mr. Joslin served as Construction Engineer for the Yadkin River Power Company, a subsidiary of the Carolina Power and Light Company, of Raleigh, N. C., on the construction of a hydro-electric plant at Pee Dee, N. C.; this work included the design and layout of the plant. He was then engaged by the Norfolk-Southern Railway Company for a few months as Locating Engineer on its Raleigh-Charlotte Branch. At this time he re-entered the service of the Yadkin River Power Company and the Carolina Power and Light Company, as Assistant to the Construction Manager and Cost Engineer and served in this capacity until April, 1913, when he went to Grace, Idaho, as Assistant to the Construction Superintendent and Cost Engineer of the Phœnix Construction Company. In this capacity he was engaged on hydro-electric surveys, design and installation of plant and subsidiary structures, and general construction.

In August, 1914, he returned to the Carolina Power and Light Company and Allied Companies, at Raleigh, where he had charge of the design and construction of substations, transmission lines, and miscellaneous work of a similar nature, until May, 1918, when he was appointed General Field Cost Engineer for the United States Housing Corporation, at Washington, D. C. He served one year in this capacity and another year as Manager of the Wilson Housing Corporation, of Wilson, N. C.

Mr. Joslin then returned to Raleigh and became associated with the North Carolina State Highway Commission as Assistant to the Chairman. He served this Commission until October, 1923, when he resigned to return to the Carolina Power and Light Company, for which he handled the design of

* Memoir prepared by George F. Syme, M. Am. Soc. C. E.

transmission lines, bridges, buildings, and other structures, and also supervised their location and construction, as well as the surveys and investigations for water-power development. He held this position at the time of his death, on November 3, 1928.

Mr. Joslin was a faithful communicant of the Protestant Episcopal Church, a member of Phi Beta Kappa Society, Delta Kappa Epsilon Fraternity, and the William G. Hill Masonic Lodge No. 218, of Raleigh.

He was a member of the North Carolina Society of Engineers and of the Raleigh Engineers' Club, having served the latter as Vice-President. He took a very active part and a deep interest in all matters pertaining to these local engineering societies, and whenever possible attended all their meetings.

He ably served on many engineering committees appointed to co-operate with various civic bodies in the handling of local public problems. His advice was eagerly and frequently sought by his contemporaries, who appreciated and respected his sound judgment on technical matters, and the ever-present friendliness with which he responded.

Mr. Joslin was well known professionally and socially throughout his adopted State, and his memory will live in the hearts of his friends, until they, too, answer the last call. After that, the enduring works he left behind will direct future generations to the accomplishments of an engineer, which time cannot erase. "By their works shall ye know them."

He was an outstanding figure in his community, and his lovable disposition, courtly manners, and splendid character endeared him to all who were privileged to know him. His untimely passing spread universal sorrow among his friends and is a distinct loss to his employers and to his profession.

Mr. Joslin was married on December 1, 1908, to Annie Devereux Hinsdale, of Raleigh, who, with four children, Ellen Devereux, Devereux, William, and John Hinsdale, survives him.

Mr. Joslin was elected a Junior of the American Society of Civil Engineers on April 6, 1909; an Associate Member on February 6, 1912; and a Member on October 8, 1918.

HOWARD GEORGE KELLEY, M. Am. Soc. C. E.*

DIED MAY 15, 1928.

Howard George Kelley was born in Philadelphia, Pa., on January 12, 1858. He was educated in the public schools of Philadelphia and was a student in civil engineering at the Polytechnic College of Pennsylvania.

On leaving school Mr. Kelley desired to follow the lure of the sea which inclination was derived from the experiences of his grandfather and his father, both sea-faring men, although his father in middle age had given up his ship and become a merchant in Philadelphia. Mr. Kelley, however, engaged to sail on a small ship of less than 400 tons from San Francisco, Calif. He became well versed in the study of navigation which he found a pleasing diversion. His grandmother, who had taken care of him in his youth, prevailed upon him to give up his sea-faring proclivities and he became a Land Surveyor in California. His later work, fortunately, gave him numerous opportunities to indulge in his love of and pleasure in ocean travel. He crossed the Atlantic a dozen times in the line of duty and during the winter of 1924 and 1925 he and Mrs. Kelley enjoyed a trip around the world.

The record of his services is most interesting in its diversity and its steady accumulations of success. It demonstrates his close attention to his chosen profession and shows the result of the intensity with which he carried on every duty in the line of his work.

In April, 1881, Mr. Kelley entered the service of the Northern Pacific Railway Company at Tacoma, Washington Territory, on the original preliminary and location surveys from Kalama, Washington Territory, to Portland, Ore., running lines on both sides of the Columbia and Willamette Rivers. He then joined the crew on the preliminary and location surveys from Sand Point, Idaho, on Lake Pend'Oreille, around the north and east sides of the lake, and thence up the Valley of Clarks Fork of the Columbia River, through the Cœur d'Alene and Cabinet Mountains, to its junction with the Missoula River in Montana, to the point now known as Paradise, at that time a totally uninhabited country.

On the completion of the surveys, he was appointed Transitman for the Division Engineer in charge of bridges and, on the retirement of the Division Engineer on account of illness, Mr. Kelley was placed in charge of the party and completed the work to the Missoula River, including the bridge over Clarks Fork at that point, then known as the "Third Crossing". This work included the design and construction of bridges, trestles, viaducts, piers, and abutments, all built of timber, and performed by company forces. In July, 1883, he was transferred to the Kalama-Portland Division as Resident Engineer in charge of bridge construction. Later in the autumn, he was put in charge of the work on the Upper Yakima River for about two months.

Mr. Kelley was then engaged for several months in making a survey of the water-front at Seattle, Wash., on which the later improvements by the Northern Pacific Railway Company were based. Subsequently, he was placed in charge

* Memoir prepared by Carl H. Gerber, Esq., Omaha, Nebr.

of the field work on the survey and soundings of Tacoma Harbor and the Lower Puyallup River. He was engaged on reconnaissance in the Cœur d'Alene Mountains, in Idaho; on the western slopes of the Cascade Range, in Washington Territory; and in the Olympic Mountains south of the Straits of San Juan de Fuca, also in Washington Territory. His work with the Northern Pacific Railway Company and allied service covered a period of four years, terminating in the spring of 1885.

During the remainder of 1885, and for the succeeding year, Mr. Kelley was engaged in mining, his work including nearly every job pertaining to a mine, incidentally, also, learning the blacksmith trade, which resulted in his being placed in charge of the development of the Mapleton and Champion Mines of the Summit Mountain Mining District.

In December, 1886, he was appointed Resident Engineer of Maintenance of Way on the St. Louis, Arkansas and Texas Railway, and, later, on the St. Louis Southwestern Railway, which extended from Birds Point, Mo., opposite Cairo, Ill., southward through Missouri, Arkansas and Texas, 395 miles of this railway having been changed from narrow to standard gauge at that time. The position of Superintendent of Bridges and Buildings was later added to his duties as Resident Engineer.

The entire original railway was rebuilt, including all the bridges over the rivers which constituted the principal drainage lines of that section of the country; one item was the sinking of two pneumatic piers with a penetration of 88 ft. below the surface of the water. This work was started under contract, but completed by company forces under Mr. Kelley's direction. During this period the railway was being extended in Missouri, Arkansas, Louisiana, and Texas, to a total of 1 228 miles, and on the completion of the grading and track-laying of these extensions, he took charge of the construction of the permanent structures and was appointed Chief Engineer.

As Chief Engineer Mr. Kelley continued in direct charge of bridges and buildings; he located and built the line from Delta to Grays Point, Mo., together with the yard and incline at Grays Point, and also located the first line to the Mississippi River for a bridge to Thebes, Ill.; he made the reconnaissance personally and reported on the terminal property required for the route to Dallas on which the line was built; he also made several reconnaissances in Texas and reports on other smaller properties.

The valuation of the St. Louis Southwestern Railway Company's properties in Texas, aggregating between 500 and 600 miles, made under a General Order of the State Railroad Commission, was carried out under his personal direction and supervision. His services with this Company extended throughout a period of eleven years.

On March 1, 1897, Mr. Kelley resigned his position to become Chief Engineer of the Minneapolis and St. Louis Railroad Company, being retained for another year as Consulting Engineer for the St. Louis Southwestern Railway Company. As Chief Engineer of the Minneapolis and St. Louis he had charge of maintenance, including bridges and buildings, real estate, and new construction.

While in the service of the Minneapolis and St. Louis Railroad Company, Mr. Kelley made an examination and report of the Iowa Central Railway, about 500 miles, and of the Des Moines and Fort Dodge Railway, about 139 miles, and on the basis of his report these lines were acquired and became part of the Minneapolis and St. Louis System. A number of important changes and extensions were made, including reconstruction for improvement in grades and alignment on the main line of this System, as well as on the Iowa Central Railway, all of which was heavy work, covering a distance of 296 miles. This reconstruction was performed by company forces with the exception of 15 miles on the Minneapolis and St. Louis Railroad between Hopkins Junction and Chaska, Minn. and 7 miles on the Iowa Central Railway which was done under contract. In addition, there was also the location and construction of 363 miles of new lines for the Minneapolis and St. Louis Railroad Company in Minnesota, Iowa, and South Dakota, and a number of reconnaissance examinations for other projected lines. The valuation of these lines, made by order of the Minnesota Railroad and Warehouse Commission, was under Mr. Kelley's direct supervision. Throughout the work he had charge of the operation of the lines under construction. His services with the Minneapolis and St. Louis Railway Company continued for a period of nine years.

In July, 1907, Mr. Kelley was appointed Chief Engineer of the Grand Trunk Railway System, for both the American and Canadian lines, aggregating 4 785 miles. After four years in that position, in October, 1911, he was made Vice-President in charge of operation, maintenance, and construction. Six years later, in October, 1917, he was elected President of the entire Grand Trunk System, the Grand Trunk Pacific Railway, and its steamship lines, in all more than 8 000 miles of railway. He also served as Chairman of the Board of the Central Vermont Railway Company, President of the Toronto Terminal Company, and Director of the Chicago and Western Indiana Railroad Company, and the Belt Railway Company of Chicago, which positions he retained until the Grand Trunk Railway System was taken over and made part of the Dominion of Canada Government Railways in 1922.

Important among the noteworthy items accomplished during this period of fifteen years was a substantial improvement of the physical condition of the property and a very heavy increase in business; also the reconstruction of bridges over the St. Lawrence and Niagara Rivers; the improvement of grade line and elimination of grade crossings from York through Toronto to Mimico, Ont., Canada; the construction of the Union Station building, at Toronto; the elimination of grade crossings, covering several miles, at Detroit, Mich.; the preliminary plans for the abolition of grade crossings in the City of Montreal, Que., Canada, covering more than six miles and including three terminal yards, and the preliminary plans for a new terminal station; the plans and estimates for an entirely new terminal for the Chicago and Western Indiana Railroad Company in Chicago, Ill.; the electrification of the St. Clair River Tunnel from Sarnia, Ont., Canada, to Port Huron, Mich.; the construction of the Montreal and Southern Counties Railway, an electric freight and passenger line of 44 miles; the construction of 4.5 miles of new line

between Birch and Wybridge, Ont., Canada, and 18.8 miles of new line from Cass City to Bad Axe, Mich.

The valuation of the American lines under orders from the Interstate Commerce Commission, including the lines of the Central Vermont Railroad Company, was started and subsequently carried on by the Valuation Department of the Grand Trunk Railway System. The valuation of the entire Grand Trunk System, together with a report on its physical condition, was made in 1920 and 1921, in connection with the arbitration proceedings under which the property was taken by the Dominion Government. This included all the owned and partly owned properties of the System; the Grand Trunk Railway, American and Canadian Lines; the Grand Trunk Pacific Railroad and Steamship Lines; the Central Vermont Railroad; the Detroit Terminal Company; the Toledo Terminal Company; the Detroit and Toledo Shore Line Railroad; the Chicago and Western Indiana Railroad and Belt Railway of Chicago; the Montreal and Southern Counties Railroad (Electric); the Oshawa Railway (Electric); the car ferries on Lakes Michigan and Ontario; the Central Vermont Transportation Company steamships; the Grain Elevator Companies; the Hotel Companies, and a number of other properties.

A noteworthy accomplishment, demonstrating Mr. Kelley's ability, energy, and tireless attention to meet emergencies, was his success in directing the movement of men, munitions, and supplies, occasioned by the World War. The record shows efficient and prompt movement of all traffic and, further, that no ship assigned to transportation overseas for Canada's participation in the war was delayed more than 24 hours in the whole 4-year period.

At the close of his services with the Grand Trunk System, he had planned to take a well-earned vacation and intended to go on a purely pleasure trip to Europe, but before he could put that plan into effect he was called to Boston, Mass., for a conference with the members of the Joint New England Railroad Committee, and in October, 1922, was selected as Technical Adviser to that Committee which he served until November, 1923, when the work was completed.

The Joint New England Railroad Committee was composed of the Chairmen of six State Committees appointed in the six New England States by their respective Governors. The members had been selected from among the leading bankers and business men for the purpose of studying the transportation and industrial situation and to report on such study with recommendations for the future advancement of New England and for the consolidation of the railways.

The work required a study of the manufacturing industrial situation of New England, the present and possible future markets, the transportation facilities to reach such markets, the various routes of distribution by rail, ocean, and lake, and the possible development of the principal ocean ports. It also included an inspection, study, and analysis of each of the several railroads of New England, their financial structures, operating conditions, methods and results, maintenance, facilities, requirements, and the probable effect on them and on the New England industries of the several methods of possible consolidation.

It involved a series of public hearings held in Boston, Hartford, Conn., Providence, R. I., and Montpelier, Vt., the States of New Hampshire and Maine being heard in Boston. The published report of the Committee required a book of 334 pages, supplemented by maps and charts, but the actual data assembled filled several thousand pages.*

From June until late in November, 1924, Mr. Kelley was engaged upon an analysis and report covering the location, construction, operation, value, and earning power of the Virginian Railway Company, together with its branches and terminal properties. This study included a complete review of this property from its inception to date (1902 to 1924) and covered the original location, operating grades secured, character of country traversed, type and character of construction, conditions under which construction had been conducted, the motive power and equipment, the operating results throughout the period of its existence, the business, past, present, and prospective, available for traffic and, finally, the earning power and value of the railway.

This was supplemented during the months of October and November, 1925, by a re-arrangement of the data contained in the report of 1924 for direct testimony presented in hearing before the Bureau of Valuation of the Interstate Commerce Commission in connection with the valuation case of the Virginian Railway Company.

In November, 1925, within a week after the completion of the Virginian hearing, Mr. Kelley left New York City to go to Russia to make an examination of two railways in Southern Russia, aggregating more than 3 000 miles.

The work involved a detailed inspection, study and analysis of the roadway, engine terminals, shop facilities, station and other buildings, and all other physical elements; an analysis of operating performances and statistics covering the period of years after the World War and for several years prior to the war; an estimate for the completion of the rehabilitation work undertaken by the Russian Government and the requirements for increasing the capacity and extending the lines of these two railways to properly serve the coal, iron ore, and manganese mines and the several steel plants in the Ukraine Province. It also included the examination of the seaports on the Black Sea. Nearly three months were required to complete the inspection and to obtain the desired data in Russia. A report on the project was compiled after Mr. Kelley's return to New York City and completed in June, 1926.

During August and September, 1926, an analysis and report were made of the Buffalo, Rochester and Pittsburgh Railroad Company, which report was used in the testimony presented before the Interstate Commerce Commission in connection with the hearing relating to the proposed lease of the Buffalo, Rochester and Pittsburgh by the Delaware and Hudson Company to form a part of the Loree project for an additional trunk line from New York City westward.

On May 20, 1927, Mr. Kelley again sailed from New York City, this time to make a study and an analysis of the State Railways of the Kingdom of Roumania, including their location, physical condition, equipment, operating

* Part of Interstate Commerce Comm. Docket, 12964.

methods and results, and earning power. These lines covered a total of 11 085 km., or 6 888 miles, including 150 miles of second track. The work involved a detailed inspection of the physical properties, the obtaining of data on operating performances and results, and an estimate for the rehabilitation and extensions to serve properly the traffic requirements of Roumania, including all commodities produced or transported within and throughout that country.

Mr. Kelley returned to New York on August 26, 1927, and for the next three months was occupied in compiling a report on his findings which he completed in December, 1927, at Omaha, Nebr. Subsequently, he was called to New York (January, 1928) for discussion and conferences in connection with both the Russian and Roumanian work. Concluding his stay in New York, he went to his home in Dallas, Tex., to attend to an accumulation of matters relating to his personal affairs and in April, 1928, went to San Diego, Calif., for rest and recreation.

His plans at that time were made in expectation of further service in connection with the two foreign projects, and he anticipated returning to Europe some time during June or July, 1928, to continue the investigations and conferences incident to the negotiations with the two Governments; but fate willed otherwise, and he passed on to that bourne from which no man returns on May 15, 1928, at San Diego.

Mr. Kelley was affiliated with numerous religious, fraternal, social, and business organizations, including the Protestant Episcopal Church and the Church of England; the Masonic Order; the Mount Royal Club; the Forest and Stream and Mt. Bruno Country Clubs (Montreal); the New York Yacht Club (New York City), the Congressional Country Club (Washington, D. C.), and many others.

He was a member of the Executive Committee of the American Railway Association from June, 1919, to January, 1923; the Standing Committee of the Association of Railway Executives from its inception until he retired from the Grand Trunk System; the Committee on Relations (now Section V) of the American Railway Association from 1911 to 1921, inclusive; the Per Diem Rules Arbitration Committee (one of five members); the American Railway Engineering Association, of which he was President for two years; the Institution of Civil Engineers, of London, England; the Canadian Institute of Civil Engineers; and a Director of the Royal Trust Company of Canada, from 1917 until his death.

Mr. Kelley was married in 1897 to Cora Lingo, of Denison, Tex., who survives him. He is also survived by two brothers, Walter S. Kelley, of Wheeling, W. Va., and Henry Kelley, of Big Spring, Tex.; and one sister, Mrs. Edith Homan, of Oklahoma City, Okla.

The passing of Howard G. Kelley is a grievous loss and he is mourned by many. His character and personality were of the highest type, his ability recognized by all, and his energy and thoroughness known to those with whom he came in contact. He was honored and respected as was his due.

Kindly and considerate, appreciative and generous, with that unusual understanding of conditions and personal temperament affecting those who worked

with him and for him; always ready to listen and to give sound counsel to every one; charitable to all; and the most delightful companion in every phase of life—these are only a few of the excellent attributes which he possessed.

His power of analysis and his sound judgment were accepted in determining methods and rules for guidance in the successful direction and advancement of transportation affairs by the owners and executives of the railways of the United States and Canada. His capacity for work seemed almost unlimited and his success in the railroad and business world are proof of his motto, "Without work, nothing".

Mr. Kelley was elected a Member of the American Society of Civil Engineers on May 1, 1889.

JAMES HENRY KENNEDY, M. Am. Soc. C. E.*

DIED OCTOBER 21, 1927.

The passing of James Henry Kennedy laid to rest one more of those fine old personalities who link this somewhat materialistic age with the romance of the railway builders of 40 or 50 years ago. That splendid group of pioneers have given much color to the history of National development on this Continent. Their part in those great enterprises which traversed the vast and beautiful expanse of Nature in the Northern and Western wilds, fashioned in them a nobility of character and purpose which has endeared them to all and rightly added to the pride and pleasure in their achievements. As Mr. Kennedy was an honored and respected representative of that passing generation of nation builders, it seems fitting that this brief narrative of his life should endeavor to retain at least some trace of the spirit which lifted him out of the humdrum of uneventful existence into adventure and success as a pioneer engineer in a realm of great and noble enterprise.

James Henry Kennedy was born on March 3, 1852, at Stittsville, Ont., Canada, which is just a few miles from Ottawa. His boyhood was spent on a farm in Elgin County, Ontario, near St. Thomas. There he developed a sturdy physique, a clean healthy mind, and a stirring ambition. His religious ideals were fostered in a Baptist atmosphere, and the habits of youth remained constantly with him to the end.

His early education was received at a rural school, and it was not until his twenty-fifth year that he commenced his higher education at Woodstock College, Ontario. Two years later, in October, 1879, he entered, as a Freshman, the old School of Practical Science, now recognized as the Faculty of Applied Science and Engineering of the University of Toronto. Under the personal instruction of the late Dean John Galbraith, with whom he formed a lasting friendship, he was graduated with honors in Civil Engineering in 1882, at the age of thirty. This marked the commencement of his professional career.

It was typical of Mr. Kennedy's modesty that he habitually termed himself "an awful duffer at school", but the fact that he attempted and gained a university education without a single failure, at such a mature age, is significant of his strength of character and mental ability. During his latter days he was the recipient of much honor and frequent congratulations in recognition of his being the oldest living graduate of the School of Practical Science, and the possessor of the degree of Civil Engineer awarded to him by the University of Toronto in 1886.

His first engineering job was as Rodman and Field Draftsman on a survey for the Canadian Pacific Railway during the summer of 1882, but in September of that year he was appointed Assistant Engineer on the re-measurement of Section "B", and in April, 1883, was promoted to be Assistant Engineer on the location and construction of the Lake Superior Division, where he continued until March, 1885.

* Memoir prepared by P. H. Buchan, Esq., Vancouver, B. C., Canada.

After spending three years in the wilds, Mr. Kennedy evidently felt the attraction of civilization for, in July, 1885, he was articled to A. D. Baikie, Provincial Land Surveyor, at St. Thomas, with whom he remained until he obtained his Ontario Land Surveyor's certificate (O. L. S.) in the spring of 1887. In May, 1887, he was re-engaged by the Canadian Pacific Railway Company as Locating Engineer on the Detroit Extension, between Woodstock and London, Ont., and afterward on the location and construction of the Temiscouata Railway in Quebec and New Brunswick. In May, 1889, he went to Minnesota to enter private practice in Winona as Deputy County Surveyor with the late M. S. Parker, M. Am. Soc. C. E.; but shortly afterward he was employed as Inspector of Tracklaying on the Neighart Branch of the Montana Central Railway.

For the next five years, Mr. Kennedy was very active on railway construction in the United States. In July, 1889, his services were engaged by the Great Northern Railway Company as Engineer in charge of surveys and construction on the Rocky Mountain Division of the Pacific Extension in Montana, through what is now known as Glacier National Park. To have progressed thus far, from an inexperienced Rodman on a survey party, in only seven years, points strongly to his enthusiasm and skill. He remained with this great project until March, 1892, after which he spent eighteen months on the construction of the Minneapolis, St. Paul, and Sault Ste. Marie Railway extensions in North Dakota. During this period he made examinations and reports on all the bridges in the "Soo" System for the late W. W. Rich, M. Am. Soc. C. E., then Chief Engineer of the "Soo" Lines.

In August, 1894, the spell was broken for the second time, and Mr. Kennedy resumed private practice as a Land Surveyor under his own name at St. Thomas. Concurrently, he became interested in a machine shop and bicycle factory in that city. However, three years of life in civilized parts appeared to satisfy him, for in February, 1898, he engaged with MacKenzie and Mann, under the direction of Mr. T. H. White, to go to the Stickine River in charge of Yukon Railway surveys between Telegraph Creek and Teslin Lake, in British Columbia. He remained there until mid-summer and then went south to take charge of the location of a line in the Okanagan, from Penticton to Midway, B. C. Later, he made several surveys for the British American Coal Company in the vicinity of Crows' Nest Pass, which occupied him until the spring of 1900.

He spent two years in British Columbia, his future home, and then returned to Ontario, where he was engaged to locate an electric railway from London to Port Stanley, near the scenes of his boyhood. The call of the wilderness, however, soon lured him away to Michipicoton Harbor, where he took charge of three survey parties for the Algoma Central Railway Company, from the great Algoma iron mines to Sault Ste. Marie. It was during the winter of 1900-01 that he made a reconnaissance on snowshoes down the Agawa River to Agawa Bay, in company with the late William McCarthy.

Having reached the age of forty-nine years, Mr. Kennedy once more turned his face westward, this time to stay. In February, 1901, he re-entered

the service of MacKenzie and Mann as Assistant Chief Engineer on the construction of the Vancouver, Victoria and Eastern Railway and Navigation Company's line from Penticton to Midway, on the location surveyed by himself in 1899. This line was acquired by the Great Northern Railway Company during 1901, and Mr. Kennedy acted in the same capacity with the latter Company. Nine years had elapsed since his previous engagement with the Great Northern in Glacier National Park. It was not long before he was promoted to the post of Chief Engineer of the Vancouver, Victoria, and Eastern Railway Company, from Laurier to the Pacific Coast, which position he retained until his retirement on August 15, 1915, at the age of sixty-three.

Much of his work in this connection involved heavy construction through rough mountainous country, the most difficult portions being the branch line from Laurier to Grand Forks, B. C., through the Kettle Valley, and the longer section of main line between Chopaka and Brookmere through the Similkameen and Tulameen Valleys. This construction called for a high degree of engineering initiative and skill to bring it to a successful conclusion, and Mr. Kennedy believed it to be the most difficult piece of railway construction he had ever undertaken. His retirement completed seventeen years with the Great Northern Railway Company on railway extensions.

In 1916, he opened an office for consulting practice at Vancouver, specializing in railway construction. He was also engaged on inspection work for the British Columbian Government during 1916 and 1917, on the construction of the Pacific Great Eastern Railway. From 1918 to 1922 he was retained by the Brooks, Scanlon, O'Brien Logging Company as Consulting Engineer on logging railway construction. In the summer of 1923 he made an inspection and report on the Edmonton, Dunvegan, and British Columbia Railway for the Alberta Government, and did further work of the same nature on this line in the late fall of 1926. During 1924 and 1925 he acted as Inspector of State Highway work for the Great Northern Railway Company at Rock Island, Wash.

That Mr. Kennedy kept in harness until he was nearly seventy-five years of age is no slight tribute to his splendid physical and mental qualities. His professional career covered a period of forty-five years. On January 20, 1887, he joined the Canadian Society of Civil Engineers as an Associate Member, his election to Membership occurring on May 18, 1893. Toward the close of his career he was granted Life Membership by the Engineering Institute of Canada (the successor of the Canadian Society of Civil Engineers) and also by the Society.

On October 6, 1923, Mr. Kennedy sat for a group photograph comprising T. H. White and the late H. J. Cambie, Members of the Engineering Institute of Canada, and himself, in commemoration of their distinguished services as Pioneer Railway Builders in British Columbia. An enlargement of this group was presented by the Institute to the Provincial Library at Victoria in 1924. This group is unique for several reasons, not the least interesting being the fact that Mr. Kennedy, although seventy-two, was the youngest member of the trio.

Among his varied interests during his later years, he was Vice-President of the Pacific Investment Corporation of Vancouver, and served as a member of the Executive of the Convocation of the University of British Columbia. He was a member and regular attendant of the First Baptist Church of Vancouver.

On June 30, 1884, he was married to Annie Huntley, at Toronto, Ont. He is survived by his widow, two sons, Edward and Arthur, and one daughter, Alice (Mrs. Harold P. Cowan, of Toronto). There are four grandchildren. Mr. Kennedy failed noticeably in his last year, although he believed that a contemplated trip to California would restore his former vigor. He passed away quite suddenly at his home in Vancouver and was buried in Ocean View Cemetery, leaving to his native Canada a long record of honorable achievement in his chosen career of Pioneer Railway Builder.

Mr. Kennedy was elected a Member of the American Society of Civil Engineers on May 2, 1900.

WILLARD KENT, M. Am. Soc. C. E.*

DIED DECEMBER 22, 1924.

Willard Kent was born on October 27, 1851, at Marshfield, Mass., the son of Warren and Eliza W. (Weston) Kent. His ancestry extends back through various family branches to ten or twelve of the *Mayflower* Pilgrims.

His early life was spent in Marshfield where his father was a Building Contractor and where his primary education was commenced in the public schools. He afterward attended academies at Hanover, Mass., and Woonsocket, R. I.

From 1875 to 1884 Mr. Kent was employed as Chief Engineer in the office of the late John W. Ellis, M. Am. Soc. C. E., Consulting Engineer, of Woonsocket, during which time he managed the engineering work for the Providence and Worcester Railroad Company (now a part of the New York, New Haven, and Hartford Railroad Company), including the design and erection of repair shops at Valley Falls, R. I., as well as several passenger stations.

He was in charge of the design and building of the Woonsocket Water-Works, during 1883 and 1884, on the completion of which he was made Superintendent. In 1884, he opened offices in Woonsocket and Narragansett Pier, R. I., for private practice as a Consulting Engineer and Architect. He remained in charge of the Woonsocket Water-Works, however, until 1890.

Mr. Kent served as Consulting Engineer to the Woonsocket Electric Machine and Power Company, one of the very early municipal electric power plants of New England, the Nourse Mill of Woonsocket being the first textile mill in the United States to be electrically illuminated. He was in charge of the design, construction, and initial operation of the electric light plant at Woonsocket and also of the first electric street car lines in New England—a double trolley system put into operation about 1887.

Mr. Kent was married in 1876 to Jennie Moorhead, of Marshfield, who died in 1893, leaving two sons and a daughter. Later, he was married to Charlotte Angel, of Greystone and Narragansett Pier, R. I., who survives him. He maintained his legal residence in Woonsocket, although he lived principally at Narragansett Pier from 1893 until his death from cancer on December 22, 1924.

He was a member of various Masonic bodies in Rhode Island, as well as of the Boston Society of Civil Engineers and of the New England Water Works Association, having served as Secretary of the latter for many years.

Mr. Kent was elected a Member of the American Society of Civil Engineers on October 2, 1907.

* Memoir prepared by J. Parker Snow, M. Am. Soc. C. E.

PAUL KIRCHER, M. Am. Soc. C. E.*

DIED JULY 10, 1927.

Paul Kircher, the son of the Rev. Johannes G. and Louise C. (Nieman) Kircher, was born in Chicago, Ill., on July 27, 1890.

Mr. Kircher's early education was received under the direction of a tutor, following which he entered the Francis W. Parker School, from which he was graduated in 1908. He then entered the Engineering School of the University of Illinois, but by reason of extra work and diligent study in the Liberal Arts College, he received, in three years, the degree of Bachelor of Arts (1911) and his Bachelor of Science degree in 1912. The degree of Civil Engineer was conferred in 1918 on the presentation of his thesis, the subject of which was "Concrete Ships". While in college, he was a member of Triangle and of Scabbard and Blade (honorary) Fraternities. His height, 6 ft. 2 in., made him an imposing Colonel of the University Regiment. He was also an honor student, having been elected to Sigma Xi Fraternity. In 1910, during his college career, he was employed as Chainman for a City and County Surveyor of Chicago, and the following year as Rodman for the City of Chicago Heights, Ill.

Following graduation from college, Mr. Kircher spent a year traveling in Europe. He then entered the employ of the Illinois Central Railroad Company as a Draftsman, remaining until November, 1916, when he resigned to take employment with the Universal Portland Cement Company of Chicago as an Engineer in the Promotion Bureau. In October, 1917, he became identified with the C. F. Massey Company, and, later, its successor, the Massey Concrete Products Corporation, with which organization he remained until his death. During this period, he served, first, in the capacity of Office Engineer, and, later, as Sales Engineer, Resident Manager, and, finally, Vice-President of the Canadian Concrete Products Company, Limited, a subsidiary, and also as Resident Manager of the Union Switch and Signal Company. For a period of five years, from 1920, he had responsible charge of the operation of the centrifugal concrete pole business of the Company and developed the theory and checked by experiments the designs of hollow reinforced concrete poles and beams.

From 1919 until his death, he also served as a member of the Joint Concrete Culvert Pipe Committee, representing the American Concrete Pipe Association.

Mr. Kircher was a man of high technical capacity, possessing a keen, mathematical mind. He was of great value to his Company and to the committees that he served as a Technical Adviser. His personality also endeared him to all who knew him or came in contact with him.

He was married in October, 1914, to Catherine Planck who, with three children, Paul, Joanne, and Robert Emerson, survives him.

* Memoir prepared by Charles Gilman, M. Am. Soc. C. E.

He was a Licensed Professional Structural Engineer in Illinois and Canada. He was also a member of the Chicago Engineers Club, the Toronto Engineers Club, the Montreal Engineers Club, the Midland Club of Chicago, and the Marlborough Golf Club.

Mr. Kircher was elected an Associate Member of the American Society of Civil Engineers on October 8, 1918, and a Member on June 16, 1924.

BATTLE HARGROVE KLYCE, M. Am. Soc. C. E.*

DIED MAY 23, 1928.

Battle Hargrove Klyce was born in Carpenteria, Calif., on December 10, 1882, the son of a minister of the Methodist Episcopal Church. In his early childhood his parents moved to Tennessee. His primary education was received in the public schools of the State until he became old enough to prepare for college. He then attended the Webb School for Boys at Bellbuckle, Tenn., where he studied under the famous Sawney Webb—founder of the school—who enjoyed the distinction of being one of the outstanding teachers and developers of boys' character in all the Southland. On the completion of his course at the Webb School, Mr. Klyce entered Vanderbilt University, at Nashville, Tenn., enrolling in the course in Civil Engineering; he was graduated from Vanderbilt in 1906 with the degrees of Bachelor of Arts and Bachelor of Engineering. His work in college was of the highest order, winning for him the honor of membership in Phi Beta Kappa. He also won the Founders' Medal for scholarship, the highest honor to be achieved at Vanderbilt University.

Immediately after his graduation, Mr. Klyce was employed as Assistant City Engineer of Jacksor, Miss., which position he occupied for about three years, when he was made City Engineer. He held this position until January, 1911, when he became associated with Solomon and Norcross, of Atlanta, Ga., for which firm he supervised the construction of municipal improvements in several Southern cities. In 1912, he became City Engineer of Waycross, Ga., where he remained for about a year and one-half, after which he returned to private work with the late James N. Hazlehurst, M. Am. Soc. C. E., at Miami, Fla. On the completion of this engagement he was employed by the City of Miami to take charge of the design and construction of various municipal improvements, including sewers, sewage pumping station, sewage disposal works, incinerator, paving, etc. This work extended over a period of three and one-half years.

In June, 1916, Mr. Klyce became associated with W. J. Kackley, M. Am. Soc. C. E., under the firm name of Klyce and Kackley, of Nashville, Tenn., engaged in general engineering business in Florida, Georgia, Tennessee, and Arkansas. Mr. Klyce also acted as Project Engineer for the U. S. Housing Corporation for the proposed housing development at Wrigley, Tenn., and as Supervising Engineer to the Construction Quartermaster for the Aviation Gunnery School at Chapman Field, Miami.

His outstanding work was the design and construction of the Miami Causeway, a structure which extends a distance of three and one-half miles across Biscayne Bay, and which is a monument to his engineering ability.

The partnership of Klyce and Kackley was dissolved in 1920, after which Mr. Klyce continued in business in his own name for several years. In 1923, he became associated with C. N. Harrub, M. Am. Soc. C. E., later changing the firm name to Klyce and Harrub. The new firm continued in municipal

* Memoir prepared by C. N. Harrub, M. Am. Soc. C. E.

engineering work, and at the time of Mr. Klyce's death, was serving many cities in Tennessee, Kentucky, and Mississippi.

In 1912 he was united in marriage to Marion Watkins, of Jackson, Miss., who, with their five children, Erskine, Battle H. Jr., Shelby, Billie, and Mary Alice, survives him.

Soon after Mr. Klyce's return to Nashville from Florida, he connected himself with the Blakemore Methodist Episcopal Church of that city, and became one of its leaders. He was Chairman of the Building Committee for the construction of the new church in 1924, and, subsequently, was also Chairman of the Finance Committee.

Mr. Klyce's varied experience in many States of the South made for him an unusually large circle of friends, as all who knew him liked him and respected him for his manliness and high Christian character. He was a member of the Engineering Association of Nashville, of which he was President in 1927. He was also a Past-President of the Nashville Local Section of the Society. He was a member of the Nashville Automobile Club and the Lions' Club.

Mr. Klyce enjoyed the respect and esteem of his engineering colleagues, and his death is a blow to the profession which will long be felt; his associates in church and business will find his place difficult to fill.

Mr. Klyce was elected an Associate Member of the American Society of Civil Engineers on June 30, 1911, and a Member on March 9, 1920.

OSCAR FRANCIS LACKEY, M. Am. Soc. C. E.*

DIED DECEMBER 19, 1928.

Oscar Francis Lackey was born in Washington, D. C., on July 1, 1874. He was the son of the late Milford Fiske Lackey, who served for many years as Chief Auditor of the Treasury Department. The family moved to Baltimore, Md., when Oscar was thirteen years old. He was educated at Rock Hill College and was graduated from Johns Hopkins University in 1896. In 1897, he went to Santiago, Chile, as an Engineer of the War Department under the late Gen. Leonard Wood, U. S. A. He survived an attack of yellow fever and returned to Cuba on dock construction work and, later, went to Panama on an engineering engagement connected with the construction of the Panama Canal.

Mr. Lackey returned to the United States in 1905 and was appointed Principal Assistant to the late N. H. Hutton, M. Am. Soc. C. E., who was then Chief Engineer and President of the Harbor Board of Baltimore. When Major Hutton died, a few years later, Mr. Lackey succeeded him in this important post and had charge of important dock and pier construction. He was one of the first, if not the first, engineer to utilize reinforced concrete piles in pier construction. He held this position until 1915, and his extensive harbor development plans and recommendations for a $50 000 000 loan for this purpose were looked upon as fanciful at the time. Later developments, since the end of the World War, have thoroughly justified Mr. Lackey's vision, and a loan of this amount has been passed by the Maryland Legislature and voted by the people.

In 1912, Mr. Lackey was selected as one of the five Directors of the Association of Seaport Authorities and, in 1914, he was elected President of the Association of Port Authorities.

In 1915, he became Assistant to the President of the Poole Engineering Company, of Baltimore, and in this position negotiated the purchase of a manufacturing plant in Lafayette, Ind., engaged in the manufacture of shells for the British Government; he operated the plant for two years. In 1918, he was appointed Supervising Engineer in the War Department, under the late Maj.-Gen. George Goethals, U. S. A., M. Am. Soc. C. E., for the construction of the Atlantic Port terminals in Boston, Mass., Philadelphia, Pa., Brooklyn, N. Y., Norfolk, Va., New Orleans, La., and Charleston, S. C.

Mr. Lackey returned to Cuba on consulting engineering work in 1921 and, in 1922, he went to Colorado Springs, Colo., as Vice-President and General Manager of the Colorado Springs Light, Heat, and Power Company. On the change of ownership of this Company, he returned to the East and was engaged as Consulting Engineer on several dock and pier projects. In 1924, in addition to his consulting work, he was appointed head of the Transportation Bureau of the City of Baltimore, which position he held

* Memoir prepared by Ezra B. Whitman, M. Am. Soc. C. E.

until 1927. Shortly before his death, he was engaged by the State Roads Commission of Maryland to pass upon the plans of the proposed $10 000 000 bridge across Chesapeake Bay.

While in Panama, Mr. Lackey was injured on the work, and although this injury troubled him until the time of his death, his indomitable spirit kept him going when men of lesser courage would have given up. He was of the stuff that never yields to misfortune, but turns defeat into victory. He was intensely loyal to his friends and was ready at all times to fight for what he believed to be right. His uncompromising spirit, his undeviating loyalty to high personal principles and to professional standards marked him as a man in whom others could put their trust. To his professional work, he gave not only his head, but his heart, and whatever he did was done with all his might. He was never lukewarm nor a slacker in anything, and he never failed to make good where it was humanly possible to do so.

Mr. Lackey died in Baltimore on December 19, 1928, of pneumonia, after an illness of less than a week. His death was a great shock to his many friends and came only a few weeks after his appointment by Governor Ritchie to the important position as Chairman of the State Roads Commission of Maryland.

Mr. Lackey was elected a Member of the American Society of Civil Engineers on April 6, 1909.

CHARLES WELLFORD LEAVITT, M. Am. Soc. C. E.*

DIED APRIL 22, 1928.

Charles Wellford Leavitt, the son of C. W. Leavitt and Sarah Allibone Leavitt, was born at Riverton, N. J., on March 13, 1871. He was educated at the Gunnery School, at Washington, Conn., and at the Cheltenham Military Academy of Pennsylvania.

Mr. Leavitt's engineering career began in 1888, when he accepted a position as Assistant Superintendent of Construction with his father's contracting firm. A year or so later, he became Assistant Engineer of the Caldwell, N. J., Railroad and was subsequently promoted to the position of Chief Engineer.

In 1892, he became Chief Engineer of the New York Suburban Land Company, engaged in the development of Essex Fells, N. J. Mr. Leavitt remained with this Company for three years, finally leaving it to enter the employ of the East Jersey Water Company.

In the fall of 1896, Mr. Leavitt formed a partnership with Rudolph Ulrich, a Landscape Architect, well known for his abilities. This partnership continued for about two years, at the end of which time Mr. Leavitt opened an office and established himself as a Civil and Landscape Engineer, concentrating on this work, which gave him so much pleasure and held so much of interest during his lifetime. A review of some of the outstanding results of Mr. Leavitt's life work shows how diversified were his attainments within the scope of his field.

Among the larger private estates which were developed under his guidance were those of William C. Whitney, Daniel Lamont, Foxhall Keene, and Charles M. Schwab.

Belmont Park, Saratoga, Empire City, Havre de Grace, and the Montreal Jockey Club are race-tracks on which Mr. Leavitt's planning had a controlling influence.

He made plans for the Palisades Interstate Park; Stamford Park at Stamford, Conn.; Monument Valley Park, at Colorado Springs, Colo.; Schenectady Park, Schenectady, N. Y.; Mahlon Stacy Park and the State House Park, at Trenton, N. J.; Saratoga Springs Park, Saratoga, N. Y., and for the Fairmount Park Commission of Philadelphia, Pa. He was also Landscape Engineer for the Camden County, New Jersey, Park Commission.

Among the Country Clubs which were developed under Mr. Leavitt's landscape plans were the Westchester-Biltmore, Rye, N. Y.; the Rumson Country Club, Rumson, N. J.; the Englewood Golf Club, Englewood, N. J.; the Lido Country Club, Long Beach, Long Island, and the New Orleans Country Club, New Orleans, La.

Many large real estate developments were planned and supervised by Mr. Leavitt, among which may be mentioned those for the Pennsylvania Steel Company at Steelton, Pa.; for the Worth Brothers, at Coatesville, Pa.; the Kilgour and Stettinius Estates, at Cincinnati, Ohio; Milner Heights, Birmingham, Ala.; and Long Beach, Long Island, N. Y.

* Memoir prepared by M. W. Weir, M. Am. Soc. C. E.

University and institutional grounds also attracted his interest, and among those which he laid out were: Tome Institute; the New York Juvenile Asylum; the Peabody College for Teachers; Oglethorpe University; the Presbyterian College of South Carolina; Lehigh University; and Fordham University.

Among the cemeteries which Mr. Leavitt planned are the Gate of Heaven Cemetery, at Kensico, N. Y., and part of Woodlawn Cemetery, at Woodlawn, N. Y.

His city planning practice also included work done for Camden, N. J.; Garden City, N. Y.; Trenton, N. J.; Brunswick, Ga.; West Palm Beach, Fla.; Lakeland, Fla.; and Mount Vernon, N. Y.

Mr. Leavitt was a member of the American Society of Landscape Architects, Past-President of the American Institute of Consulting Engineers, a member of the Engineering Committee for the Plan of New York and Its Environs, the Architectural League, the National Conference on City Planning, the American City Planning Institute, the Interstate Metropolitan Planning Conference, the International Garden Cities and Town Planning Federation, the National Conference on State Parks, and the Garden Club of America.

He was a member of the Union Club, the Transportation Club, the Westchester-Biltmore Country Club, the Racquet Club, Philadelphia, the Adirondack League Club, the Play and Players Club, Philadelphia, and the New England Society of New York.

He was also a member of the New York State Chamber of Commerce, the Westchester Chamber of Commerce, the American Civic Association, and the New York State Board of Real Estate Boards.

Mr. Leavitt was a man of great energy and his interest in public affairs was keen, although he took no part in politics. Of clear mental vision, his judgment was sage and well founded. His imagination could always be depended upon to look forward, and from this quality, coupled with business acumen and a driving personality, came, in a large measure, the successes for his clients in his chosen profession.

With these attributes, his congeniality, and his ready wit, Mr. Leavitt was a delightful companion, a splendid friend, and an inspiring leader. The influence of such a life cannot be estimated, but of this one may be sure, it was great, and its reflection will persist for the good of all.

He was married to Clara Gordon White on September 26, 1899, and is survived by his widow and four children, Gordon, Kent, Charlotte, and Dundas.

Mr. Leavitt was elected an Associate Member of the American Society of Civil Engineers on January 4, 1899, and a Member on May 2, 1905.

FRANK McDOWELL LEAVITT, M. Am. Soc. C. E.*

DIED AUGUST 6, 1928.

Frank McDowell Leavitt was born at Athens, Ohio, on March 3, 1856. He was the second son of the Rev. McDowell Leavitt and Bithia (Brooks) Leavitt. His paternal grandfather, Humphrey Howe Leavitt, as a young lawyer, had moved from Eastern Massachusetts to Southern Ohio and later became, in turn, Congressman for the Cincinnati District and Judge of the United States District Court. His maternal grandfather, Moses Brooks, when a young man, had moved from Western New York to Cincinnati, Ohio, where he became a substantial merchant and then a prominent member of the bar of that city.

In 1868, Mr. Leavitt's father moved to New York, N. Y., and subsequently became President of St. John's College, at Annapolis, Md., and of Lehigh University. On arrival in New York, young Frank was entered in the famous Hunter Public School on 13th Street, but, in 1869, the lad was forced to leave because the family moved to Orange, N. J. After two years of school in Orange during which he had shown the most pronounced predilection for engineering, and decided qualities of self-discipline, industry, and self-reliance, he entered Stevens Institute of Technology from which he was graduated in 1875. His Alma Mater conferred on him the degree of Mechanical Engineer in 1905, and the degree of Doctor of Engineering, on the Fiftieth Anniversary of the Institute, in June, 1921.

Immediately after graduation, Mr. Leavitt entered the employ of the late Fred E. Sickels, M. Am. Soc. C. E., a prominent engineer of that day. One of his first assignments was the development of a steam steering gear for the U. S. S. *Trenton*, which vessel was lost in the great Samoan hurricane about 1888.

In August, 1876, he became Head Draftsman for Bliss and Williams, of Brooklyn, N. Y., and was employed there until early in 1881. He then decided to try other branches of engineering and for nearly a year was Master Mechanic of the Texas Division of the Mexican National Railroad, with headquarters at Corpus Christi, Tex. Late in 1881, he returned to New York and became Superintendent of the Graydon and Denton Manufacturing Company, of Jersey City, N. J., manufacturers of rock drills and mining machinery. He remained in this work for two years and patented a number of important improvements in the tools he was then manufacturing.

In 1883, however, Mr. Leavitt withdrew from the mining machinery field and returned to the E. W. Bliss Company (successor to Bliss and Williams), as Assistant Superintendent, and, in 1884, was appointed Superintendent of that Company. From this time until about 1900, he was actively engaged in designing and manufacturing a most varied line of sheet-metal working machinery.

* Memoir prepared by Logan Cresap, Commander, U. S. N. (*Retired*), New York, N. Y.

The records of the Patent Office commenced to show his name as an inventor within a year or two of his graduation from Stevens Institute, and from that time until 1921 or 1922, a constant stream of patents aggregating approximately three hundred, testify to his mechanical skill and inventive genius. The outstanding accomplishment of the early years of this productive life was the invention and development of the first automatic tin can body-making machine. Until that time, such tin cans as were used in the United States were made practically by hand and to Mr. Leavitt belongs the honor and distinction of having been the first man to conceive and develop a fully automatic machine which would perform all the necessary operations in the production of such can bodies. At that time the rate of speed at which this machine made these bodies was considered tremendous and so far beyond the normal requirements of can users that much difficulty was encountered in selling it. Meeting little or no encouragement in this country the machine was sent to the Paris Exposition about 1880 in the hope that some of the large canners of England or Continental Europe would appreciate its economic value. Unfortunately, however, only failure met this effort and the machine had to be brought back to Brooklyn and for a time was regarded practically as a "white elephant". Finally, however, one of the large can makers and packers in the Chicago District became interested and purchased it. Its use gave a tremendous impetus to canning in America and very properly may be regarded as the first stage in the modernization of that industry.

Another machine of Mr. Leavitt's which soon came into wide and ever-expanding use was the toggle drawing press for use in the manufacture of all sorts of hollow drawn ware, kitchen utensils, etc. His early inventions in drawing and stamping machines were the initial steps in the development of the huge power presses used to-day, particularly in this country, in the automobile industry for the quantity production of automobile bodies, frames, and accessories.

In addition to these two specific machines, on which improvements naturally were made later, Mr. Leavitt patented many original types of other machines, such as, drop hammers, punching presses, clutches, air compressors, shaft couplings, pumps, etc.

In the late Eighties, the Navy Department was making efforts to introduce into the United States the manufacture of up-to-date ordinance. These efforts resulted in the purchase of many European patent rights by American firms and the introduction of the manufacture of the latest types of armor-plates, armor-piercing projectiles, built-up guns, and automobile torpedoes into American industry. The Bethlehem Steel Company, the Carpenter Steel Company, and the E. W. Bliss Company were among the important commercial pioneers in this movement.

After an extensive tour abroad, during which he visited the British, Austrian, and German torpedo and projectile manufacturing plants, Mr. Leavitt, representing the E. W. Bliss Company, purchased the American rights to the Whitehead torpedo and, in 1890, introduced its manufacture into America. To the surprise of the vendors, he purchased no patent rights

or machines involved in the complicated manufacture of the torpedo, but immediately on his return, set to work to develop his own manufacturing equipment. In this, he was so successful that the original manufacturers were soon outstripped in economical and accurate production. During this same period he designed and installed the plant of the United States Projectile Company, in which small and medium caliber "common" projectiles were manufactured.

Subsequent to 1890 Mr. Leavitt's activities were gradually shifted from metal-working machines to automobile torpedoes and from 1900 until just prior to the World War, the Patent Office records show a steady stream of developments in torpedoes under his name. When he first undertook the manufacture of the Whitehead torpedo, it was a puny bronze instrument about 11 ft. long and 17 in. in diameter, with a range of about 800 yd., uncertain directive control, and carried an explosive charge of about 50 lb. of gun cotton. Mr. Leavitt gradually improved the torpedo by the introduction of steel for the air flask, the Curtis turbine for propulsion, the combustion of fuel in the air supply, the generation of steam in connection with that combustion, an entirely new and dependable gyroscopic steering apparatus, and many other innovations. His development of the gyroscope, alone, was an important contribution to mechanical engineering, and found application in other fields.

In order to secure the time to assemble and properly develop his ideas for this new torpedo, he left the E. W. Bliss Company shortly after 1900, and for a year or more established his own office and drafting-room in New York. On the issue of the patents for this new torpedo and their purchase by the E. W. Bliss Company he returned to that Company as an Officer and Director. This new torpedo became known as the Bliss-Leavitt torpedo and from about 1910 until the present time it has been, and still is, the standard equipment of the United States Navy. At the beginning of the World War this torpedo was about 21 ft. long and 21 in. in diameter, capable of reliable and accurate control over a range of about 13 500 yd. It was propelled by a super-heat steam and combustion gas turbine, operating at a temperature of about 1 000 to 1 100° Fahr., the most efficient torpedo in any navy, and carrying an explosive charge of more than 200 lb. of tri-nitro-toluol.

At the outbreak of the World War Mr. Leavitt offered his services to the Navy Department and shortly thereafter was placed in charge of a small committee known as the "Committee on Experimental Power", to which the Bureau of Steam Engineering assigned the task of developing a steam plant for the propulsion of aircraft. For this work, Mr. Leavitt was commissioned on a dollar-a-year basis. Having by this time practically retired from active connection with the E. W. Bliss Company, except as Director, he could devote his entire time to this work, which he proceeded to do with his usual vigor. At the end of the war the Navy Department decided to continue the work of this Committee, as it was believed that although the boiler plant which had been developed might not actually become a competitor of the gasoline engine, for aircraft use, such promising and interesting features had been produced or, were under investigation, which possibly might have a much

wider application in naval engineering, particularly in submarine propulsion, as to warrant the continuation of the experimentation. The Committee, therefore, was reduced in size and was authorized to complete its investigation under Mr. Leavitt's direction. It continued to function for nearly two years, and when finally dissolved, turned over to the Navy Department plans and test records for an aircraft boiler which, with all appurtenances, control apparatus, and the necessary water, delivered about 1 000 h. p., with a total weight of about 2 000 lb. This was practically the last engineering work which Mr. Leavitt undertook.

He was known in the Engineering Profession, and particularly among his friends and associates in that profession, as a genius in conceiving and designing mechanism to accomplish, with the utmost simplicity, a given purpose or necessity. His remarkable ability to visualize a problem, and his knowledge of mechanical motion and force, enabled him to picture the most difficult mechanism in the simplest of forms, to design its parts in detail, and to direct its construction in the shop, ofttimes without even assembling the parts on drawings.

Mr. Leavitt was a gentle, modest, and friendly man, simple in his tastes and personal requirements, and these qualities endeared him to those who knew him personally, and claimed, and held, the respect of his business associates. His principal diversions were painting in oils and reading. He was an omnivorous and broad reader, possessing the happy faculty of retaining what he read, and the profundity of his knowledge, when unconsciously revealed, was a source of wonder and enjoyment to his friends. In his personal relationships, his outstanding quality was a kindness and willingness to assist others, with that help which relieves the necessity, and the manner that graces the act.

In 1893, Mr. Leavitt was married to Gertrude Mitchell Goodsell, of New York, the daughter of Charles Morgan and Elizabeth Mitchell Goodsell. He is survived by his widow and a daughter, Beatrice Leavitt.

He was a member of the American Society of Naval Architects and Marine Engineers, the American Society of Mechanical Engineers, and the Engineers' Club of New York, the University Club of Washington, D. C., the Riding and Driving Club, and the Montauk Club, of Brooklyn, the Scarsdale Golf Club, of Scarsdale, N. Y., and the Sankaty Head Golf Club, of Siasconset, Mass.

Mr. Leavitt was elected a Member of the American Society of Civil Engineers on December 2, 1885.

GUSTAV LEHLBACH, M. Am. Soc. C. E.*

DIED MARCH 26, 1926.

Gustav Lehlbach was born in Baden, Germany, on July 3, 1844. The son of a Lutheran minister of progressive tendencies—a man who thought of principle first and safety afterward—he was brought to this country by his parents when, with Carl Schurz and Baron Friedrich von Steuben, they were forced to flee from Germany on account of his father's active participation in the rebellion of 1848. The family settled in Newark, N. J., where the Rev. Mr. Lehlbach accepted the pastorate of the old Mulberry Street German Evangelical Church.

Gustav Lehlbach attended the public schools in Newark and then started his preparation for an engineering career in the old way—by apprenticeship to a successful engineer. This connection was severed temporarily when, at the age of sixteen, at the outbreak of the Civil War, he marched off as a volunteer in General Kearney's unit. The pioneering spirit of his forebears found early expression when, one cold March morning, Mr. Lehlbach, with a single comrade, swam the Rappahannock River stripped to the skin, in order to be the first in the enemy's rifle-pits. Fortunately, the two adventurers were right in their conjecture that the Confederates had abandoned the pits during the night.

In 1861 he was severely wounded in his first engagement at the Battle of South Mountain. On his recovery he was assigned to the Signal Corps, and, toward the close of the war, was stationed as one of President Lincoln's bodyguard at Arlington Headquarters. Whether from the contacts of that period, or from subsequently acquired appreciations, he, like so many others on both sides of the Mason and Dixon Line, came to have an admiration for Abraham Lincoln which grew to reverence deep enough perhaps to have had something to do with later attitudes and ideals. Particularly in his later judgments of men in public life, and in the formation of his own views on political, social, and religious subjects, Mr. Lehlbach was much influenced by Lincoln—and by Jesus of Nazareth. He saw the Nazarene as Lincoln saw Him—clearly, undistorted by the refracting media of church, sect, and dogma.

After General Lee's surrender at Appomattox, Mr. Lehlbach took up his engineering apprenticeship where he had left it in 1861. In two short years he was Resident Engineer, locating and constructing the Newark and New York Railroad, not then a branch of the New Jersey Central, but an independent project backed by Newark men. Owing to his foresight, no grade crossings over Newark's streets were permitted, except at Mulberry Street, and this was eliminated later. He also sought to have the line carried at a high level over Broad Street to tap the Oranges, but in this he was overruled.

Bridge design in those days was a very much simpler matter than it is now; so that by continuous hard work, made possible by an exceptionally sturdy physique, Mr. Lehlbach acquired a working knowledge of that subject,

* Memoir prepared by Henry G. Babcock, Assoc. M. Am. Soc. C. E.

and, if the writer's recollection serves him rightly, was thus enabled to design the bridge across the Passaic River. The caisson foundations for the center pier of this old swing-bridge were, it is believed, his choice of construction method and were sunk under his direction.

From 1869 until the fall of 1871 he was Chief Engineer on the location and construction of the Port Royal Railroad from Augusta, Ga., to Port Royal, S. C., and subsequently Resident Engineer on the construction of the New York and Long Branch Railroad. On April 19, 1872, he became, as City Surveyor of Newark, the head of the Engineering Department of that city.

For five years, from 1875 to 1880, Mr. Lehlbach was engaged in private practice as a partner in the firm of Lehlbach Brothers at 196 Market Street, Newark, a business still carried on at the same address by his nephews, Herman B. and Milton Lehlbach.

In 1880, came another chance for that railroad pioneering which enlisted his enthusiasm more than any other engineering activity. First, in this period, came the Dover and Rockaway Railroad for the Central Railroad Company of New Jersey. Then, about 1883, he located the line of the Denver and Rio Grande Western Railroad, in Utah. Accurate information covering this part of Mr. Lehlbach's life is meager, but probably there should be assigned to it an episode in itself well enough authenticated. While engaged in reconnaissance, Mr. Lehlbach covered many miles on horseback and unaccompanied. Many of these lonely expeditions were through uninhabited desert, and on one of them he unwittingly drank some of the poisonous alkaline water in which those deserts abound. Soon taken violently ill and unable to ride farther, he dismounted and lay helpless on the sand through two or three days, each of which must have seemed weeks, of the burning desert heat, while his horse foraged at will, presumably with very little success. The attack finally wore off. He recovered his horse and rode back into camp.

Similar episodes attended his work in Mexico where he acted for the Mexican Government, once more on railroad reconnaissance. Although his party numbered 30 or 40 men, Mr. Lehlbach, as usual, made many solitary expeditions. On one of these occasions, in attempting to ford a stream which he had traced for 30 miles, his horse suddenly struck quicksand. By grasping the overhanging limbs of a tree, he was able to pull himself to safety and then to coax and encourage his horse to struggle back to *terra firma*. Unable, on account of the quicksand, to retrace his steps, he seemed to be facing another desperate situation, as he knew of no settlement within a hundred miles. He gave his horse the bridle and the creature's instinct brought him to a trapper's cabin where he found food and shelter for the night, and whence he eventually found his way back to camp.

While in Mexico Mr. Lehlbach experienced real Mexican hospitality in the home of General Bustamante. During the Civil War the General had been the delegate in Washington of the Mexican patriots who were trying to oust Maximilian, and were seeking President Lincoln's help. President Lincoln, as is well known, could not see his way clear to give material assistance or even recognition and open moral support to the enemies of Maximilian. Yet, he

evidently left no doubt in Bustamante's mind as to where his personal sympathies lay—and he must have left an indelible impression of his personality on the General. Perhaps, when Mr. Lehlbach asked General Bustamante to describe that impression, he was, in memory, mounting guard again at Arlington. Certain it is, however, that the Mexican General's reply found many an audience in Mr. Lehlbach's later days when railroad reconnaissance had become reminiscence. Said Bustamante, "He was another Jesus Christ."

Mr. Lehlbach was married to Anna Lydia Babcock, of Communipaw, N. J., on January 17, 1872. During his married life his engineering business came to take the place of railroad pioneering, and he eventually settled down in Newark where he ended his days. Toward the close, some visitors to his Newark home were perhaps curious about a sort of double-decked picture frame which hung from the library mantle. The lower story enclosed a portrait of President Woodrow Wilson for whom Mr. Lehlbach had acquired a warm admiration; but from the upper story of the frame, above the War President of 1917, looked out the face of the War President of 1861. The visitor who remarked about that double-decked portrait was quickly made to feel how much it meant to Mr. Lehlbach. It evidently had to do with the boyhood days at Arlington, with dreams and ideals revivified for him by the words and acts of the original of the lower portrait.

He died on March 26, 1926, his widow surviving him by less than two years. He had no children.

Mr. Lehlbach was elected a Member of the American Society of Civil Engineers on March 7, 1883.

EMILE LOW, M. Am. Soc. C. E.*

DIED MAY 25, 1927.

Emile Low, the eldest son of Sigismund and Anna (Hussell) Low, was born on April 2, 1854, in Pittsburgh, Pa. His father was a graduate of the Karlsruhe Polytechnicum, Karlsruhe, Germany, and was one of the founders of the *Pittsburgh Volksblatt.* Emile Low's education was obtained in a private school and, later, in the public schools of Pittsburgh.

His first professional work was done in 1869 in connection with the surveys of the Monongahela Valley Railroad. In 1870, he was engaged on the surveys for the Western Extension of the Pittsburgh and Connellsville Railroad (now a part of the Baltimore and Ohio Railroad), of which his father was Engineer in Charge; and during 1870 and 1871, he was employed on construction work for the Cumberland, Md., extension of the same line.

Subsequently, Mr. Low became Assistant on the Hiland Avenue Reservoir of the Pittsburgh Water-Works, with which he was connected until 1875. In 1876, he served as Assistant City Engineer. Early in 1877, he was connected with the survey of the Pittsburgh and Lake Erie Railroad Bridge across the Ohio River. Later, he entered the service of the Pittsburgh, Castle Shannon, and Washington Railroad Company as Principal Assistant Engineer; this railroad subsequently was absorbed by the Baltimore and Ohio Railroad Company. In 1879, he was engaged on work for the Shousetown Railroad and also for the Pittsburgh and Atlantic Railroad Companies.

In the fall of 1879, Mr. Low was appointed Engineer of Construction and of Maintenance of Way for the Pittsburgh and Western Railroad Company and, later, became Chief Engineer. This railroad, also, became a part of the Baltimore and Ohio Railroad. He remained with the Company until March, 1881, when his father was appointed Engineer in Charge of the Guanajuato Branch of the Mexican Central Railway, and Mr. Low accompanied him to Mexico as his Assistant. This work terminated in June, 1882. During the pursuit of his engineering career, Mr. Low encountered many dangerous situations, particularly that experienced in a silver mine in Mexico where he barely escaped with his life because of a dynamite blast discharged by careless workers.

Upon his return to the United States, he was appointed Engineer in charge of location for the Pittsburgh, McKeesport and Youghiogheny Railroad Company with which he remained until the latter part of 1884. Early in 1885 he served as Assistant Engineer with the Monongahela Railroad Company of Pittsburgh, which position he retained until March, 1885, when he was made Locating Engineer of the Pennsylvania (Schuylkill Division) Railroad. In December, 1886, he made the remarkable location of a mountain line, 20 miles long, in 10 days during winter weather, between Delano and Hazelton, Pa.

In 1887, Mr. Low was appointed Locating Engineer of the Norfolk and Western Railroad. Subsequently, he became Division Engineer and Engineer

* Memoir prepared by H. J. March, L. L. Davis, and S. T. M. B. Kielland, Members, Am. Soc. C. E.

in charge of coal operations of the Ohio Extension. In 1892, he was made Engineer of the Mathieson Alkali Works, of Saltville, Va. The late John F. Wallace, Past-President, Am. Soc. C. E., who was Vice-President of the Works, took occasion at a speech-making event to commend most highly the accuracy and thoroughness of Mr. Low's work. He stressed the thought that a great many engineers, like Mr. Low, spend their lives in obscure sections of the country and in consequence nothing praiseworthy is heard of them; therefore, when opportunity presents itself for commendation, it should be given freely. Mr. Low's connection with the Mathieson Alkali Works terminated in 1896, after which he became associated with Maj. Thomas W. Symons, Corps of Engineers, U. S. Army, in the preparation of a report on the Erie Canal. He also was associated with Major Symons in the preparation of the well-known report for a canal from the Great Lakes to the Hudson River.*

From 1897 to 1903, Mr. Low was Resident United States Assistant Engineer, in charge of the building of the Buffalo Breakwater under the direction of Colonel Symons. He was awarded the Norman Medal by the Society in 1904 for the presentation of a paper describing this work.†

Mr. Low continued as U. S. Assistant Engineer until June 1, 1904, after which he was in the service of the State of New York as Resident Engineer in charge of the Barge Canal work in Oneida County, having been granted a three-year furlough from the U. S. Engineer Department. While he was engaged in this work which involved some difficult engineering problems, he published a number of interesting papers, one of which was entitled "Wash-drill Borings in the New York State Barge Canal",‡ and another, "Hydraulic Dredging on New York State Barge Canal".§ On April 1, 1907, Mr. Low re-entered the Federal Service as Assistant Engineer at Buffalo, N. Y., where he remained until his retirement in April, 1924, having served under the following officers of the Corps of Engineers, U. S. Army: Col. H. M. Adams, Col. W. L. Fisk, Col. J. G. Warren, M. Am. Soc. C. E., Maj. L. V. Frazier, Col. Clarke S. Smith, M. Am. Soc. C. E., Maj. William E. R. Covill, and Maj. P. S. Reinecke, M. Am. Soc. C. E.

Mr. Low was married on January 23, 1883, to Estelle Reed, of Zelienople, Pa.; there were three children, Estelle Low, Emile Reed Low, and Mary Virginia Low.

Mr. Low was esteemed most highly by his fellow engineers of Buffalo for his remarkable professional attainments. He was an indefatigable worker in every engineering pursuit which he followed. In this respect he was an exemplary character for so many engineers who take joy in service for their fellow men and their country and who contribute of their energy of mind, body, and soul, as it were, with little or no personal reward.

Mr. Low was elected a Member of the American Society of Civil Engineers on May 2, 1888.

---

FRANK OSCAR MAXSON, M. Am. Soc. C. E.*

DIED JANUARY 21, 1928.

Frank Oscar Maxson was born in Stillmanville, Conn., on August 8, 1851, of pioneer stock. When he was three years of age his family, influenced by the Western movement of the times, went to California, making the journey by the long circuitous route of the Isthmus of Panama. Eight years were spent in the mining districts of California, and Mr. Maxson's two younger brothers and a sister were born there. In 1862, however, ill health compelled his mother to return to her home in Rhode Island, and the four children accompanied her.

After his mother's death, Mr. Maxson and his brother, Louis, "boarded out", helping to support themselves by carrying papers before school in the mornings, the younger children being cared for by relatives. The two older boys attended the public schools of Norwich, Conn., and, later, the Norwich Free Academy; Mr. Maxson then entered the Sheffield Scientific School of Yale University, at New Haven, Conn. Later, he returned to the Norwich Academy and taught for one year, after which he re-entered Yale for a year of post-graduate work.

After he had completed his studies, Mr. Maxson began his long and faithful service to the United States Government, as Topographer of a party engaged in surveying the States of Colorado, New Mexico, and Arizona. The work also included a survey of the Yosemite Valley in California, and Mr. Maxson made one of the earliest authentic maps of that beautiful and far-famed region. He continued in this work for seven years, half of each year being spent "in the field", the other half in Washington, D. C., plotting and computing the data which he had acquired.

In October, 1881, Mr. Maxson successfully passed an examination for appointment to the Corps of Civil Engineers, U. S. Navy. He was commissioned on October 29 of that year and assigned to duty at the Navy Yard, Pensacola, Fla. He served successively at the New York, Boston, Mass., Washington, and Mare Island, Calif., Navy Yards. During the early days of the war with Spain he was sent to the Norfolk, Va., Navy Yard where he served during the war period. He attained the rank of Lieutenant Commander in 1898, Commander in 1901, and Captain in 1906. Following the close of the war with Spain, Captain Maxson returned to the Boston Yard.

In 1901, he was ordered to the Philippine Islands to take charge of public works and public utilities at the Naval Stations at Cavite and Olongapo. He returned to the United States early in 1904 and was detailed to the League Island Navy Yard at Philadelphia, Pa. Following subsequent duties at Portsmouth, N. H., and Key West, Fla., he was transferred to the retired list with the rank of Captain in August, 1913. In 1915, he was recalled to active duty and detailed to assist the Department of Justice in Washington in the prosecution of several lawsuits involving Navy contracts. He completed this duty in February, 1917, and reverted to an inactive status on the retired list.

* Memoir prepared by DeWitt C. Webb, M. Am. Soc. C. E.

The outbreak of the World War made it necessary again to recall Captain Maxson to active service. In October, 1917, he was placed in charge of all Naval public works in the Seventh Naval District, with headquarters at Key West. He performed meritorious service in this capacity, having charge of the construction of many important Naval war-time projects, including quay walls, piers, barracks, hospital buildings, and the Air Station, at Miami, Fla. He was relieved from active duty in October, 1919, and shortly thereafter moved to Coupeville, Wash., where he resided at the time of his death. He contracted pneumonia about the middle of January, 1928, and passed away after a few days' illness.

Captain Maxson's career as a civil engineer was praiseworthy. All his work exemplified his careful foresight and professional attainments. His patriotism and generous consideration for his fellow men were outstanding characteristics. Any undertaking for the welfare of his country or community received his whole-hearted support.

On December 26, 1877, he was married at Washington, D. C., to Evelyn M. Van Doren. He is survived by his widow, two sons, Dr. Frank T. Maxson and Dr. Louis H. Maxson, of Seattle, Wash., and one daughter, Evelyn Maxson, of Coupeville, Wash.

His home life was ideal and continued for over half a century. On December 26, 1927, the golden wedding anniversary of Captain and Mrs. Maxson was celebrated at their home in Coupeville, at which all the members of the immediate family were present.

Captain Maxson's natural gifts combined with the wide range of his experience and reading made him an interesting conversationalist on a great variety of subjects. He had a most agreeable personality and a keen understanding of human nature. These traits, together with a delightful sense of humor which was habitually expressed in good-natured banter, deeply endeared him to all.

For many years Captain Maxson was an Elder of the Metropolitan Presbyterian Church, of Washington, D. C., and at the time of his death was a Trustee in the Coupeville Congregational Church. He also taught large Sunday School classes in Washington, Key West, and elsewhere. He was not a man whose religious spirit was confined to the church, but rather one who carried it with him into his everyday life, as shown by his innumerable kind deeds and generous service for others.

Captain Maxson was elected a Member of the American Society of Civil Engineers on May 1, 1889.

JAMES C. NAGLE, M. Am. Soc. C. E.*

DIED APRIL 6, 1928.

James C. Nagle was born in Richmond, Va., on October 9, 1865, the son of John and Ellen Mary (Smith) Nagle. His parents moved to Travis County, Texas, where his childhood was spent on a farm, and his primary education was obtained in a country public school near Austin. He received the degree of Bachelor of Science in Civil Engineering from the University of Texas in 1889, and the degree of Master of Arts in 1892. The same year he obtained the degree of Civil Engineer from the University of Pittsburgh and the degree of Master of Civil Engineering in 1893 from Cornell University.

Mr. Nagle's first professional experience was as Field and Office Assistant for the St. Louis Southwestern Railway Company in 1887. He was Assistant Engineer for the Austin and Northwestern Railway Company in 1888. In 1889 and 1890 he was employed as Assistant Geologist, chiefly on topography for a geological survey of Texas.

In 1890, he became Professor of Civil Engineering at the Texas Agricultural and Mechanical College and, in 1911, was appointed Dean of the School of Engineering.

In 1913 Mr. Nagle resigned this position to accept an appointment on the Texas State Board of Water Engineers. He served as the first Chairman of this Board from September, 1913, to September, 1917, when he resigned to return to the Texas Agricultural and Mechanical College as Professor of Civil Engineering, Dean of the Engineering School, Director of the Texas Engineering Experiment Station, and Consulting Engineer for the Prairie View State Normal and Industrial College.

Mr. Nagle served the Texas Agricultural and Mechanical College in these positions until September, 1922, when he resigned to devote his entire time to the business of the Nagle, Witt, Rollins Engineering Company, which he had organized in 1919 and of which he became the Senior member. He was still an active member of this firm at the time of his death.

From 1923 to November, 1927, Mr. Nagle was associated with R. A. Thompson, M. Am. Soc. C. E., on the investigation, design, and construction of a $5 000 000 water supply reservoir for the City of Dallas, Tex.

In 1903, Mr. Nagle was married to Emily St. Pierre Davis (*née* Morgan), at Union, S. C. He is survived by his widow, two step-daughters, Mrs. Robert J. Potts, of Waco, Tex., and Mrs. F. F. La Roche, of Atlanta, Ga., a step-son, Major John F. Davis, U. S. A., of Fort Leavenworth, Kans., and two brothers, Judge M. Nagle, of El Paso, and John Nagle, of Manor, Tex.

In addition to numerous professional and technical papers, Mr. Nagle was the author of a "Field Manual for Railroad Engineers"; of three published reports on the "Silt-Carrying Capacity of Texas Streams"; and of *Bulletin 222*, on "Irrigation in Texas", of the United States Department of Agriculture.

* Memoir prepared by A. P. Rollins, M. Am. Soc. C. E.

He was a member of the American Association of Engineers, the Cornell Society of Civil Engineers, the Society for the Promotion of Engineering Education, the Southwestern Geological Society, and a Fellow of the Royal Society of Arts, London, England. He was also a member of the Protestant Episcopal Church, a Scottish Rite Mason, and a member of Ben Hur Temple, A. A. O. N. M. S.

Mr. Nagle devoted his life to his work in and for the State of Texas, and he was loved by all who knew him. The following tribute is quoted from the editorial column of the *Houston Chronicle* under date of April 8, 1928:

"Word that J. C. Nagle, former Dean of Engineering at A. & M., is dead, will bring regret to many thousands of men now active in the industrial life of Texas and the Southwest. This splendid engineer gave his talents for many years to training youths at the great Texas Mechanical College.

"His personal influence probably meant as much as the technical knowledge he imparted. He was a leader of men as well as a teacher. A State can never know what it owes to such men; their work lives in the lives of other men. Those other men know, however, and many of them will grieve to-day over the loss of their friend and mentor."

Mr. Nagle was elected a Member of the American Society of Civil Engineers on June 6, 1905.

GEORGE NAUMAN, M. Am. Soc. C. E.*

DIED SEPTEMBER 28, 1927.

George Nauman was born at Lancaster, Pa., on June 20, 1870. He was graduated from Lehigh University in 1890 with the degree of Civil Engineer.

In September, 1890, he entered the service of the Pennsylvania Railroad Company as a Rodman in the Engineering Department. He was successively promoted to the grades of Transitman in September, 1890, Assistant Engineer in February, 1899, and Assistant to the Chief Engineer in July, 1918, which position he held at the time of his death.

In his various capacities, Mr. Nauman had a wide experience in railroad location and construction. It was in the latter work that he found the most enjoyment during his very useful life. An executive, a worker, a co-ordinator, and a doer, he was most content when handling and expeditiously completing the many large construction projects that were under his supervision.

Among the larger projects constructed under his direction were the Delaware River Bridge from Philadelphia, Pa., to Delair, N. J.; the famous Rockville Bridge across the Susquehanna River, at Harrisburg, Pa.; the Shocks Mills Bridge across the Susquehanna River at Shocks Mills, Pa.; the four-tracking of the Northern Central Railroad from York Haven to Marysville, Pa.; the Enola Yards, near Marysville, Pa.; the Northumberland Yard, Northumberland, Pa.; the Montgomery Bridge at Montgomery, Pa.; the Allegheny Division improvements, including the Rockland and Kennerdell Tunnels; the Buffalo Division improvements between Oil City and Corry, Pa.; the Gardenville engine facilities, near Buffalo, N. Y.; the additional engine facilities at Pitcairn and Shire Oaks, Pa.; the Northside improvements, Pittsburgh, Pa., including the Northside track elevation; four-tracking, Pittsburgh to Sharpsburg, Pa.; and the new Sharpsburg Yard and Engine Terminal; the Beck's Run Viaduct; and the Streets Run Viaduct on the Monongahela Division, at Pittsburgh. In addition to these larger projects he planned and constructed many minor railroad improvements, including grade-crossing eliminations and branch-line extensions.

Mr. Nauman's executive superiors held him high in their esteem, recognizing his excellent judgment and abilities. He enjoyed the social side of life during his active career, making many friends who always appreciated his ready wit and repartee. His wise counsel and sympathetic nature won for him the affection of his subordinates who appreciated their contacts with such a fine outstanding character. The profession has sustained a real loss in the passing of Mr. Nauman, a foremost Construction Engineer.

He was a member of the Engineers Society of Pennsylvania, the Harrisburg Club, of Harrisburg, and the University Clubs of Philadelphia, Pa., and of Pittsburgh.

Mr. Nauman was elected a Member of the American Society of Civil Engineers on May 4, 1904.

* Memoir prepared by T. P. Watson, M. Am. Soc. C. E.

GEORGE ALBERT NOSKA, M. Am. Soc. C. E.*

DIED NOVEMBER 12, 1928.

George Albert Noska was born on April 5, 1873, in Philadelphia, Pa. He was educated in the public schools of that city and, later, attended the Philadelphia Manual Training School.

In 1891, Mr. Noska started work with the Pencoyd Bridge Company, with which he remained until 1897, when he entered the employ, as Steel Designer, of the late George B. Post, M. Am. Soc. C. E., in New York, N. Y. He held this position until 1899, with the exception of the time he spent in service during the Spanish-American War. He was Corporal of Company M, 71st New York Volunteer Infantry, and saw service in Cuba, at San Juan Hill, and in other engagements. Subsequently, he served in the New York National Guard and was commissioned First Lieutenant of the Depot Infantry, National Guard of New York, on August 2, 1916.

In 1899, Mr. Noska became associated with Francis Kimball, Architect, as Superintendent of general construction, with whom he remained until 1908, when he was employed in the offices of D. Everett Waid, Architect. In this position his time was largely taken up in passing on plans on which the Metropolitan Life Insurance Company proposed loans.

In May, 1917, when the United States entered the World War, Mr. Noska again joined the Army. He was enrolled at Madison Barracks, Sacketts Harbor, N. Y., as Student in the Cadet Engineer Corps and was assigned to the 78th Division. He was discharged from service on July 2, 1919, at Camp Dix, New Jersey, as Captain of the 303d Engineers, 78th Division. He served overseas from May, 1918, to June, 1919, and saw active service at Chateau-Thierry, Meuse-Argonne, and St. Mihiel, and was awarded two gold chevrons. After his discharge he was commissioned Major in the 1st Battalion, 303d Engineers, 78th Division, Officers Reserve Corps. He was intensely patriotic as his record shows and was 44 years old at the time of his enlistment in the World War. He refused to consider any but active service at the front and undoubtedly sowed the seed there which developed into the heart attack which caused his death.

Following his discharge in 1919, Mr. Noska became a member of the firm of Chris. J. Jeppessen, Incorporated, until 1923, when he entered into partnership with Mr. Charles L. Lange, under the firm name of Lange and Noska. He was conducting this business at the time of his death on November 12, 1928. During these latter associations involving work around New York City, he was engaged on the designs of the Canadian-Pacific Building, Saks Department Store (Fifth Avenue), the building at Broadway and 40th Street, the Williamsburgh Savings Bank, the Riverside Church, and innumerable other structures.

Mr. Noska was married, on October 9, 1905, to Margaret Peasley. He is survived by his widow and two daughters, Evelen (Noska) Douglass and Ruth Adelaide Noska.

Mr. Noska was elected a Member of the American Society of Civil Engineers on September 5, 1911.

* Memoir prepared by Charles L. Lange, Esq., New York, N. Y.

EDWARD JONES PEARSON, M. Am. Soc. C. E.*

DIED DECEMBER 7, 1928.

Edward Jones Pearson, the second eldest of a family of six children—three sons and three daughters—of Leonard and Lucy S. (James) Pearson, was born at Rockville, Ind., on October 4, 1863. His father followed railroading as his profession and held prominent positions as a railroad officer during his lifetime. The family was of English origin, John Pearson the earliest paternal American ancestor having come from England about 1630 to 1635, and having settled at Rowley, Mass.

After elementary preparation in the public schools of Chicago, Ill., Mr. Pearson entered Cornell University at Ithaca, N. Y., from which he was graduated with the degree of Civil Engineer in 1883. He was a member of the Delta Upsilon Fraternity.

He began his railroad work during the summer vacation of 1881, as a Rodman in the Engineering Department of the Missouri Pacific Railway Company, on the extension from Atchison, Kans., to Omaha, Nebr., and also on construction work in Indian Territory and in Texas. In the summer of 1882 he was engaged as Assistant Engineer in terminal construction work at Portland, Ore., and after graduating in 1883 was employed by the Northern Pacific Railway Company as Supervisor of Track, until 1884, when he was placed in charge of construction train service. From 1890 to 1892 he was Division Engineer on lines east of Livingston, Mont., and was then made Principal Assistant Engineer of the Wisconsin Central Railway Company, the Chicago and Calumet Transfer Company, and the Chicago Terminal (leased by the Northern Pacific Railway Company), in charge of terminal construction.

Up to this time Mr. Pearson's work had been engineering exclusively. He had always shown, however, a keen interest in, and the desire to be associated with, operation and in 1894 was appointed Superintendent of the Yellowstone Division. He served the Northern Pacific Railway Company as Superintendent of the Rocky Mountain and Pacific Divisions until 1902, when he was made Assistant General Superintendent. In 1903, he was appointed Acting Chief Engineer, and, in 1904, Chief Engineer.

Mr. Pearson continued in this work until December, 1905, when he took charge as Chief Engineer of the Pacific Coast Extension of the Chicago, Milwaukee and St. Paul Railway, a line through rugged country, 1 350 miles long, which he built in as many days. He organized and started the operation of this extension. In 1911, he was appointed First Vice-President of the Missouri Pacific and the St. Louis, Iron Mountain and Southern Railway Companies, in charge of operation, thus returning to the first railroad on which he had served as a Rodman thirty years before.

Mr. Pearson was associated with the Missouri Pacific Lines until April, 1915, when he left to become First Vice-President in charge of the Texas

* Memoir prepared by C. E. Smith, M. Am. Soc. C. E., and M. K. Dugan, Esq., New Haven, Conn.

and Pacific Railway. During his four years of service with the Missouri Pacific System, the physical condition and capacity of the property was greatly improved, its operation re-organized, and its earning power brought to a much higher level.

He remained with the Texas and Pacific Railway Company only about a year, that is, until March, 1916, when he was called to the service of the New York, New Haven, and Hartford Railroad Company, as Assistant to the President, and Vice-President. He became President of the Company on May 1, 1917, on the resignation of the late Howard Elliott, Affiliate, Am. Soc. C. E. During the period of Federal control, Mr. Pearson was Federal Manager of the railroad, following which he was again elected President.

When Mr. Pearson entered its service, the New Haven Railroad was ill-equipped for handling the large volume of freight business being offered. He remodeled the road from a combination of many inadequate separate yards and engine terminals, to a consolidated system with adequate terminals at central points. Heavy locomotives were provided, bridges strengthened, passing tracks lengthened to enable the handling of modern trains, and its operations were completely re-organized. Dividends, which had been suspended in 1913, were resumed shortly before his death.

It is worthy of note that, largely because of his caution in railroad operation, not one passenger was killed in a train accident on the New Haven Lines during twelve and one-half years of his administration. Mr. Pearson's service to the New Haven Railroad Company and to the territory it served is fitly expressed in the following quotation from the remarks of Dr. A. T. Hadley, Director of the New Haven Railroad, and President Emeritus of Yale University, at the funeral service:

"Never was a man faced with a more discouraging task than that which confronted this man in 1920. Only those who were at his side in those dark days can know the burdens which he was called upon to carry, and the superb way in which he bore them. Step by step, with infinite patience and undaunted courage, he brought order out of chaos in the operations and finances of the New Haven System and put it in a position to serve the community under present-day traffic conditions."

The outstanding traits of Mr. Pearson's character were his desire to avoid publicity, his modesty as to his accomplishments, and his kindly consideration and loyalty for his associates, particularly those junior in authority—his desire that they should be given every opportunity for advancement and full credit for good work well done.

In June, 1926, the degree of Master of Arts was conferred upon Mr. Pearson by Trinity College. He was a member of the American Railway Engineering Association, the Cornell Society of Civil Engineers, and the Connecticut Society of Civil Engineers; he was also a Director of the American Railway Association. He belonged to the Bankers, the Engineers, and the Metropolitan Clubs of New York, N. Y.; the Graduates and Quinnipiack Clubs, of New Haven, Conn.; the Metropolitan Club of Washington, D. C.; the New England and New York Railroad Clubs, and the Traffic Club of New England.

Mr. Pearson was married to Gertrude S. Simmons at Evanston, Ill., on June 7, 1899. His widow and a son, Harlow S. Pearson, survive him; also his mother, two sisters, and a brother, Raymond A. Pearson, President of the University of Maryland.

Mr. Pearson was elected a Member of the American Society of Civil Engineers on December 4, 1907.

WILLIAM GUNN PRICE, M. Am. Soc. C. E.*

DIED JULY 6, 1928.

William Gunn Price was born in Knoxville, Pa., on July 6, 1853. His father, William Price, was a physician of Welsh and English descent. His mother, Tryphene R. (Gunn) Price, was of Irish and Scotch ancestry. He gained his early education in the public schools of New York State, at Hartwick Seminary, and later, at Columbia University.

Mr. Price's engineering experiences began when he was eighteen years of age, in the vicinity of New York and, from 1879 to 1896, he was United States Assistant Engineer, in charge, successively, of surveys on the Mississippi River, the improvement of the Harbor of New Orleans, La., the rectification of the Red, Mississippi, and Atchafalaya Rivers, and other important works. He had charge of the construction of the two dams at the head of the Atchafalaya River, which prevented the Mississippi from flowing to the Gulf by that shorter route, in the disastrous flood of 1927. He also assisted in the first survey of the Mississippi, which previously had not been mapped accurately, and he took part in a similar survey of the Missouri River.

Mr. Price was the inventor of the electric current meter and the acoustic current meter for measuring the flow of water. Both these instruments are extensively used by engineers all over the world. At New Orleans, he designed a new and successful system of spur-dikes for protecting the banks of the river. He was also the originator and advocate of the plan for the improvement of the Lower Mississippi River, by the method which utilizes the forces of the river to dig the foundation for permanent channel-controlling works, which plan was successful as applied by him in New Orleans Harbor, the Atchafalaya River, and elsewhere. This method of construction is such that the force of the river can only sink the structure deeper in the sand while more material is being added on the top. All his inventions and improvements in engineering construction have been boldly original.

In 1896, Mr. Price became Chief Engineer for the Chicago City Railway Company, and produced the first railway track test car. This car, when run over the road at train speed, using five pens on a moving sheet of paper, recorded the location and amount of all defects in the track.

The same year he originated the momentum power brake for street cars, which was used on all the Chicago lines and by many other railways, until the advent of much larger cars necessitated the use of the air-brake. Mr. Price also invented an automatic fare box for street cars which prevented drivers from "knocking down" fares.

For a period of ten years, beginning with 1903, he was employed by the Standard Steel Car Company, of Pittsburgh, Pa., to design improvements in railway equipment. The Standard Motor Truck Company, a subsidiary Company, was incorporated especially to control the manufacture and sale of Mr. Price's inventions. During these ten years he placed with the Standard

* Memoir prepared from information on file at the Headquarters of the Society.

Motor Truck Company, on royalty, thirty-three patents of railway equipment, many of which are in extensive use in the United States and other countries.

In 1913 Mr. Price went to Yakima, Wash., and contributed to labor-saving devices in the fruit industry, such as, a fruit-sizing machine; an automatic elevator, which, in the warehouses, saves the work of several men; box-making machines; box presses; an improved gravity conveyor; a machine for sizing potatoes; and a box press for dried apples. Not the least interesting of his inventions, is an ingenious little vest-pocket pencil sharpener. His last invention was a hydraulic friction brake for automobiles.

Mr. Price had not been in the best of health for two and a half years prior to his death, having a leakage of the heart; but in the late spring and early summer of 1928 he was feeling so much improved that on June 20 he started with his wife on a trip to Central New York. They stopped en route at the Battle Creek Sanitarium for a physical examination. Receiving no benefit from a two weeks' stay at the institution, Mr. and Mrs. Price resumed their journey. Mr. Price's condition became serious, however, and at Detroit, Mich., he was taken from the train to the Fort Shelby Hotel, where he died the next day, Friday, July 6, 1928, the seventy-fifth anniversary of his birth.

He is survived by his wife, Mary Kelley Price, a native of Schenevus, N. Y., to whom he was married in Chicago, in 1879; one son, William Kelley Price, of Selah, Wash., and one grandson, William Griffin Price.

Mr. Price was a member of the American Association of Engineers, Professional Engineers, and the American Association for the Advancement of Science; he was also a Mason and belonged to the Scottish Rite and the Shrine.

Mr. Price was elected a Member of the American Society of Civil Engineers on April 3, 1895.

ARTHUR BREESE PROAL, Jr., M. Am. Soc. C. E.*

DIED AUGUST 22, 1922.

Arthur Breese Proal, Jr., was born on October 10, 1869, in New York, N. Y., the son of Arthur Breese Proal, a prominent banker and financier of New York. His mother was Sydney Mathiot, of Zanesville, Ohio, the daughter of the Hon. Josiah Mathiot.

Mr. Proal received his education at Stevens Preparatory School and was graduated from Pratt Institute in Brooklyn, N. Y. He began his first practical work in 1892 in the Electrical Testing Department of the Metropolitan Telephone Company, which later became the New York Telephone Company. He was engaged mostly in laying underground cable systems in New York City and assisted in the laying of the first cable under the Hudson River.

In December, 1892, he was engaged as Construction and Mechanical Engineer for the Newark Electric Light and Power Company of Newark, N. J. (now the Public Service Corporation of New Jersey). In this capacity, he had charge of the design and erection of steam and electric equipment, as well as the construction of several large power houses, together with detailed work for docks and intakes on the water-front.

In November, 1896, Mr. Proal was made Superintendent and Chief Engineer of the New Haven Street Railway Company, at New Haven, Conn., for which he had charge of the entire operation of the System and the extension of its service. During this period, he laid out and built a number of miles of interurban trolley line and acted as one of the pioneers in the construction and operation of Light House Park at the end of the Interurban Line.

In January, 1898, he became Superintendent and Chief Engineer of the New York and Staten Island Electric Company, which, in addition, controlled the Southfield Beach Railway Company. Mr. Proal built the latter road complete, including its entire power equipment. He was also Superintendent and Chief Engineer of the New York and New Jersey Ferry Company, the Richmond Light, Heat, and Power Company, and of several smaller companies. At this time he designed and supervised the construction and erection of the central power plant—7 000 h.p.—that furnishes all the lights and railway current in Richmond County, New York.

In January, 1901, Mr. Proal became associated with the Robins Conveying Belt Company, of New York, as Sales Engineer, with which company he remained until his death from pneumonia on August 22, 1922. He was ill but a few days.

Mr. Proal was the inventor of many devices used in the art and construction of conveyances and was particularly prominent in the planning and design of many of the important vessel-loading plants on the Atlantic Coast. He also developed and patented two types of bridge tramways for open storage of materials, which are in successful operation throughout the world to-day.

* Memoir prepared from information on file at the Headquarters of the Society.

These plants stand as worthy memorials to his remarkable character and ability.

Coupled with his exceptionally observant and perceptive nature, Mr. Proal had a very retentive memory and supplemented his extended engineering knowledge with the rare ability of being able to transmit this knowledge to others concisely and freely. His death was mourned by his associates not only because of his cheerful disposition, his great mechanical ingenuity, and his sales ability, but also because of his exceptional fund of knowledge and his willingness to impart it. He left a vacancy impossible to fill.

In October, 1906, Mr. Proal was married to Sara Francisco Harris, of Newark, N. J., who survives him.

Mr. Proal was elected a Member of the American Society of Civil Engineers on March 7, 1906.

HARLEY EDSON REEVES, M. Am. Soc. C. E.*

DIED JULY 28, 1928.

Harley Edson Reeves was born at Tampico, Ill., on March 21, 1874. He received his early education at Tampico, and afterward attended the University of Illinois where he received the degree of Bachelor of Science in Civil Engineering in 1895. While at college, he was known as one of the best football players of his time.

Mr. Reeves began his engineering career as a Sergeant and Lieutenant in the 3d Volunteer Engineers during the Spanish-American War, on topographical work, construction of temporary bridges, block-houses, field fortifications, and signal towers. His service in the Army extended from June 26, 1898, to May 17, 1899.

On October 1, 1899, he was appointed Rodman on the construction work of the Illinois and Mississippi Canal and was promoted, successively, as Inspector, on May 1, 1900; Junior Engineer on February 1, 1902; Assistant Engineer on September 1, 1911; and Associate Engineer on October 1, 1926, which position he held until his death.

Between 1900 and 1907 Mr. Reeves was in local charge of earthwork, pile-driving, construction of superstructures and concrete abutments for bridges, foundations, and concrete superstructures for aqueducts, locks, and lock foundations for the Illinois and Mississippi Canal. When the Canal was completed he was placed in local charge of the operation and care of the Western Section, and later he was in charge of a preliminary examination and survey of Rock River with a view to securing a channel from Sterling, Ill., to Janesville, Wis., and to ascertaining whether for the maintenance of navigation, storage reservoirs were necessary in compliance with the provisions of the River and Harbor Act of March 3, 1909.

He was in local charge of the construction of the Rock River Lock, at Rock Falls, Ill., completed in 1912, and of the Le Claire Canal Lock and Dam on the Mississippi River, at Le Claire, Iowa, completed in 1922. From 1922 until his death he was in local charge of a section of the Mississippi River Improvement from the mouth of the Wisconsin River to Moline, Ill.

Mr. Reeves was a capable, resourceful engineer and took great pride in carrying out the various works upon which he was engaged, from the preliminary plans to construction and operation. He was a friend of his fellow employees and was respected and beloved by all those who were privileged to know him.

He was married on November 28, 1901, to Helen Nowers, at Atkinson, Ill., by whom he is survived, with one son, James Edson, two brothers, Howell Reeves, of Albany, N. Y., and Rear-Admiral Joseph M. Reeves, U. S. Navy, and a sister, Miss Frances Reeves, of Schenectady, N. Y.

Mr. Reeves was elected a Member of the American Society of Civil Engineers on January 4, 1910.

* Memoir prepared by Richard Monroe, M. Am. Soc. C. E.

MORRIS JOHN RIGGS, M. Am. Soc. C. E.*

DIED FEBRUARY 7, 1926.

Morris John Riggs was born on his father's farm at Horton, Bremer County, Iowa, on January 14, 1862. His parents were William and Sophronia Riggs, early pioneers of that State. He was educated in the district schools of Bremer County, in the High School, at Waverly, Iowa, and in Iowa State College, at Ames, from which he was graduated in June, 1883, with the degree of Bachelor of Civil Engineering, having specialized in bridge engineering. In 1905, he obtained from his Alma Mater the degree of Civil Engineer.

Before entering college in 1880, Mr. Riggs had spent four years teaching in the district schools. He worked his way through college, milking cows and performing other services on the Agricultural Farm. He was also the first Business Manager of Athletics at Ames, and was known as the "Father of the Memorial Union", of which he was President for five years, later becoming Honorary President. It was largely due to his tireless efforts that more than $1 000 000 was subscribed to the Union. As an Alumnus he always retained great interest in his Alma Mater, making frequent visits to the college. From 1920 to 1924, he served as President of the Alumni Association.

Following his graduation Mr. Riggs was employed for about a year making county maps in Kansas. In the spring of 1885, he became Bridge Engineer for Mr. S. M. Hewett, Agent, at Minneapolis, Minn., for the Smith Bridge Company of Toledo, Ohio. In July, 1887, Mr. Riggs was appointed Draftsman, Designer, and Estimator for this Company and continued in that position until April, 1893, when he became Chief Engineer of the Toledo Bridge Company, the successor to the Smith Bridge Company. The Toledo Bridge Company, in turn, was succeeded by the American Bridge Company and in April, 1901, Mr. Riggs was appointed Manager of the Toledo Plant of this firm, in which capacity he served until his death. In connection with his duties he had charge of numerous important works, among which was the design and construction of the Toledo Plant of the American Bridge Company. During the many years he served these several bridge companies, he also acquired splendid experience in bridge engineering.

At the time of his death Mr. Riggs was President of the Toledo Section of the Society, of the Chamber of Commerce, of the Young Men's Christian Association, at Toledo, and also of the Ohio State Young Men's Christian Association. He had served the local organization as President for sixteen years and was very much interested in its work, serving also as a member of its National Council. He was a member of the Ashland Avenue Baptist Church and leader of its Men's Class. During the World War he was very active in the several Liberty Loan Campaigns. On one occasion (in 1910),

* Memoir prepared by Walter J. Sherman and George A. Taylor, Members, Am. Soc. C. E.

without solicitation he was nominated for Mayor of Toledo on the Progressive Ticket. Mr. Riggs was also a member of the Inverness Club of Toledo.

On October 11, 1893, Mr. Riggs was married to Alma M. Fassett, daughter of the late Elias Fassett, an early pioneer of Toledo.

On Thursday, February 4, 1926, Mr. Riggs complained of an earache while returning from a trip to Detroit, Mich. He became unconscious on Friday and remained so until his death on Sunday, February 7, 1926, the cause of which was announced as spinal meningitis. He is survived by his widow, Alma Fassett Riggs; a sister, Sarah M. Riggs, Head of the Department of History in the State Normal School, at Cedar Falls, Iowa; another sister, Mrs. Luderne Franklin, of Chicago, Ill.; and one brother, Marvin L. Riggs, who lives on the old 240-acre homestead at Horton, Iowa.

On February 9, 1926, memorial services were held at the Ashland Avenue Baptist Church, attended by delegations representing the Young Men's Christian Association, the Iowa State College, the Chamber of Commerce, the Rotary Club, and the American Bridge Company. Testimonials were given by officers of the Church and Sunday School and by members of the numerous delegations present.

At Rotary, silent prayers were offered and an appropriate tribute was delivered. At the time of Mr. Riggs' funeral the Chamber of Commerce was closed out of respect to the memory of one of its most valuable members, and the City Council declared in a resolution that he had been one of the City's outstanding civic leaders. His was a "life widely useful, strangely courageous, and always busy with a tenderness, persistency, and loyalty known to few men."

In the death of Morris John Riggs, the City of Toledo has lost an ideal citizen, the American Bridge Company, an efficient Managing Engineer, the Chamber of Commerce, an earnest worker for the interests of his adopted city, the engineers of Toledo a sympathetic friend, the Young Men's Christian Association of Toledo, a most liberal supporter, and the Church to which he belonged, an earnest Christian laborer.

Mr. Riggs was elected a Member of the American Society of Civil Engineers on December 26, 1899.

RUDOLF VIEDT ROSE, M. Am. Soc. C. E.*

DIED JANUARY 25, 1928.

Rudolf Viedt Rose, the only son of Adolf and Helene (Viedt) Rose, was born in Niagara Falls, N. Y., on April 27, 1876. He was of fine old German stock, both his parents having come from Germany. His father left his native town of Hameln, in the Province of Hanover, to come to America, and settled at Niagara Falls where he became an honored and successful business man.

Mr. Rose was educated in the public schools of Niagara Falls and the Central High School, of Buffalo, N. Y. His engineering education was obtained in Stevens Institute of Technology, at Hoboken, N. J., from which he was graduated in 1897 with the degree of Mechanical Engineer.

Immediately after graduation, Mr. Rose began his active work as Draftsman with a manufacturing company in Buffalo, but shortly thereafter on September 15, 1897, he returned to Niagara Falls to enter the Engineering Corps of the Niagara Falls Power Company. He remained with this Company for twenty-three years (until and following its consolidation with the Hydraulic Power Company on June 1, 1920), filling many positions from Draftsman to Construction Engineer in connection with the construction and operation of the now famous hydro-electric power development on the Niagara River. During his earlier employment with the Power Company, he spent a six months' leave in Germany, working with Allgemeine Electricitäts Gesellschaft at Berlin.

In 1920, Mr. Rose entered commercial life as President and Manager of the Consolidated Fuel and Supply Corporation, which he conducted for several years, dealing in coal, contractors' supplies, and building materials. His company was then merged with the Empire Builders' Supply Company in Niagara Falls, and he held the position of Engineer and Superintendent in this larger industry until his death.

He was intensely interested in his professional work and always active and energetic. His was a pleasing personality and he endeared himself to a large circle of friends.

In 1907, Mr. Rose was married to Joyce Grant, of Toronto, Ont., Canada, who, with their three children, Carl Grant, Rudolf William, and Joyce Helene, survives him.

He was a member of the Niagara Club, the Niagara Falls Country Club, and the Honorary Society of Tau Beta Pi. He was a Vestryman of St. Peter's Protestant Episcopal Church.

Mr. Rose was elected an Associate Member of the American Society of Civil Engineers on April 5, 1905, and a Member on February 28, 1911.

* Memoir prepared by Walter McCulloh, M. Am. Soc. C. E.

EDWARD EMMET SANDS, M. Am. Soc. C. E.*

DIED OCTOBER 27, 1923.

Edward Emmet Sands was born in Columbus, Ohio, on January 5, 1877, the son of Louis K. and Emily Sands. His early education was received in the grade and High Schools of Sparta, Wis., and his technical education at the University of Wisconsin, from which he was graduated with a degree of Bachelor of Science in Civil Engineering in 1900. This was followed by a Civil Engineer degree in 1906.

During the winters of 1900 and 1902, Mr. Sands served as Instructor in Civil Engineering at his Alma Mater; during the summers he acted as City Engineer of Sparta, designing and supervising water, sewer, and paving improvements. From 1902 to 1908 he acted as Engineer in the United States Reclamation Service and from 1908 to 1911, as Manager for the Upper Columbia Irrigation Company (part of 1911 and 1912 with the United States Reclamation Service). From April, 1912, to September, 1913, he served as Supervising Engineer for the Canadian Pacific Railway Company on irrigation and municipal projects in Calgary, Alberta, Canada.

In September, 1913, Mr. Sands became City Engineer of Houston, Tex., engaged in general city work and port development, the latter estimated at $3 500 000. During this service he designed and supervised the construction of the first "activated sludge" sewage disposal plant in America. During the World War he also acted as Supervising Engineer for Camp Logan and Consulting Engineer for the Ellington, Carstner, Brooks, and Kelly Aviation Fields.

From March, 1918, to March, 1920, he was engaged as Consulting Engineer for the Atlantic, Gulf, and Pacific Company, in New York, N. Y.; from March to September, 1920, he served as President of the Houston Construction Company, at Houston; and from September, 1920, to June, 1921, as Chief Engineer for the H. F. Friestedt Company, Chicago, Ill., and Houston.

In June, 1921, Mr. Sands entered private consultation practice in partnership with John B. Hawley, M. Am. Soc. C. E., of Fort Worth, Tex., with offices in Houston and Fort Worth. This firm designed and supervised the construction of water purification and sewage disposal works at Fort Worth, Breckenridge, Lubbock, and Sweetwater, Tex., and port improvements at Corpus Christi, Tex., totaling several million dollars, during 1921, 1922, and 1923.

In 1903, Mr. Sands was married to Isabel Garrison, of Denver, Colo. They had four children, Grace Isabel, Ruth Elizabeth, Emily Ann, and Edward Emmet, Jr.

At the zenith of his mental and professional activities, early in 1923, he was stricken with cerebral tumor; two operations failed to abate the malady, and while visiting his father at Milwaukee, Wis., the end came as he slept, on October 27, 1923.

* Memoir prepared by John B. Hawley, M. Am. Soc. C. E.

Edward Sands was known to his profession as an unusually erudite, skilful, practical, experienced, efficient, trustworthy engineer; to his engineering associates, as a sound scientist, able executive, and wise counsellor; to his social acquaintances and friends, as a genial, companionable, helpful comrade; to his family, as a considerate, loving husband and indulgent, doting father; to the writer, who will ever mourn his passing, as a dear friend and faithful coadjutor.

He was a Past-President of the Texas Section of the Society; Chairman of the Houston City Plan Commission, and a member of the following organizations: The University Club of Houston and the Houston Country Club; the Wisconsin Division of Sons of the American Revolution; Trinity Protestant Episcopal Church, of Houston; the Masonic Fraternity, having been a member of Hiram Lodge No. 5 of Madison, Wis.; and the Shrine, Arabia Temple, Houston.

Mr. Sands was elected a Member of the American Society of Civil Engineers on February 4, 1913.

GLENN MASON SCOFIELD, M. Am. Soc. C. E.*

DIED DECEMBER 21, 1926.

Glenn Mason Scofield was born in Hermon, N. Y., on May 3, 1873, the son of George Vincent Scofield and Emily Jane (Mason) Scofield, both of whom were of typical New England stock, their families having landed in Connecticut and worked their way northwestward to Northern New York. His father, who was born in Jefferson County, New York, on October 20, 1831, was a Hydraulic Engineer at a time when small power plants were the rule and hydraulic engineering was in its infancy. His mother was a woman of beautiful character, a school teacher before her marriage, and always a faithful worker in the church and social affairs of her town.

Mr. Scofield's early education was acquired in the Grammer School and High School at Hermon. He then entered the Engineering Department of Union College, at Schenectady, N. Y., from which he was graduated in 1897 with the degree of Civil Engineer.

His first professional experience was as Engineer with the Youngstown Bridge Company, after which he became Assistant Manager of the New York Office of the Company, and, finally, Manager of this office, handling work throughout the Eastern States.

In 1903, he and his brother, Edson Mason Scofield, M. Am. Soc. C. E., formed the Scofield Engineering Company of Philadelphia, Pa. A few years later the two brothers associated with themselves, Mr. Frank Daugherty, a Nationally known electrical engineer. In 1920, these three, with Mr. Ford J. Twaits, a well-known structural engineer, organized the Scofield Engineering Construction Company, of Los Angeles, Calif. These principals have handled engineering and construction work amounting to more than $300 000 000, of which the following are samples: A coaling station for the U. S. Navy, at Guantanamo, Cuba; the steel work for a coaling station for the U. S. Navy, at Manila Harbor, Philippine Islands; dry docks for the U. S. Navy, at League Island Navy Yard, Philadelphia, Pa., and at the Mare Island Navy Yard, San Francisco, Calif.; power stations for the Harwood Electric Company, at Hazleton, Pa., and for the City of Jacksonville, Fla.; concrete ships for the U. S. Shipping Board, during the World War, at San Diego, Calif.; the Pacific Mutual Life Insurance Building; the Biltmore Hotel; the Biltmore Theatre; the Hellman Bank Building; the Pershing Square Building; the Elks Club Building; the Barker Building; the Commercial Club; the Ebell Club; the Hospital of the Good Samaritan; the Title Insurance and Trust Building; and the Sears-Roebuck Buildings, all of Los Angeles, Calif.; the Cooper Arms Apartments, at Long Beach, Calif.; and the Pacific Southwest Trust and Savings Bank, at Pasadena, Calif., and many other similar examples of high-class construction.

Mr. Scofield had a wonderful personality and a great sense of humor, he was a good mixer and the life of the party wherever he might be. Although

* Memoir prepared by J. C. Davenport, Cost. Engr., Scofield Eng. Constr. Co., Los Angeles, Calif.

he was educated as an engineer, he early had concentrated his efforts on the selling end of the business in which his temperament and character made him specially effective. He never forgot a face and took such a personal interest in every new acquaintance that he could repeat the details of the meeting after years of separation.

Had he been spared longer, undoubtedly his works would have been greatly enlarged, although now they stand as an impressive monument to his talent and industry, and to that of his associates. Mr. Scofield is survived by his partners, Messrs. Edson Mason Scofield, Ford J. Twaits, and Frank Daugherty, who are carrying on the work he so ably helped to create. He was a member of the Union League of Philadelphia, and the University Club, the Elks Club, the Commercial Club, the Jonathan Club, and the Breakfast Club of Los Angeles.

He was married at Youngstown, Ohio, on September 14, 1899, to Rosa May Clevely. He died at Los Angeles on December 21, 1926, while in the prime of life. He left, in addition to his widow, a daughter, Marion Adele, and a son, Glenn Mason Scofield, Jr.

Mr. Scofield was elected a Member of the American Society of Civil Engineers on September 7, 1904.

ADDISON MOFFAT SCOTT, M. Am. Soc. C. E.*

DIED APRIL 27, 1927.

Addison Moffat Scott, the son of Chauncey L. and Margaret L. (Moffat) Scott, was born in Dryden, N. Y., on February 20, 1843. He was of mixed Scotch-Irish and English ancestry.

When he was about sixteen, and for several years thereafter, he attended the Ithaca Academy, at Ithaca, N. Y., directing his studies in large part to mathematics and surveying. While attending the Academy, he usually taught school during the winters.

In the spring of 1866 Mr. Scott made a trip to the Northwest and at St. Paul, Minn., joined a party then organizing under Gen. G. K. Warren, U. S. Corps of Engineers, for a survey of the Upper Mississippi River. On the disbanding of this party at St. Louis, Mo., late in 1866, Mr. Scott returned home and renewed his studies at the Ithaca Academy. While he was attending school in the fall of 1867, General Warren offered him a position as Assistant Engineer on the improvement of the Upper Mississippi, which was then in progress. He accepted this position with much hesitation, as it interfered with his plan of study, which included a course at college. He remained on this work for several years, having been employed the latter three years of the time, as Assistant Engineer on the construction of a large railroad and highway bridge built by the United States Government across the Mississippi River, between Rock Island, Ill., and Davenport, Iowa. He was active in this work from the first survey for the location of the bridge until its completion in the spring of 1873. On the completion of the bridge, General Warren, who had been transferred to the East with headquarters at Newport, R. I., tendered Mr. Scott a position under him there. This would have been accepted but for another, and what appeared a more promising, offer made about the same time.

In that year, 1873, the United States Government undertook the improvement of the Great Kanawha River, which was in the Ohio River Department, then in charge of the late Col. William E. Merrill, U. S. Corps of Engineers, M. Am. Soc. C. E., with headquarters at Cincinnati, Ohio. Mr. Scott was placed in local charge of this work, residing at Charleston, W. Va. Throughout the several changes that took place in the organization of the river improvement force, Mr. Scott was continuously retained in his position as Chief Assistant or Resident Engineer. During his long service there, he devoted himself with persevering zeal and energy to the duties of his professional position, mastering thoroughly the theory and practical details of the Chanoine movable dams which the Government adopted in the improvement of the Great Kanawha River. The first movable dams in America were built in this river.

Mr. Scott remained in local charge of the Great Kanawha River Improvement until the fall of 1901, when he resigned, establishing a record of continuous service of more than 28 years on that work and of 34 years as Civil Engineer in the United States Corps of Engineers. A reference to his pro-

* Memoir prepared by C. P. Fortney, M. Am. Soc. C. E.

fessional service should not omit the following tribute paid to him by a distinguished Engineer Officer, the late Gen. William P. Craighill, Past-President, Am. Soc. C. E., under whom he served for 21 years, a period embracing the beginning and nearly the entire completion of the lock and dam system of the Great Kanawha. General Craighill resigned from command of the Baltimore Division of River and Harbor Works, which included the Great Kanawha Improvement, in 1895, when promoted to the highest office in his Corps, the Chief of Engineers of the Army. In an article on the Kanawha Improvement,* General Craighill stated:

"I desire also to call attention in the most emphatic way to another member of the American Society of Civil Engineers, who has for more than twenty-five years been connected with this important improvement which has been most successful from a commercial as well as an engineering standpoint. I refer to Mr. A. M. Scott, who was Principal Engineer on this work when I took charge of it for the United States in 1874; he has remained on it up to the present time when it is completed. The conduct of the work has been most economical, wise and excellent in every way. Mr. Scott has exhibited an unusual degree of skill as a designing and constructing engineer in the management of the improvement and in dealing with the many perplexing problems which have presented themselves for solution in its progress. To him is due, more than to any other person, the success of this work. I say what I know, and it gives sincere pleasure thus to bear record to the merit of a most faithful and deserving man."

To all his subordinates Mr. Scott was always courteous and kind, winning their respect and esteem, while he himself possessed the unbounded confidence and kind regards of superior officers. In his profession he achieved an enviable reputation for capacity, skill, and executive ability. In his general intercourse with the public Mr. Scott was a modest, unassuming, courteous gentleman. He was accurate, prompt, and thoroughly reliable in all business engagements and transactions.

Mr. Scott continued to make Charleston his home until the time of his death. At one time he was Vice-President of the Charleston Chamber of Commerce; he was a Mason of long standing—Past High Priest of Royal Arch Masons and Past Eminent Commander of Knights Templar of the Charleston Commandery. He was long identified with the Kanawha Presbyterian Church of Charleston and was a member of its Board of Trustees. Although never prominent in politics, Mr. Scott took a real interest in all public matters. He was a life-long Democrat.

He was married in 1907 to Florence L. Jeroloman, a daughter of Judge John Jeroloman, of New York City, who survives him.

Mr. Scott was elected a Member of the American Society of Civil Engineers on June 2, 1886.

---

* *Engineering Record*, June 17, 1899.

JOHN HENRY STAATS, M. Am. Soc. C. E.*

DIED JULY 6, 1928.

John Henry Staats, the son of John Henry Staats and Jennie (Mapes) Staats, was born in New York, N. Y., on November 18, 1855. His ancestors on his father's side were among the first families who settled in Albany, N. Y., having come from Holland in 1629. On his maternal side he was descended from the Mapes family who came to the United States before the Revolutionary War, and made its home in Coxsackie, N. Y.

Mr. Staats received his education in the public schools of New York City, and at City College. In 1872, he entered the office of Gen. Charles K. Graham to take up the study and practice of civil engineering.

In 1876 he was employed in the Department of Docks of New York City under General Graham, who had succeeded Gen. George B. McClellan as Chief Engineer of that Department. Mr. Staats served in the Department until 1882, at which time he had risen to the position of Assistant Engineer of Construction.

From 1882 to 1884 he was connected with the firm of Ross and Sanford, of Jersey City, N. J., which was engaged in river and harbor work in New York City and vicinity.

In 1888, with his brother, the late Robert Parker Staats, M. Am. Soc. C. E., he formed the partnership of R. P. and J. H. Staats which, later, was incorporated, and of which Mr. Staats served as Vice-President. During the time of its existence this firm constructed many notable works in New York Harbor, among which might be mentioned the North German Lloyd Docks in Hoboken, N. J., which were afterward used for the embarkation of troops during the World War, the Holland-American Line Docks, also in Hoboken, and three of the so-called Chelsea Piers in New York City below West Twenty-third Street. Mr. Staats was considered an expert on harbor work and dock construction and was retained by several of the transatlantic steamship companies in a consulting capacity.

In 1915, the Company was sold to the Snare and Triest Company of New York and Mr. Staats became Vice-President and Consulting Engineer of the latter firm. This position he held until his retirement from business in 1917.

He died suddenly at York Harbor, Me., on July 6, 1928, and is survived by his widow, Edythe Tillinghast Staats, and two daughters, Mildred Staats Nelson and Fredericka Staats Tuttle. He was a member of the Union League Club of New York, the Holland Society, and the Sons of the Revolution.

Mr. Staats was elected a Member of the American Society of Civil Engineers on March 5, 1884.

* Memoir prepared by Gerald Staats Rinehart, Assoc. M. Am. Soc. C. E.

CADY STALEY, M. Am. Soc. C. E.*

DIED JUNE 27, 1928.

Cady Staley was born at Scotch Bush, N. Y., on December 12, 1840, the son of Harmanus and Evaline (Darrow) Staley. He worked on his father's farm and attended a district school and Jonesville Academy until he was sixteen years old, when he entered the Classical Institute, in Schenectady, N. Y. He went from there to Union College, where he took the course in Civil Engineering under Professor Gillespie. He was graduated with honors in 1865 with the degree of Bachelor of Arts, and, in 1866, he was given the degree of Civil Engineer.

As soon as Mr. Staley was graduated from college, he crossed the plains with a wagon train as the driver of an ox team, and after part of a year spent in prospecting for gold, he was employed by the Central Pacific Railway Company as a Civil Engineer. As such he was engaged on tunnel construction during 1866 and 1867, after which he returned to Union College as an Instructor in Civil Engineering. In 1868, on the death of Professor Gillespie, under whom he had served, he was made Professor of Civil Engineering.

Professor Staley, in 1876, became Dean of the Faculty, which position he held until 1886 when he was called to Case School of Applied Science, Cleveland, Ohio, as Professor of Civil Engineering and President of the Faculty.

As a result of his years of experience at Union College, Dr. Staley brought to Case well-defined ideas as to the organization and administration of an Engineering School. Requiring that he have full charge of the work done in the school, and ever willing to assume responsibility therefor, he, nevertheless, allowed the head of each department full power in the administration of that department, looking to him for results only. The success of Case School has proved the soundness of Dr. Staley's judgment, and what it is to-day is a monument to him as an organizer and administrator.

During the time that he taught at Union College and during the first years at Case School of Applied Science he was active in the practice of his profession, devoting his time to Sanitary Engineering. Dr. Staley early recognized the merits of the separate system of sewerage, and was one of the pioneers in promoting its adoption. In this work he had associated with him, George S. Pierson, M. Am. Soc. C. E., and together they designed and superintended the construction of separate systems of sewerage in West Troy, and Schenectady, N. Y., and in Dayton, Ohio.

Due to the lack of suitable texts on stresses in framed structures, Dr. Staley privately printed, during his early years at Union, the following booklets: "Notes on Bridge Engineering" (1875); "Strength of Materials and Stability of Structures" (1876); and "Elements of Truss Bridges" (1878). During this time he also revised and republished Gillespie's "Surveying" and "Roads and Railroads", and he, together with Mr. Pierson, published "The Separate System of Sewerage". After his retirement in 1902, he edited "The Teaching of Jesus".

* Memoir prepared by Frank H. Neff, M. Am. Soc. C. E.

In 1886, Union College conferred on him the degree of Doctor of Philosophy, and, in 1888, he received the degree of Doctor of Laws from both Union College and Ohio Wesleyan University. In 1920, Union College conferred on him the degree of Doctor of Science.

Dr. Staley was married at Waterford, N. Y., on December 29, 1869, to Kate Holcomb, daughter of Elvin and Philetta (Hall) Holcomb.

After coming to Case School Dr. and Mrs. Staley traveled abroad a great deal during their summer vacations. He brought back from these trips a wealth of architectural material which he gave to his classes in a series of illustrated lectures. These lectures were also open to the general public and were largely attended.

Dr. Staley retired in 1902, in order that he and Mrs. Staley might have ample leisure to travel, for which both had a great liking. After a trip around the world, they made their home either in Florida, or in Amsterdam, N. Y., where he had purchased a farm at Minaville, near the place where he was born. They continued, however, in their foreign travels.

Dr. Staley was a great lover of the horse, and during his earlier years at Case he planned to retire upon a stock farm which he was starting in the West. He had imported Percheron stock from France, and looked forward with pleasant anticipation to the raising of heavy draft horses. However, a series of bad years caused him to abandon this plan and dispose of his stock and farm.

As a teacher, Dr. Staley had the faculty of presenting the principles of the comparatively simple science that Civil Engineering was in his early teaching days, in a way that fixed them in the minds of his students. In his duties as President, he ever had the welfare of the individual student uppermost in his heart. Whenever the application of a rule, well-designed for the good of the student body, might injure the future of an individual boy, he never hesitated to set it aside; and many a student of slow development, or whose preparation had been poor, owed his opportunity to start an engineering education, or his chance to make good after having started, to this quality of Dr. Staley.

Although retaining the title of Professor of Civil Engineering at Case for a number of years, Dr. Staley early turned over the teaching to those who were to succeed him, so that comparatively few had the privilege of working under him in engineering classes. Those who did, cherish the memory of the intimate personal relationship of the classroom, his lack of formality, and his sympathetic attitude toward their work. Although few had the classroom contact, there is no former student, nor member of the Faculty, who was at Case during the sixteen years that Dr. Staley directed its affairs, who does not hold his memory in highest esteem.

Dr. Staley was elected a Member of the American Society of Civil Engineers on March 17, 1869.

JOHN TRUESDALE STEWART, M. Am. Soc. C. E.*

DIED JUNE 9, 1928.

John Truesdale Stewart was born at Loda, Ill., on January 13, 1868, the son of William R. and Nancy (Barr) Stewart. He was of Scotch-Irish descent, his ancestors having emigrated to the United States before the Revolutionary War. One great-grandfather served in the War of the Revolution and another in the War of 1812.

Mr. Stewart was graduated from Grand Prairie Seminary, Onarga, Ill., in 1888. In 1893, he was awarded the degree of Bachelor of Science from the University of Illinois, Urbana, Ill., and, in 1909, that of Civil Engineer from the same University.

While Mr. Stewart was known principally as an authority on agricultural drainage, his activities took him into other engineering fields in various parts of the country. Beginning his engineering career as Rodman on land drainage work in 1890, he spent the years 1891 to 1892 on railroad work. From 1893 to 1897 he was engaged in general engineering practice in Illinois. During the following two years he was occupied in both drainage and railroad work, holding several positions during this period. In 1899, Mr. Stewart was appointed Field Assistant with the United States Geological Survey, a position which he held until 1904, when he became Drainage Engineer, in the United States Department of Agriculture, on drainage and irrigation work in South Dakota, North Dakota, Minnesota, Arkansas, and Florida.

In 1908 he was made Professor and Chief of the Division of Agricultural Engineering, at the University of Minnesota, Minneapolis, Minn. At this time he conducted research work on the drainage and development of peat lands, the durability of drain tile, and the efficiency and maintenance of open ditches; he also prepared as sole or co-author numerous papers, several of which have been published by the United States Department of Agriculture. Among these are: "Drainage of the Eastern Parts of Cass, Traill, Grand Forks, Walsh, and Pembina Counties, North Dakota";† "Farm Drainage, Minnesota Extension";‡ "Installation of an Experimental Drainage System, Minnesota Experiment Station";§ "Review of Drainage Legislation";‖ and numerous other papers on land drainage. In addition, he was senior author of "Engineering on the Farm".

Imbued with a strong sense of loyalty and patriotism, Professor Stewart was active in the military service of the United States. In 1893, he was made Brevet Captain in the Illinois National Guard. With the outbreak of the Spanish-American War, he organized a volunteer company of which he was elected Captain. He became a Major in the Engineers Reserve Corps in

‖ New York State Library, 1905-08.

1917, and served as Lieutenant-Colonel of Engineers in 1918. Although much against his desire he was not permitted to serve overseas, he distinguished himself so as to receive honorable mention from his superior officers. He held a commission as Colonel in the United States Engineers Reserve Corps at the time of his death.

Following the close of the World War, Colonel Stewart was connected with the Portland Cement Association. In 1922, he resumed his consulting practice as a recognized authority on drainage and wet land development.

Always courteous, friendly, and interested, Colonel Stewart had many friends, both in and out of the engineering fraternity. He was a student of natural history, always fond of outdoor life, and he especially enjoyed hunting and fishing.

He was a member of the Society of American Military Engineers, the Western Society of Engineers, the American Society of Agricultural Engineers, the Engineers' Society of St. Paul, the American Legion, the Sons of the Revolution, the Society of the War of 1812; and Tau Beta Pi, Sigma Xi, Alpha Zeta, and Gamma Sigma Delta Fraternities.

On January 1, 1900, he was married to Ida Belle Wilson who survives him. He died June 9, 1928, and was buried in Arlington National Cemetery, with full military honors.

Colonel Stewart was elected an Associate Member of the American Society of Civil Engineers on September 6, 1905, and a Member on October 10, 1916.

KIRBY LEE STRICKLAND, M. Am. Soc. C. E.*

DIED DECEMBER 10, 1927.

Kirby Lee Strickland, the son of Thomas and Frances (Sewell) Strickland, was born on November 12, 1871, in Coweta County, Georgia. He was educated at the North Georgia Agricultural College, a branch of the University of Georgia, where he was in attendance three and one-half years.

In July, 1896, Mr. Strickland entered the employ of the Edgemoor Bridge Works, as Timekeeper and Assistant Engineer on the erection of steel structures, with which Company he remained until 1901, at which time the American Bridge Company was organized. The Edgemoor Bridge Works was one of the various companies which were amalgamated into the American Bridge Company, and on account of his field experience Mr. Strickland was appointed to inaugurate an accounting system for the Erecting Department of the newly organized Company. He was subsequently transferred to field duties, where he remained until late in 1901, when he entered the General Office at Pencoyd, Pa., as Assistant to Manager of the Erecting Department.

In April, 1904, Mr. Strickland was appointed Assistant to the Manager of the Eastern Division Erecting Department, with offices in Philadelphia, Pa., in which capacity he was employed until July, 1915. During this time he supervised the erection of steel structures of every description, including the Baltimore and Ohio and the Pennsylvania Railroad Bridges over the Susquehanna River at Havre de Grace, Md., and numerous bridges on the New York, New Haven and Hartford, the Philadelphia and Reading, and Southern, Railroads.

In July, 1915, he was appointed Division Erecting Manager of the American Bridge Company, at Chicago, Ill., which position he held until the time of his death. During this period he was in charge of the erection of many large and important structures, a few of which are the Chicago, Burlington and Quincy Railway Bridge across the Missouri River, at Kansas City, Mo.; the Union Pacific Bridge across the Missouri River, at Omaha, Nebr.; the St. Joseph and Grand Island Bridge across the Missouri River, at St. Joseph, Mo.; the Bismarck and Mandan Highway Bridge, over the Missouri River at Bismarck, N. Dak.; the Atchison, Topeka and Santa Fe Railway Bridge across the Mississippi River, at Fort Madison, Iowa; the large steel ore docks at Duluth and Two Harbors, Minn.; the Illinois Steel Company's open hearth buildings, at Gary, Ind., and South Chicago, Ill.; and many other erection projects for the United States Steel Corporation. During the World War Mr. Strickland was active in the erection of various projects for supplying the United States Government with war materials, notably the large powder plant for the du Pont de Nemours Company, at Nashville, Tenn.

The last, and one of the most important, structures erected under Mr. Strickland's supervision was the large highway bridge across the Carquinez Straits of San Francisco Bay, which was completed during the summer of

* Memoir prepared by the following Committee of the Illinois Section: Messrs. Albert F. Reichmann and O. F. Dalstrom, Members, Am. Soc. C. E. and the late A. F. Robinson, M. Am. Soc. C. E.

1927. It was while he was on a trip in connection with the completion of this work that he was taken sick with what proved to be his final illness.

Mr. Strickland was a man of pleasing personality with numerous friends and admirers, who knew him also as a man of unusual resourcefulness resulting from his broad experience. He was an interesting narrator of experiences and anecdotes, and took keen delight in relating stories pertaining to his boyhood days in the "Old South." He was held in high esteem by all his associates throughout his long term of service with the American Bridge Company, and he numbered among his friends many men prominent in the Engineering Profession throughout the United States. He was a member of the Western Society of Engineers and the Engineers' Club of Chicago.

Mr. Strickland had made his home in Evanston, Ill., a suburb of Chicago, since 1915. On March 16, 1907, he was married to Charlotte Barney, of Pottstown, Pa., who died in 1921. Two daughters by this marriage, Eleanor and Elizabeth, survive him. On November 17, 1923, he was married to Amy Louise Halvorsen, of Chicago, who, with a son, Kirby Lee, survives him. Mr. Strickland is also survived by his mother, Mrs. Ellen Byram, who has remained at the ancestral home in Georgia.

Mr. Strickland was elected a Member of the American Society of Civil Engineers on October 15, 1923.

PAUL BERTRAM TALLMAN, M. Am. Soc. C. E.*

DIED JULY 29, 1926.

Paul Bertram Tallman was born at East Orange, N. J., on January 24, 1884. He was the son of the late Stephen Sands Tallman and Martha Broadmeadow Tallman. His great-grandfather, Simeon Broadmeadow, came to the United States from England in 1825 and by a Special Act of Congress he was made a citizen. He was one of the early promoters of the manufacture of steel and gas in this country, besides being an inventor of National fame.

Mr. Tallman's early life was spent in East Orange, where he fitted himself for college. On account of ill-health, he was forced to abandon his course, but from this time forward, he became a student and completed his education as an engineer even more thoroughly than college curricula require. His daily work in engineering was followed with careful study of the related problems during his hours of leisure. His greatest recreation was the complete and successful study and solution of these problems and the systematic recording of his findings.

His practical engineering experience began during the summer of 1902, with the Clearfield Bituminous Coal Company at Rossiter, Pa. In January, 1903, he entered the service of the New York Central and Hudson River Railroad Company, in the Terminal Engineer's Office, where he served, successively, as Chainman, Rodman, Instrumentman, and Draftsman on work in connection with the Grand Central Terminal improvements. In 1906, he resigned his position with the Railroad Company and accepted that of Engineer and General Superintendent with Bunn and Nase, General Contractors, of New York, N. Y.

From 1909, until his death, Mr. Tallman was in the employ of the firm of Warren and Wetmore, Architects, of New York City. While in this position, his work was of a most varied character and comprised largely the design and installation of mechanical equipment and plants, and the supervision of the construction of numerous buildings, principal among which were the Union Station, Houston, Tex.; the Broadmoor Hotel, Colorado Springs, Colo.; the Ritz-Carlton Hotel, Atlantic City, N. J.; and the Plaza Addition, the Heckscher Building, Aeolian Hall, and the Goelet Building, New York City.

In 1923, when a new department was organized by the firm for conducting architectural and engineering supervision for loaning institutions, Mr. Tallman was selected as its head. Here, again, his records and studies were of great assistance in organizing and conducting the work. Notable among the buildings under supervision by this Department, were the Cooper Department Store Building, Los Angeles, Calif.; the Michigan Theatre and Office Building, Detroit, Mich.; the Penn Athletic Club, Philadelphia, Pa.; and 200 Madison Avenue, and the new Paramount Theatre and Office Building, New York City.

* Memoir prepared by P. M. Corry, M. Am. Soc. C. E.

The high esteem in which Mr. Tallman was held by his fellow members of the Building Committee for the new Paramount Theatre and Office Building, is shown in the following resolutions:

"*Whereas,* on the 29th day of July, 1926, there departed this life in Rockville Center, Long Island,

PAUL B. TALLMAN

one of the Members of the Building Committee of The Paramount Building, New York City. At a meeting of the said Committee duly held on the 2nd day of September, 1926, it was

"*Resolved,* that out of respect to the memory of the deceased, suitable action should be taken to mark the high regard in which he was held at all times as a gentleman and engineer of ability and wise counsel; and

"*Resolved,* that we deeply deplore his death and extend to his widow and son our deepest sympathy in the hour of their great grief; and

"*Resolved,* that a copy of these resolutions be forwarded to his family."

On October 21, 1909, Mr. Tallman was married to Edna Davey, of East Orange, who, with a son, Stephen, survives him.

Mr. Tallman was of a highly sociable nature and enjoyed the company of his many friends. He was an untiring worker and never spared himself when his time and energies were needed by his friends or business associates. In business dealings he never took advantage of another's mistakes. He was instinctively honest and fair. His oldest friends were his best friends.

He took an active interest in civic and religious affairs. He was a life-long member of the Presbyterian Church—the last four years a devoted member of the Rockville Centre Presbyterian Church. He was President of the Board of Trustees and also very active in the Men's Club and in the Sunday School.

In 1922, he was elected a Fellow in Perpetuity by the Metropolitan Museum of Art, New York City. He was also a member of the American Railway Association.

Mr. Tallman was elected a Junior of the American Society of Civil Engineers on October 3, 1905, an Associate Member on September 10, 1910, and a Member on May 28, 1923.

EUGENE AUGUSTUS HOFFMAN TAYS, M. Am. Soc. C. E.*

DIED JULY 22, 1928.

Eugene Augustus Hoffman Tays was born at West Point, N. Y., on October 24, 1861, the son of the Rev. Joseph Wilkin Tays and Jennie (Crowell) Tays. At the time of his birth his father was teaching mathematics at the United States Military Academy. His ancestry on his father's side was Scotch-Irish, whereas on his mother's side it was English.

Mr. Tays received his early training in the Maysville, Ky., Institute and the Burlington, N. J., Military College. In the fall of 1880 he matriculated at Union College, Schenectady, N. Y., where he studied Civil Engineering, but owing to illness he was compelled to leave college at the close of his second year. While he was at Union he joined the Delta Upsilon Fraternity, and took several prizes in his military course for tactics and marksmanship.

Mr. Tays' first work in his chosen field was as Rodman, Leveler, and Topographer for the Mexican Central Railroad Company, on which road he later served as Division Engineer of Construction (1882-1883). In 1884 he was an Engineer on the Topolobampo and Pacific Railroad, and in 1885 he was engaged as Engineer in charge of the irrigation of a vast tract of land in the District of Fuerte, Sinaloa, Mexico.

In 1886, Mr. Tays went into private practice and was employed successively by the Mexican-American Construction Company of Sinaloa, the Sinaloa and Chihuahua Railroad Company, and the Mexican Western Railroad Company. In 1891 and 1892, he was Chief Engineer of the Topolobampo Canal, and, in 1893, Engineer and Superintendent of the San Javier Silver Mines of Sinaloa.

At this time Mr. Tays left the field of Civil Engineering for that of Mining Engineering, in which he became an expert, called on by the United States Government in expert testimony. He spent twenty or more years in this field of endeavor. During this time he was connected with the Palmarejo Mining Company of Palmarejo, Chihuahua, Mexico; the Mexican Mineral Railroad Company; the San Agustin Mining Company of San Rafael, Chihuahua; the Anglo-Mexican Mining Company of San José de Gracia, Sinaloa; the Compañía Minera de Santo Tomás y Anexas at San José de Gracia; the Maconí Mines, Maconí, Querétaro, Mexico; the United Mining Company of New York; the United Sugar Companies, Los Mochis, Sinaloa, Mexico; and the Compañía Minera Occidental Mexicana of South America, at San Blas, Mexico.

Because of the unsettled conditions in mining operations in Mexico in 1924, Mr. Tays turned to agriculture, and organized the Liga Agrícola Occidental Mexicana, of which he was the Managing Director. He was engaged in this most successful venture at the time of his death.

Mr. Tays was a constant contributor to scientific publications on mining, milling, metallurgy, geology, etc. One of his contributions was on "The

* Memoir prepared by the Rev. W. N. P. Dailey, New York, N. Y.

Economics of Mining". His studies as published in the *Mining World, Engineering and Mining Journal, Mining and Scientific Press, Western Mining World,* and the *Transactions* of the American Institute of Mining and Metallurgical Engineers, are notable contributions. He was affiliated with the following technical, scientific, and social organizations: The American Institute of Mining and Metallurgical Engineers; the United States Public Reserve (during the World War); the American Geographical Society; the Santa Cruz Club, of Nogales, Ariz.; the Society of Arts, London, England; and the American Association for the Advancement of Science.

He was married, in 1885, to Rosaura Vega, daughter of the Governor of the District of Fuerte, Sinaloa, Mexico. They had eight children, José W., Eloisa, Eugene, Clement I, Linda, George, Alexander, and Clement II, six of whom, with his widow, survive him.

Mr. Tays seems to have had at least three strong ties with which he bound himself up in life—his home and family, his profession and service, and his college and class. An Episcopalian in religion, he nevertheless held himself as a servant of all men wherever he might be of use, and through the years of his life felt that he was worshiping his Creator in a most accepted way by even the lowliest types of service in which he found himself of aid to his fellow men. A workman of distinction and varied acceptance in his chosen profession, he also possessed a high-mindedness of soul and fineness of character—attributes not as common as they ought to be among men of the present time. Even in the day of his departure, his was the vision splendid of better service and greater usefulness in the years to come—an indomitable spirit of optimism, his home and work holding the center of his affections and dreams.

Mr. Tays was elected a Member of the American Society of Civil Engineers on April 6, 1898.

STURGIS HOOPER THORNDIKE, M. Am. Soc. C. E.*

DIED FEBRUARY 16, 1928.

Sturgis Hooper Thorndike was born on June 11, 1868, at Beverly, Mass., the son of Samuel Lothrop and Anna Lamb (Wells) Thorndike. Of English ancestry, his earliest known paternal ancestor was William Thorndike, who died at Little Carlton, Lincolnshire, England, in 1539. His earliest paternal ancestor in America was John Thorndike, who came from Little Carlton to Ipswich, Mass., in 1633, but who returned to England, leaving in America his son, Paul, who settled in Beverly, Mass. His earliest known maternal ancestor was Harold de Vallibur (*i. e.*, Welles), who lived in Cumberland County, England, early in the Twelfth Century; his descendant, Hugh Wells, came from Essex County, England, to Watertown, Mass., in 1630, later going to Hartford, Conn., and then to Hadley, Mass.

Sturgis Thorndike's boyhood was spent largely in Boston and in Cambridge, Mass. After preparation at a private school, he entered Harvard College, where he received his Bachelor of Arts degree in 1890. Later, having decided to follow an engineering career, he entered the Massachusetts Institute of Technology, from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1895.

Entering the office of the City Engineer of Boston in 1895, at the beginning of a period of notable activity in city bridge construction, he gained during the next eighteen years a broad experience in the municipal engineering service of that city, primarily in its bridge building undertakings. In 1906 he was appointed to the position of Assistant Engineer in charge of bridge design. In 1911, on the consolidation of the Engineering, Street, and Water Departments into the Department of Public Works, he became the Designing Engineer of the Bridge and Ferry Division of this, the largest of Boston's municipal departments. In this position he was in charge of the design of bridges and of other municipal structures.

Among the more important Boston bridges with which Mr. Thorndike had engineering connection, may be mentioned the Charlestown, Summer Street, Northern Avenue, Chelsea Street, Chelsea North, Meridian Street, Broadway, and Atlantic Avenue (or Cove Street) Bridges, all over tide-water and each having an important draw-span; the Cambridge Bridge (now known as the Longfellow Bridge), across the Charles River between Boston and Cambridge, the most notable of the bridges of Greater Boston; and many important bridges on land, spanning railroad locations.

During this period, under leave of absence from the City Engineer during term time, Mr. Thorndike served as Instructor at the Massachusetts Institute of Technology in the scholastic years of 1904-05 and 1905-06, teaching hydraulics, stereotomy, bridge design, and surveying.

* Memoir prepared by Frederic H. Fay and Charles M. Spofford, Members, Am. Soc. C. E.

In October, 1911, he resigned from the position of Designing Engineer of the Bridge and Ferry Division of the City of Boston, to engage for a time in private engineering practice.

On July 1, 1914, Mr. Thorndike joined with Frederic H. Fay, M. Am. Soc. C. E., former head of the Boston Bridge and Ferry Division of the City of Boston, and with Charles M. Spofford, M. Am. Soc. C. E., the head of the Civil Engineering Department of the Massachusetts Institute of Technology, in forming the engineering firm of Fay, Spofford, and Thorndike. In this organization he was an active partner until his death.

Among the more important engineering projects under the direction of the firm in which Mr. Thorndike participated, may be mentioned the design and the engineering supervision of construction of the Boston Army Supply Base, one of the larger water-front terminals built during the World War for the use of the United States War Department; the Hampden County Memorial Bridge across the Connecticut River at Springfield, Mass., a monumental structure of reinforced concrete arches; and the water supply, sewage disposal, central heating plant, and other engineering features for the Town of Mariemont, in the suburbs of Cincinnati, Ohio. In all these projects and in many investigations and reports, both engineering and economic, Mr. Thorndike's contributions were valued by reason of his sound judgment and his highly analytical mind.

Thoroughness and painstaking analysis were characteristics of Mr. Thorndike's professional work and, indeed, of whatever he undertook, whether within or without the field of engineering. Inheriting, perhaps, a "legal" mind from his father, who was a lawyer of distinction, he early gave particular attention to the legal form of engineering contracts, and although without special legal training, he became an authority in this important branch of engineering work. Always keenly interested in fair play and the advancement of ethical standards, he was a most active member of the Committee of the Northeastern Section of the Society which formulated the Code of Practice, adopted in 1927 by the Society.

He was long active in the work of the Northeastern Section of the Society, of which he was President at the time of his death. For thirty-two years he had been a member of the Boston Society of Civil Engineers, serving on many of its committees and also as a Director in 1919 and 1920. He was a member of the American Water Works Association, the New England Water Works Association, and the American Society for Municipal Improvements. He frequently contributed papers to these professional societies. He was an active member of the Boston Building Congress, the aim of which is to promote improved conditions in the building industry in Boston and in New England.

Mr. Thorndike was a member of the Harvard Club of Boston, the Harvard Club of New York, and the Harvard Engineering Society. He was long a member of the St. Botolph and Engineers Clubs of Boston and of the Boston City Club, as well as of the Boston Chamber of Commerce.

The Protestant Episcopal Church and its affiliated interests, a vital part of his life, equally with his professional work, claimed much of his time, effort, and energy. From his boyhood—for fifty-two years—when in town, he occupied his place in the family pew at the historic Christ Church in Cambridge. For thirty-five years he was elected to the Vestry, and at one time was a Warden of that parish, of which he was always a most loyal supporter. He was also connected with St. Anne's Church in Lincoln, Mass., near his country home, serving on the Vestry there and giving to that parish his fostering care and intense interest.

Shortly before the war he assisted in organizing the Conference for Church Work, an annual gathering of workers in the Episcopal Church throughout the country and from abroad. Starting in a small way, the organization has outgrown the accommodations of the Harvard Divinity School, where its summer conventions were held for a time, and, in recent years, has met in the early summer at Wellesley College. For many years, Mr. Thorndike was the managing executive of the Conference; through his efforts it was incorporated; and one of the last things he did was to finish the preparation of a code of practice for the conduct of its business.

His interests extended to many enterprises for the betterment of humanity; he was a member of the Fellowship of Reconciliation and of the Church League of Industrial Democracy; he was a member of the New China Committee, and the Japan Committee; he was long active in the support of missionary work in the Protestant Episcopal Church; and he was a liberal contributor, not only to church activities, but also to many other good causes.

For many years Mr. Thorndike made his summer home at Stony Farm, in Weston (and Lincoln), Mass., and during the latter part of his life, Weston was his legal residence. He was interested in the affairs of the town, but never held office until 1926, when he was elected a member of the Water Supply Investigating Committee. In 1927 he was elected a member of the Board of Water Commissioners.

One of his chief characteristics was his love of Nature; he was never more happy than when he was at Stony Farm. He knew and loved every tree on the place and every living creature was his companion and friend. Mt. Monadnock in Southwestern New Hampshire frequently lured him to its slopes, and for many years he was a constant visitor at The Ark, at Jaffrey, at the base of this mountain. One of his pastimes, in which he was often joined by his partner, Mr. Fay, was the surveying and the mapping of the many trails on the slopes of this beautiful isolated mountain.

Mr. Thorndike remained a bachelor throughout his life. A loyal friend and delightful comrade, with qualities of sincerity, unselfishness, and earnestness rarely found, Sturgis Thorndike in his sixty years' span of life exerted a helpful influence among all with whom he came in contact, an influence far greater than he himself ever realized.

Mr. Thorndike was elected a Member of the American Society of Civil Engineers on January 6, 1915.

EDWIN HALL WARNER, M. Am. Soc. C. E.*

DIED JUNE 17, 1927.

Edwin Hall Warner was born in New York, N. Y., on February 21, 1858, the son of William H. and Anna Pamela (Conger) Warner. He attended the University of the City of New York, (now New York University), and was registered in the Polytechnic Engineering Department of the School of Applied Science.

Mr. Warner's technical career was varied and important. During the period from 1884 to 1886, he was engaged on the Mexican National and Mexican Central Railways, as Instrumentman and Assistant Engineer in charge of various construction works. During 1887 and 1888 he was Assistant Engineer and Acting Division Engineer, Maintenance of Way, for the Union Pacific Railway Company, with headquarters in Denver, Colo. In 1888 and 1890 he acted as Assistant Chief Engineer for the Seattle, Lake Shore and Eastern Railway Company (now the Northern Pacific System), with headquarters in Seattle, Wash. During this engagement he located and built 110 miles of railway from Snohomish, Wash., north to the Canadian boundary.

From 1891 to 1898 Mr. Warner was in private practice in Seattle, engaged in the development of mining properties, hydraulic power investigations, and installation of mining power plants; and for a part of the time, he acted as City Engineer for Seattle, on extensive construction of sewers. From May, 1898, to January, 1899, he was Assistant Chief Engineer for the White Pass and Yukon Railway Company in charge of location north of the Canadian Boundary. He located and built the first miles of track extending out of Skagway. Mr. C. E. Hawkins was Chief Engineer of this extremely difficult and arduous work.

From 1899 to 1903 Mr. Warner was engaged in private practice in Republic, Ore., as Engineer for the Republic Mining Company, and also on various mine investigations and installations. In 1903, he became Principal Assistant Engineer for the Columbia Improvement Company (Stone and Webster Syndicate), on the Puyallup Power development at Electron, Wash., the Engineer in charge being Mr. J. C. Cunningham who was succeeded by George S. Binckley, M. Am. Soc. C. E. This was a 20 000 h.p. installation, and during the early stages the forces under Mr. Warner's supervision included as many as 1 400 men.

In 1904 he moved to California and became Chief Engineer of the Abbot Kinney Company, at Venice, supervising the canals and bridges for this, one of the early play areas of Los Angeles. In this period Mr. Warner was associated with the late James Dix Schuyler, M. Am. Soc. C. E., and, in 1905, became Chief Engineer of the Tri-State Land Company, at Scottsbluff, Nebr. —a project for which Mr. Schuyler was Consulting Engineer. The location of 100 miles of canal, for a 1 750 sec-ft. flow, and the construction of 25 miles

* Memoir prepared by William S. Post, Assoc. M. Am. Soc. C. E., and Philip Schuyler, M. Am. Soc. C. E.

under his direct supervision, was part of Mr. Warner's accomplishment. From June, 1906, to January, 1907, he again undertook construction at Mr. Schuyler's instance. He became Assistant Chief Engineer of the Mexican Light and Power Company, for the construction of the dam at Necaxa, Mexico, where he had responsible charge of dam, tunnel, conduit, and machine shops and the construction of 22 miles of railway.

From 1907 to 1910 he was engaged in private practice in Los Angeles, Calif., designing irrigation projects, buildings, and ocean piers. From 1910 to 1916 he was Constructing Engineer for the Southern California Edison Company, with headquarters at Los Angeles. His duties included the construction of the 65 000 h. p. generating station at Long Beach, Calif., about twenty-five sub-stations, and the direct supervision of a large power tunnel on the Kern River. From 1916 to 1919 he was again in private practice, acting, among other engagements, for the American Trona Company at San Pedro and Searles Lake, Calif., in potash production.

From 1919 to 1921 Mr. Warner served as Construction Engineer for two important concrete dams in California, namely, the Kerckhoff Dam, of the San Joaquin Light and Power Company, on the San Joaquin River, and the Snow Mountain Power Company Dam on the Eel River.

In 1922, he re-entered private practice, first maintaining an office in San Francisco, and, finally, removing to Burlingame, Calif., where he and Mrs. Warner established a delightful home. It was in his office in Burlingame that he died of heart failure on June 17, 1927.

In Burlingame, Mr. Warner was also able to devote himself to civic affairs, for which his broad outlook, enjoyment of social and economic problems, fine tact, and personality, peculiarly fitted him. It is notable in the career of this engineer, absorbed in the main with the interests and perplexities of his clients, that he also gave generously to public service. An editorial, published a year before his death testifies to the thorough attention and organizing ability, which was an element of his success, and also to the appreciation of the community:

"A Word of Praise*"

"When a man has labored faithfully and well in public service, and particularly when that service has been unremunerative and has been performed in a quiet, unassuming sort of way, a word of praise is not amiss.

"Edwin H. Warner, last Monday night, tendered his resignation to the City Board of Trustees, after years of duty in the position of Secretary of the Park and Playground Commission. The plain truth of the matter is that Warner did practically all the work in connection with the functioning of the Commission and that he accomplished an amazing amount during the past two years.

"He resigned simply because the duties of the Commission had become an increasing burden, encroaching upon his private business, and because two years of free and voluntary labor at such a task certainly entitles a man to the privilege of relinquishing the responsibility to some one else.

* * * * * * * *

"Warner, on his own initiative, made practically a complete survey of all the trees in Burlingame. He consulted experts on the culture and diseases

* *Burlingame Advance-Star*, May 19, 1926.

of trees, determined the best trees for the city, and approached the entire problem in a thorough and scientific manner.

"And the main burden of the work has been the innumerable complaints and requests of property owners concerning their own tree problems. Warner maintained the consistent policy that these property owners were entitled to an immediate answer. This involved almost daily investigation on his part, the continual giving of time and energy to the work, and a large amount of correspondence. And that at no small sacrifice for a busy professional man to make.

"It is a matter of record that most men who have labored so faithfully in the service of the public come sooner or later to the disheartening realization that appreciation of their efforts is very seldom expressed by their fellow men and that the general public is relentlessly stingy with its praise. People walk miles or write page after page to kick about something, but they usually have no time or energy for commendation. Bearing this in mind, this is only an attempt to give a bit of honest praise where it is deserved."

Technically, Mr. Warner was known as a brilliant Location Engineer. In administrative work and construction his strongest forte perhaps was initiative. He possessed great organizing ability, in which he exercised a personal charm and sense of humor, which appealed not only to his friends, but to construction foremen and laborers as well. His tastes were fine; he was cultivated and very well read; and an excellent conversationalist.

One of the writers had the good fortune, as City Engineer of Ocean Park and Venice, from 1904 to 1905, to become intimately acquainted with Mr. Warner, later following him to Nebraska as an Assistant on the construction of the Tri-State Land Company Canal Project. Mr. Warner was a tall, slender, erect, handsome man, dignified and austere on first acquaintance, but possessed of a rare sense of humor and the ability to "play". He frequently organized minstrel shows, acting equally well the part of interlocutor and end-man. In short, he could play with his subordinates and at the same time retain their respect.

Mr. Warner was married on August 21, 1890, at Seattle, to Frances B. Ferguson, the daughter of Colonel David Ferguson, a distinguished figure in the Sixties in California and later of the American Colony in the City of Mexico. With sympathy and pride in her husband's engineering achievements Mrs. Warner was a constant companion in his various engagements in the Western United States and Mexico.

Mr. Warner was elected a Member of the American Society of Civil Engineers on October 4, 1893.

FRANCIS REPETTI WELLER, M. Am. Soc. C. E.*

DIED JANUARY 13, 1929.

Francis Repetti Weller was born in Washington, D. C., on February 16, 1880, the son of Michael I. and Rita (Repetti) Weller. He was educated at Mount St. Mary's College, near Emmitsburg, Md., and then attended the Columbian University, at Washington, D. C., which is now known as George Washington University. He was graduated from Columbian University with the degree of Bachelor of Science in Civil Engineering in 1899, and in June, 1900, received the degree of Civil Engineer.

From 1899 to 1903 Mr. Weller was employed in the Engineering Department of the District of Columbia, principally on bridge design, and, in addition, was an Instructor at Columbian University. In September, 1903, he entered private practice as a Consulting Engineer, with headquarters at Washington.

Mr. Weller specialized in the design of steam-electric and hydro-electric power plants, transmission lines, and water-works plants. He also always had been closely connected with public utility work. For the Municipal Service Corporation, he designed and enlarged plants in Salem, Ohio, Alexandria and Staunton, Va., and Coatesville, Pa. He was the Consulting Engineer on the design and construction of hydro-electric plants for the City of Richmond, and the City of Bedford, Va., the Watauga Power Company, at Bristol, Tenn., and the Virginia Alberene Corporation; he also made enlargements of the electric plants of the Keystone Power Corporation, at Ridgway, Pa., and the Potomac Electric Power Company, at Washington.

Mr. Weller was one of the pioneers in power development in Southwestern West Virginia and built the first power plant in that State at Logan. This plant was primarily owned by the General Utilities Operating Company, of Baltimore, and, later, by the Kentucky and West Virginia Power Company, and is now the property of the American Gas and Electric Company. Mr. Weller maintained his connections during all these changes of ownership and was responsible for many additions to the property, as well as transmission lines connecting it to plants at Sprigg, W. Va., and Hazard, Ky.

In 1917, and during the World War, he was employed by the Navy Department, Bureau of Yards and Docks, to design additions to a great many of the Navy Yards on both the Atlantic and Pacific Coasts. During this period he had a large designing force in his employ and made plans for extensions and enlargements at the Brooklyn, N. Y., Navy Yard, the Navy Yards at Philadelphia, Pa., and Norfolk, Va., the Submarine Base at New London, Conn., and a Naval Station at New Orleans, La., together with about ten other smaller projects. He was also Engineer for the United States Housing Corporation during this same period. In recognition of his excellent work for the Bureau of Yards and Docks he was made Lieutenant Commander in the United States Naval Reserve.

* Memoir prepared by M. X. Wilberding, Pres., Francis R. Weller, Inc., Washington, D. C.

In 1923 Mr. Weller was employed as Consulting Engineer for the Virginia Western Power Company and built steel tower transmission lines from Charlottesville to Staunton, Va., revamped the power house at Charlottesville, and constructed sub-stations at both Charlottesville and Staunton. The following year he built steel tower transmission lines for the same Company from Clifton Forge, Va., to Ronceverte, W. Va., and wood pole distribution lines between Goshen, Buena Vista, Lexington, and Clifton Forge, Va.

In 1925, he organized a public utility holding company known as the Interstate Utilities Corporation. This holding company had properties in Central and South Georgia and Mr. Weller was its President, as well as the President of all its subsidiary companies. These properties were afterward purchased by the Southeastern Power and Light Company, and Mr. Weller then formed the Allied Utilities Corporation, another public utility holding company, of which he was President. The principal holdings of this Company were in the State of West Virginia. The Company was dissolved in 1927 and its properties were sold to the Allied Utilities Company, of which Mr. Weller was President at the time of his death.

In the spring of 1926, Mr. Weller was employed as Consulting Engineer by the Fitkin Interests to build transmission lines in Florida and South Georgia. These consisted of steel power and wood-pole lines from Tarpon Springs, near St. Petersburg, Fla., through Inglis and Jasper to Valdosta, Ga. The installation included a great many sub-stations, and the construction work continued for a period of approximately two years.

In June, 1928, he incorporated his engineering practice under the name of Francis R. Weller, Incorporated, and, at the time of his death, he was President of this organization.

Mr. Weller was a member of the American Institute of Electrical Engineers and a Charter Member of the Washington Society of Engineers. He took a great interest in civic and charitable organizations. He was a Director of the Washington Board of Trade and President of the Roman Catholic Charities of Washington. Mr. Weller was greatly interested in the Community Chest work and just before his death was made a Vice-President of the Washington Community Chest. His active work in the Washington Board of Trade and his engineering training gave him the Chairmanship of the Water Supply Committee of that body and through it he was instrumental in bringing about the present improved conditions of the Capital City's water supply.

Mr. Weller was a member of a great many social organizations and clubs in Washington, among which were the Knights of Columbus, the University Club, the City Club, the Rotary Club, the Racquet Club, the Congressional Country Club, and the Columbia Country Club. At the time of his death he was a Director of the East Washington Savings Bank and the Federal American National Bank. He was also a director of Edmonds Art Stone Company and the Washington Wimsatt Company.

In 1911, he was married to Sallie A. Harlow, of Alexandria, Va., by whom he is survived. He also left four children, Francis Harlow, Sallie Rita,

Richard Hartman, and George Harlow Weller. Mr. Weller was always a devoted family man, and he took a great interest in his summer home which was located at Buena Vista, Pa.

He occupied the position of an outstanding citizen in the City of Washington and was greatly interested in questions pertaining to it and especially to its charity work. His passing was mourned by thousands of friends and especially by the poor and needy whom he had helped so often.

Mr. Weller was elected a Junior of the American Society of Civil Engineers on February 5, 1901; an Associate Member on November 1, 1905; and a Member on April 30, 1912.

BERTRAND THORP WHEELER, M. Am. Soc. C. E.*

DIED MARCH 20, 1928.

Bertrand Thorp Wheeler was born in Lempster, N. H., on November 25, 1863, the son of Daniel Bingham and Maria Wheeler. His boyhood days were spent in Cambridge, Mass., where he attended the public schools until he reached the age of 15. In 1879, he entered Dartmouth College at Hanover, N. H., where he took a scientific course, and was graduated in 1884 with the degree of Bachelor of Science.

Mr. Wheeler's first employment was in 1885 as Rodman with the Old Colony Railroad Company, now part of the New Haven System. In 1886, he was made First Assistant to the Chief Engineer of the "Old Colony", which position he held until 1895. During this period he had charge of second-track construction, grade separation, and other minor work. He originated and promoted the plans for separation of grades at West Fourth Street, Boston, Mass., involving a new bridge over Fort Point Channel which was among the first works of this character accomplished in Massachusetts.

From 1895 to 1896, and from 1900 to 1901, Mr. Wheeler held the office of Superintendent of Streets for the City of Boston under the Republican administrations of Mayors Curtis and Hart, making a splendid record in this onerous position. He was engaged in private practice from 1896 to 1900.

In 1902 he entered the service of the New York, New Haven, and Hartford Railroad Company as Assistant Engineer of Construction, which position he held until 1907, when he was made Engineer of Construction. During this period he had charge of the work in connection with the elimination of grade crossings at Dudley Street, and Savin Hill to Neponset (Boston), Hyde Park, Attleboro, Worcester, and other points.

From 1910 to 1912, Mr. Wheeler was also Engineer of Construction of the Boston and Maine Railroad Company. On November 1, 1912, he severed these connections and accepted the office of Chief Engineer of the Maine Central Railroad Company (succeeding the late Mr. T. L. Dunn), taking up his residence at Portland, Me. He was also Chief Engineer of the Portland Terminal Company, a subsidiary of the Maine Central. In this position he was responsible for the condition of right of way and structures on more than 1 100 miles of road, for property valued at nearly $50 000 000, and at times he had more than 3 500 men working under his direction.

During his service as Chief Engineer of the Maine Central Railroad, the line was extensively modernized and many new structures were created under his direction, some of the more notable of which were the double-tracking of the main line between Clinton and Waterville, Me., the erection of railway bridges across the Kennebec River at Augusta and Fairfield, and the construction of the Rigby Terminal Yards, in South Portland, Me.

Mr. Wheeler was a man of brilliant intellect, sound sense, and good judgment, possessing a rare faculty of analyzing a problem or looking over a plan and intuitively picking out any flaws it might contain. He was noted for

* Memoir prepared by A. H. Morrill, M. Am. Soc. C. E.

the courage of his convictions and would stand by his guns under fire. His intolerance of incompetency, the bluntness and directness of his judgments, and his ever-constant desire for results often caused him to be misjudged by those who did not know him intimately. His associates and employees could see farther than the rather brusque exterior of the man, recognizing and prizing his uniform and constant justice, impartiality, and loyalty. Among them the feeling of sadness for a friend departed is tempered by the thought that his work and his memory will long endure.

Mr. Wheeler had not been in the best of health for two years previous to his death. On February 22, 1928, he was operated on for sinus and antrum trouble at the Maine Eye and Ear Infirmary, in Portland. Although he rallied from the operation, the respite was brief and he failed gradually, passing away on March 20.

In 1888, he was married to Mabel Cole, the daughter of George H. Cole, proprietor of the American House, at Fitchburg, Mass., by whom he is survived. He also left six children, Bertrand C. Wheeler, of Chicago, Ill., Allan T. Wheeler, of Wellesley Hills, Mass., Donald B. Wheeler, of Buffalo, N. Y., Mrs. Warren B. King, Mrs. Theodore K. Thurston, and Miss Ruth Wheeler, of Portland. Mr. Wheeler was always a devoted family man and took great interest in his summer home which was beautifully located on Great Diamond Island in Casco Bay, near Portland.

He was a member of the Boston Society of Civil Engineers, the Dartmouth Club of Boston, and the Massachusetts Society of Colonial Wars and Sons of the American Revolution.

Mr. Wheeler was elected a Member of the American Society of Civil Engineers on June 30, 1910.

NISBET WINGFIELD, M. Am. Soc. C. E.*

DIED FEBRUARY 24, 1928.

Nisbet Wingfield was born at "Cloverdale", the summer home of his family, in Dade County, Georgia, on September 23, 1861, the second son of Alfred and Julia (Lea) Wingfield. He attended the University of Mississippi and also the University of Tennessee from which he was graduated in 1880.

Immediately upon his graduation he engaged in railroad engineering, continuing in that field on various railroads in the South until January, 1885, when he went to Chattanooga, Tenn., as Chief Engineer of the Water-Works. He remained in Chattanooga until 1895, when he removed to Atlanta, Ga., where he made his headquarters while engaged on the design and construction of water-works and sewerage projects at various places.

In 1898, he was called to Augusta, Ga., to take charge of the enlargement of the City Water-Works, and, later, became City Engineer and Commissioner of Public Works, holding this position until 1919, when he engaged in private practice as Consulting Engineer. While City Engineer of Augusta, Mr. Wingfield planned and constructed a system of levees for the protection of the city against the flood waters of the Savannah River. This was the outstanding achievement of his career, and will serve as a monument to him. The *Augusta Chronicle*, speaking editorially, stated:

"The security of the city against flood waters has been proven time and time again and Nisbet Wingfield was the man who suggested a levee, who planned it, supervised its construction, and its success is too well known to need accentuating".

He also planned levees for Chattanooga and for West Point, Ga.

Among the projects constructed by Mr. Wingfield are several bridges in various parts of the South, including the Archibald Butt Memorial Bridge, at Augusta, a structure of pleasing architectural design, as well as the water-works at Augusta, Montgomery, Ala., Meridian, Miss., Greenwood, S. C., and a number of smaller cities. As a Consulting Engineer he was widely known throughout the Southeast and his opinion was sought on many large projects. During the World War he was retained by the Government as Project Engineer on the construction of Camp Hancock at Augusta, and on the housing project which was commenced for the enlargement of the Navy Yard at Charleston, S. C. At the time of his death, he was Consulting Engineer for the Savannah River Electric Company, in connection with this Company's proposed hydro-electric development of the Savannah River above Augusta.

Mr. Wingfield was a man of charming personality, kind and courteous to all men; cultured and polished, a delightful companion to old and young; and a man of unimpeachable integrity. His friend, Thomas Barret, former Mayor

* Memoir prepared by James Houstoun Johnston, James J. Gaillard, and James E. Parker, Members, Am. Soc. C. E.

of Augusta, said of him that he was "a golden-hearted gentleman, an honest public official, and one of America's really great engineers; an entire city deplores his passing".

Mr. Wingfield loved his profession and was ever an honor to it. Broad-minded and liberal, he was always strict yet perfectly fair in all his dealings with those with whom he worked. The Society, in which he was always active and, in particular, the Georgia Section, in which he also took a lively interest and had served as Vice-President, have lost a valued member, and those who had the pleasure of his acquaintance and his professional association keenly regret his passing.

Mr. Wingfield was elected a Member of the American Society of Civil Engineers on May 1, 1895.

ANDREW LEWIS ACKHART, Assoc. M. Am. Soc. C. E.*

DIED MARCH 11, 1928.

Andrew Lewis Ackhart, the son of Nathan and Eva (Deyo) Ackhart, was born at Clintondale, N. Y., on April 3, 1887. He received his preliminary education in the schools of Highland and Poughkeepsie, N. Y., and, later, attended Cornell University at Ithaca, N. Y., from which he was graduated on June 22, 1911, with the degree of Civil Engineer. He supported himself at the University as a pioneer salesman of aluminum cooking utensils and by other activities.

Mr. Ackhart's first engineering engagement was as Inspector with the Farris Engineering Company, of Pittsburgh, Pa., on a concrete substructure for a 970-ft. highway bridge, which occupied his time from November, 1911, to January, 1912. Subsequently, from January to October, 1912, he held the position of Rodman and Instrumentman on extensive stadia topographical surveys with the Costa Rica and Panama Boundary Arbitration Commission.

In February, 1913, Mr. Ackhart accepted a position with Mackenzie, Mann, and Company of Toronto, Ont., Canada, in which he had charge of the design of concrete bridge foundations, retaining walls, and culverts for the Canadian Northern Ontario Railway. In May, 1913, he entered the employ of James McAlear, of Toronto, as Draftsman on heating, lighting, and ventilating installation for office buildings, hospitals, schools, and factories. From July to August, 1913, he was engaged as a Draftsman by J. H. Trommanhauser, of Toronto, on the design of machinery for a grain elevator for the Quebec Harbor Commission.

In September, 1913, Mr. Ackhart returned to Mackenzie, Mann, and Company, where he served until January, 1915, as Assistant Superintendent on the construction of round houses, machine shops, pumping stations, and all other division buildings at Fitsback, Ont., Canada. His work also included the construction of tanks, and a section house, along 100 miles of the Canadian Northern Ontario Railway.

From April to June, 1915, he had charge of the construction of a private water supply and sewerage system at Clintondale, N. Y. Having been refused for service in the Army, because of a defective eye, he "did his bit" as a Head Inspector of 4½-in. shells at various munition plants throughout Ontario, for the Canadian Inspection and Testing Laboratory, Limited. From June to December, 1916, he was engaged by the Buffalo Construction and Equipment Company, of Buffalo, N. Y., in charge of 4 miles of a catenary tower concrete foundation, and bridge abutments and culverts for the International Railway Company. During January and February, 1917, he served as Draftsman with the Castner Electrolytic Alkali Company, of Niagara Falls, on structural steel design and machinery layouts; and from February to October, 1917, as Draftsman with the Hooker Electro-Chemical Company, of Niagara Falls, on the design of a pump-house and intake for a pumping station with

* Memoir prepared by Ernst G. Kaufmann, Assoc. M. Am. Soc. C. E.

a daily capacity of 24 000 000 gal., as well as on plant extension design and a complete design for the extension of hydrogen installation.

On October 8, 1917, Mr. Ackhart accepted the position of Assistant Engineer with the Eastern Concrete Steel Company, of Buffalo, where he had responsible charge of estimates. It was during this time that he supervised the erection of the New York Central Railroad Express Station and other structures, which consisted of a grade-crossing viaduct, a concrete building, etc.

In 1919, he was engaged by The Boldt Construction Company, of Cleveland, Ohio, as Engineer and Estimator, and he held this position until his death on March 11, 1928.

On April 29, 1922, Mr. Ackhart was married to E. Louise Haner, who with two daughters, Sally Louise and Barbara Lucille, survives him.

Mr. Ackhart was a Knight Templar, a Shriner, and a Thirty-second Degree Mason, holding a great respect for this Order, of which he was a staunch supporter.

A man greatly admired and honored, he had a good word for all with whom he came in contact. He was a diligent worker and possessed a strong, magnetic personality.

Mr. Ackhart was elected a Junior of the American Society of Civil Engineers on March 4, 1913, and an Associate Member on September 10, 1918.

FREDERICK BAIRD ADAMS, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 13, 1926.

Frederick Baird Adams was born on March 6, 1875, at Reading, Pa., the son of E. Ralph and Loretta (Loag) Adams. His education was acquired in the public schools of Reading.

In September, 1893, Mr. Adams entered the service of the Philadelphia and Reading Railway Company as Rodman, and in March, 1894, he accepted a position in the same capacity with Mr. W. H. Dechant, of Reading. From September, 1894, to June, 1895, he was a student of civil engineering at the University of Pennsylvania, following which he became Timekeeper with Mr. O. N. Wieand, on the construction of heavy masonry walls and foundations at Reading.

From January, 1896, to May, 1897, Mr. Adams served as a Clerk in the Maintenance-of-Way Department of the Philadelphia and Reading Railway Company. In 1897, he was engaged as a Transitman for the City of Reading in charge of sewer and other municipal work. Subsequently, he was appointed Engineer in charge of the construction of house sewers for the City of Reading, which position he held until April, 1900.

In July, 1900, Mr. Adams accepted a position as Assistant Supervisor for the Philadelphia and Reading Railway Company and, in December, he was appointed as Supervisor at Shamokin, Pa. In March, 1910, he was transferred to Pottsville, Pa., and on November 1, 1925, he was made Supervisor at Reading, which position he held at the time of his death.

He was a remarkably fine type of man, fond of his home and family, and active in his affiliation with the Protestant Episcopal Church. He was very popular with his business associates. He was always attentive to his duties, and showed considerable energy and capacity for work. He was particularly successful in the construction of the trackage in the Saint Clair Yards of the Reading Company, in 1910, and for several years thereafter. His general characteristics were those of a student, and he specialized at one time in bridge design.

He died on November 13, 1926, at the Homeopathic Hospital, in Reading, after a brief illness.

Mr. Adams was married on October 6, 1903, to Lulu G. Felix, of Reading, who survives him.

He was a member of the American Railway Engineering Association, the Engineers' Society of Pennsylvania, and a Certified Member of the American Association of Engineers.

Mr. Adams was elected an Associate Member of the American Society of Civil Engineers on August 31, 1925.

* Memoir prepared by John S. Goodman, M. Am. Soc. C. E.

HIRAM ELLSWORTH BALDWIN, Assoc. M. Am. Soc. C. E.*

DIED APRIL 16, 1927.

Hiram Ellsworth Baldwin was born in Youngstown, Ohio, on May 2, 1862, the son of George Simeon Baldwin and Hannah (Grey) Baldwin. Both parents were of sturdy American pioneer stock and spent their lives in Youngstown and the neighboring town of Niles, Ohio.

Mr. Baldwin's early education was obtained in the public schools of Niles. Following his steadfast boyhood desire for an engineering training, he entered the Massachusetts Institute of Technology, graduating therefrom in the Class of 1890 with the degree of Bachelor of Science.

Immediately following his graduation, he secured employment with The Brown Hoisting Machinery Company, of Cleveland, Ohio. His choice of this Company was a deliberate one, as he was greatly impressed with the developments then being carried on in machinery for the handling of ore and coal by Mr. Alexander E. Brown, the inventor. Mr. Brown had drawn around him a brilliant staff of young engineers, many of whom were to make names for themselves in later years. Mr. Baldwin was placed at once in the Engineering Office and his advance was rapid. While with this Company he not only achieved splendid success in the office, but also was sent on important engineering and erection work in Europe as well as in the United States. An especially notable accomplishment was the installation, under his direction, of the 100-ton capacity, balanced crane on the *Hercules*, of the U. S. Navy, the largest floating crane at that time.

He was appointed Chief Engineer of Special Work by The Brown Hoisting Machinery Company, and under his supervision came many developments in machinery for the rapid and economical handling of ore, coal, limestone, and other materials. Furnace hoists, bins, larries, locomotive cranes, overhead cranes, trollies, etc., were also designed and developed.

Mr. Baldwin left The Brown Hoisting and Machinery Company in 1908, and became identified as Chief Engineer with The Variety Iron Works Company, of Cleveland, Ohio. In this capacity, his work was of a most varied character, including the design of furnace hoists, open-hearth furnaces, ore and coal bins, as well as general structural steel work.

During the World War period he was instrumental in designing and building much important work for the United States Army and Navy, on which he labored indefatigably to the detriment of his health.

He resigned his position with The Variety Iron Works Company in 1922, to become Chief Engineer of The Brown Hoisting Machinery Company, with which he remained until ill health compelled him to resign. His death occurred on April 16, 1927; interment was at his boyhood home in Niles.

Mr. Baldwin was married on September 19, 1893; he had three children, one girl and two boys. One son was killed in action in the Argonne during the World War. Mr. Baldwin's widow, two children, and a sister, Lida F. Baldwin, survive him.

* Memoir prepared by E. C. Pierce, Esq., Cleveland, Ohio.

He was a member of the Cleveland Engineering Society, the National Aeronautic Association, the Cleveland Chamber of Commerce, and the Chagrin Valley Country Club.

He had a strong and forceful character, and was beloved by his friends and respected by all with whom he came in contact. His was a keen and analytical mind, and his work in his chosen profession was always well done and frequently most brilliant. His loss is a distinct one.

Mr. Baldwin was elected an Associate Member of the American Society of Civil Engineers on January 2, 1895.

HOWARD PAUL BAYLY, Assoc. M. Am. Soc. C. E.*

DIED AUGUST 22, 1927.

Howard Paul Bayly was born October 22, 1884, in Washington, D. C. He was educated in the public schools in the District of Columbia, and was graduated from McKinley Manual Training School in 1903. He received the degree of Bachelor of Science in Civil Engineering from the George Washington University in 1912. In connection with his school and college activities, it should be mentioned that Mr. Bayly took a prominent place in the field of athletics in support of his class interests. He was President of the Engineering Group in his graduating class, and was a member of the Sigma Phi Epsilon Fraternity and President of the Local Chapter. After graduation he followed the development of these same characteristics and held a prominent place in both business and social activities.

Mr. Bayly had varied experience in engineering work of a laboratory nature with Mr. Emile Berliner, in connection with the perfecting of phonograph records, in the United States and Canada. After his graduation from George Washington University he was connected with the Southern Railway Company in construction and engineering work, in charge of its transfer yards at Spencer, N. C., and other important projects in the central southern section of the country. For a time he was Assistant Engineer, with headquarters in Richmond, Va.

In 1918 he left the employ of the Southern Railway Company and joined a contracting firm, Saville and Claiborne, of Richmond. In connection with this firm's work, he was in charge of the residential development which it was carrying on, and he was also engaged in water-works and sewage disposal projects for a number of small cities in Virginia.

With the entry of the United States into the World War, Mr. Bayly was placed in charge of a part of the construction of the cantonment at Camp Lee. Following the completion of this very important project, he was in charge of the DuPont de Nemours housing and industrial project at Hopewell, Va. After the closing of the war projects, Mr. Bayly returned to the building industry in Richmond in association with the firm of Claiborne and Taylor, Contractors, enlarging his activities to include all branches of construction work.

In 1923, he left the firm and engaged in business for himself, confining his activities principally to the very best grade of residences and to more important individual projects rather than to general development work.

Mr. Bayly was married on May 7, 1914, to Alice Burritt, of Washington, D. C., who survives him.

He was a member of Dove Lodge No. 10, A. F. and A. M. The news of his sudden death on August 22, 1927, was keenly felt by his many friends and associates.

Mr. Bayly was elected an Associate Member of the American Society of Civil Engineers on April 16, 1918.

* Memoir prepared by William S. Gordon Dulin, Esq., Charleston, W. Va.

MERLIN CROSS CRAWFORD, Assoc. M. Am. Soc. C. E.*

DIED FEBRUARY 11, 1928.

Merlin Cross Crawford was born at Chilton, Tex., on August 21, 1889, the son of William B. and Alice Crawford.

He was graduated from the University of Texas at Austin, Tex., in 1912, with the degree of Bachelor of Arts, and in the following year received the degree of Electrical Engineer.

Mr. Crawford's first work after leaving the University was in the Testing Departments of the General Electric Company at Schenectady, N. Y., and Pittsfield, Mass. After having served a year with this Company he returned to his native State, where the work of reclaiming lowlands by drainage ditches and levees constructed by dragline excavators was in its infancy and where the construction of highways was creating a demand for gravel. Although he had been educated as an Electrical Engineer, Mr. Crawford foresaw the enormous amount of reclamation work in prospect and decided to cast his lot into that engineering field. He therefore joined the forces of Callahan and Crawford in the operation of gravel properties in South Texas.

His next position was with the W. E. Callahan Construction Company at Ennis, Tex., in the capacity of Superintendent in charge of a large number of reclamation projects, including parts of two of the largest projects in the State, namely, the Storage Dam near Seymour, built for the Wichita Falls Water Improvement District No. 1, and the Garza Dam, built for the City of Dallas. This connection continued until 1927, when he entered business for himself. At the time of his accidental death on February 11, 1928, which resulted from a fall from a hotel window in San Antonio, Tex., he was engaged in the beginning of his largest individual contract—the erection of the steel in the thirty-two story Smith-Young Tower.

Had it not been for his untimely death, Mr. Crawford would undoubtedly have made for himself, in an even greater degree, a record for achievement, as he possessed to a remarkable extent the qualities that make for success in the construction and engineering world. His energy was unbounded and he had the happy faculty of being able to build up an organization that was ever ready, through a spirit of unfaltering loyalty, to give to him the same whole-hearted support that he had always given to his employers. His cheerful, genial personality, and his unswerving devotion to his friends made him an always welcome addition to any group.

He was a member of Hella Temple, of Dallas, and the Dallas Athletic Club. He was also a member of Sigma Alpha Epsilon Fraternity.

Mr. Crawford was married in June, 1917, to Jean Figh, of Dallas, who survived him only one month. He left, in addition to his widow, two daughters, Jean and Patricia.

Mr. Crawford was elected an Associate Member of the American Society of Civil Engineers on May 8, 1922.

* Memoir prepared by E. S. Heyser, Assoc. M. Am. Soc. C. E.

CHARLES KENNETH CURRY, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 17, 1927.

Charles Kenneth Curry was born on April 15, 1895, at Jackson, Mich., the son of the Rev. and Mrs. E. R. Curry. The family lived for a time in Jackson and also in Flint, Mich., when Mr. Curry answered a call in New Jersey. From New Jersey they went to Omaha, Nebr., where Charles Kenneth Curry was graduated from High School in 1913. He entered the University of Colorado the following September, and received the degree of Bachelor of Science in Civil Engineering in 1917.

A few months later, Mr. Curry enlisted in the Army and went to France with an artillery regiment. He served in five major engagements when his superior officers recognized his ability and he was sent to the Engineer Officers School at Langres, France. From this school he received a commission as Second Lieutenant in the Engineer Officers Reserve Corps. When the Armistice was signed he was sent into Germany with the Army of Occupation. He afterward entered the University of Nancy where he studied for four months.

On his return to the United States in September, 1919, Mr. Curry was engaged as Draftsman with the American Bridge Company at Gary, Ind., for a short time until a better opportunity was presented by the Robins Conveying Belt Company, Chicago, Ill., with which he was associated until 1921. In 1921, he was employed by Allen and Garcia Company, of Chicago, and his work with this firm, both in the office and in the field, was attended with success. He spent some time in Mexico on construction work at a coal mine. In 1927, he was sent to Price, Utah, by his Company to assist in putting into operation a coal tipple which he had designed. While engaged on this work he was stricken with appendicitis and died on September 17, 1927, following an operation.

As an engineer Mr. Curry's success seemed assured. He was only thirty-two years old at the time of his death, but he had laid an unusual foundation for his work and had accomplished that which would do credit to a much older man. He was practical and possessed as well a good working knowledge of theory. He had executive ability and men liked to work with him. He was a man of high ideals and charming personality.

On August 28, 1926, Mr. Curry was married to Mary Allen, of Chicago, who survives him. He was a member of the Hyde Park Baptist Church.

Mr. Curry was elected an Associate Member of the American Society of Civil Engineers on October 1, 1926. He was also an Associate Member of Western Society of Engineers.

* Memoir prepared by T. E. Lutz, Esq., Chicago, Ill.

ROBERT WAITE DAVIS, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 18, 1927.

Robert Waite Davis, the son of Thomas Burt and Alice Elizabeth (Finch) Davis, was born in Wartrace, Tenn., on January 16, 1890, of Welsh ancestry. He was educated in the public schools and later attended and was graduated from the Branham-Hughes Military Academy, at Spring Hill, Tenn., in 1906. He afterward worked for several years before entering the University of Tennessee, from which he was graduated in 1918.

Mr. Davis began his engineering career in 1907 as Rodman, Chainman, Mapper, etc., on land surveys. From March, 1909, to January, 1910, he was employed as Surveyor, Rodman, Concrete Inspector and Tester on lock and dam construction for the War Department, U. S. Engineer Office. From January to September, 1910, he was Assistant to the Construction Foreman, Instrumentman, and Material Chaser on plant construction for the Tennessee Coal, Iron, and Railroad Company. In 1915, he returned to that Company as Instrumentman and Temporary Chief of Party on mineral land surveys.

In December, 1915, Mr. Davis accepted a position with the Nashville, Chattanooga and St. Louis Railroad Company as Office Assistant to the Location Engineer, also acting as Draftsman, Computer, etc. He held this position until September, 1916. From June to September, 1917, he was engaged as Draftsman in the office of the Louisville and Nashville Railroad Company in Louisville, Ky.

In the fall of 1917 and spring of 1918 Mr. Davis finished his education at the University of Tennessee and immediately upon his graduation in June, 1918, he joined the U. S. Coast Guard and, later, was transferred to the Engineer Officers' Training Camp, at Camp Humphreys, Virginia, where he remained until the Armistice was signed. He was honorably discharged from the Service in December, 1918.

In April, 1919, Mr. Davis accepted a position as Resident Engineer on railroad construction with the Cuyamel Fruit Company, in Honduras, Central America. He remained in this position until October, 1919, at which time he returned to the United States. In January, 1920, he again went to Honduras and until October of that year, acted as Resident Engineer and Locating Engineer on railroad construction and location for the Cuyamel Fruit Company.

After Mr. Davis returned to the United States in October, 1920, he accepted a position as Resident Engineer on highway construction with the Louisiana Highway Commission. His first assignment was on the construction of the Federal Aid Highway between Covington and Slidell, La. This project was completed in 1921; and he was then sent to Mansfield, La., as Resident Engineer on the Evelyn-Mansfield Highway, which was completed in 1922. Each of these two projects involved grading, drainage, structures, and gravel surfacing on approximately twenty-five miles of highway. After the disastrous floods in the Mississippi Valley in the spring of 1922, Mr. Davis was sent to

* Memoir prepared by N. E. Lant, M. Am. Soc. C. E.

Poydras, La., a short distance below New Orleans, where the levees and highway had been destroyed by the Poydras Crevasse. He superintended the rebuilding of the highway at this location, the work being done on a day-labor basis and under great difficulty, due to the wet weather and heavy traffic.

Due to exposure at Poydras, Mr. Davis suffered a recurrence of tropical fever which he had contracted in Honduras. As a result of this he spent several months in the fall of 1922 at Hot Springs, Ark., trying to regain his health. In November, 1922, after recovering his strength somewhat, he returned to the Louisiana Highway Commission, at Baton Rouge, and worked in the office as Checker and Computer during the winter. In the spring of 1923, he asked to be placed on construction work again and was sent to Slidell, as Resident Engineer on the Federal Aid Highway project, extending from Rigolets, La., to Slidell and from Pearl River Station, La., to the Mississippi State line. Each of these sections was approximately six miles long. The work at Slidell required Mr. Davis to be in the swamps and marshes practically every day, both sections of this road being through a virgin country without a trail of any kind over which to drive. Considerable relocation was necessary on the northern section, from Pearl River to the Mississippi State line, and this was all carried on with dispatch and accuracy. In the spring of 1925, contracts were let for the bridges over the East Pearl and West Pearl Rivers, and as the highway construction which Mr. Davis had in charge was rapidly approaching completion, he was given charge of the construction of these two bridges, both of which were steel truss bridges on concrete piers.

Mr. Davis continued in charge of the highway and bridge construction at Slidell until August, 1925, when due to ill health he was unable to continue this work. He was given a furlough and lived at Slidell several months before moving to Birmingham, Ala., where he died of a combination of tropical diseases and inflammatory rheumatism on November 18, 1927.

Mr. Davis was a careful and accurate engineer, fully investigating all details of each problem which presented itself to him. On highway location and construction, his notes and records were always complete and reliable. His sickness and death proved a great loss to the Louisiana Highway Commission and to his fellow employees.

He was a member of the Slidell Lodge of Masons, and of the American Geographical Society. Although he was not affiliated with any church, Mr. Davis had a strong Christian character and high moral standards.

He was married in 1924, to Constance Osborne, who, with one child, a daughter, is now living in Louisville.

Mr. Davis was elected an Associate Member of the American Society of Civil Engineers on November 21, 1921.

JOSEPH FRANCIS SINNOTT DONNELLY, Assoc. M. Am. Soc. C. E.*

DIED MARCH 5, 1926.

Joseph Francis Sinnott Donnelly was born in Philadelphia, Pa., on March 25, 1884. He was the sixth son of James A. Donnelly and Marguerite A. (Pope) Donnelly, both of whom were born in Philadelphia.

After graduating from the Central High School in 1902, he entered the Towne Scientific School of the University of Pennsylvania, receiving the degrees of Bachelor of Science and Master of Science in 1906 and 1907, respectively. While at College, he was a member of the Plumb Bob, the Civil Engineering Society, and the Newman Club, and, after his graduation, he became affiliated with the General Alumni and Civil Engineering Associations, and the University of Pennsylvania Club of New York.

During the summer of 1906 Mr. Donnelly was employed as Inspector by the American Dredging Company, of Philadelphia. On the completion of his college work in 1907 he entered the employ of the American Bridge Company at its plant in Elmira, N. Y., as he had decided that structural engineering offered the most compatible field to him. In Elmira, he went through the preliminary stages of office work on structural design—tracing, detailing, etc.—remaining there until early in 1909, when he left to work on layout plans for the American Heating and Ventilator Company, of Philadelphia.

Later, in the same year, Mr. Donnelly accepted a position with the New York Central and Hudson River Railroad Company as Draftsman in the Office of the Engineer of Structures, Exterior Lines. He remained in this position about four years, detailing, designing, and checking plans of railway structures of various kinds.

In 1913, he accepted a position with the Cuba Railroad Company at Camaguey, Cuba, becoming, in turn, Chief Draftsman, Bridge and Building Engineer, and Office Engineer, which last named position he held at the time of his death.

The greater part of the thirteen years during which he was associated with the Cuba Railroad Company (which later became the Consolidated Railways of Cuba) was spent in Cuba. He also served for a time in the New York Office of the Company checking plans of structures for a new branch line and for new shop buildings. He was active in military service during the World War and was commissioned a First Lieutenant of Engineers, doing training and camp service.

During the time spent in Cuba, Mr. Donnelly was placed in charge of many important works of varied character. Extensions and branch lines were built, requiring new structures; lines were acquired, which also necessitated new, remodeled, and strengthened structures; and consolidation with the Cuba Northern Railway added greatly to the duties and responsibilities of his position.

* Memoir prepared by R. F. Patterson, Esq., Camaguey, Cuba.

Mr. Donnelly filled his several positions with the Cuba Railroad Company and elsewhere with marked ability which was attested by his steady advancement under each employer. His never-failing cheerfulness and tact, and his willingness to help other departments, as well as branches of his own, were highly appreciated by his employers and fellow workers alike.

He was a member of the American Railway Engineering Association and an organizer and Charter Member of the Knights of Columbus, of Camagüey, Cuba.

On December 27, 1919, Mr. Donnelly was married to Meta Jean Apeldorn, of Philadelphia, who, with two children, Ida Marguerite and Joseph Apeldorn, survives him.

Mr. Donnelly was elected an Associate Member of the American Society of Civil Engineers on August 31, 1915.

GUY BANKER EDWARDS, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 4, 1927.

Guy Banker Edwards, the son of Dr. John Edwards and Myra (Banker) Edwards, was born at Gloversville, N. Y., on April 6, 1875. His boyhood years were passed in Gloversville, where he received his education in the public schools. He then attended the Clinton Liberal Institute at Fort Plain, N. Y. After his graduation from this preparatory school, he attended Philips Academy at Andover, Mass., and, later, continued his studies in Civil Engineering at Union College, Schenectady, N. Y., from which institution he was graduated in 1895.

From 1895 to 1906 Mr. Edwards held the position of Inspector of Public Works or Assistant Engineer at Gloversville. From 1906 to the spring of 1909, he was employed as Construction Engineer and Superintendent with Townsend and Fleming, Landscape Architects, of Buffalo, N. Y. During this time he was in charge of important and extensive landscape construction programs on a number of large private estates.

In 1909 he entered the employ of Mr. Warren H. Manning, Landscape Architect, in Boston, Mass. During his association with Mr. Manning he was in charge of large private estate construction work. In October of that year and during 1910, he was employed in the operation of stone quarry and stone sawing plant.

From April to December, 1911, Mr. Edwards was Resident Engineer of the Iowa Engineering Company at Clinton, Iowa, in which position he was in charge of asphaltic concrete paving and sewer system and disposal plant construction. He later accepted a most important position with F. A. Barbour, M. Am. Soc. C. E., of Boston, and E. G. Bradbury, M. Am. Soc. C. E., of Columbus, Ohio, as Resident Engineer in charge of extensive water supply developments, including a large distributing reservoir for the City of Akron, Ohio.

From July, 1915, to June, 1916, Mr. Edwards was Supervising Engineer on sewage and garbage disposal plant construction at Akron, for the late R. Winthrop Pratt, M. Am. Soc. C. E., Construction Engineer, of Cleveland, Ohio. Immediately following this engagement he accepted a position as Resident Engineer for the Cleveland and Youngstown Railroad Company in charge of important construction work, and from September, 1921, to September, 1923, he was employed by Mr. A. D. Taylor, of Cleveland, in charge of general construction work and as Resident Engineer on several housing developments in the Gogebic Range of Northern Michigan.

From September 1, 1923, to the time of his death, Mr. Edwards was in the employ of the Oglebay-Norton Company as Efficiency Engineer. The work for which he was responsible during the last two or three years was as follows: Insurance, safety, welfare and housing problems for iron ore mines under the

* Memoir prepared by Albert D. Taylor, Landscape Archt., Cleveland, Ohio.

Oglebay-Norton Company management, at the Montreal, Ottawa, Eureka-Asteroid, Berkshire, Bristol, and Feigh Mines.

During his work as a Civil Engineer, Mr. Edwards exhibited sterling qualities of mature manhood and profound knowledge of his field of activity. No one in the Engineering Profession who came in contact with him had other than the highest respect for his engineering ability, his seriousness of purpose, his principles of honesty, and the consistent application of his physical and mental energy to the completion of the tasks for which he was made responsible.

Mr. Edwards was elected an Associate Member of the American Society of Civil Engineers on March 13, 1917.

JOHN MARTYNN GRENFELL EDWARDS, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 24, 1928.

John Martynn Grenfell Edwards, the son of John and Lydia Edwards, was born in the small Cathedral City of Truro, Cornwall, England, on November 8, 1882. His father was an accountant, journalist, and artist, and was well known throughout the County of Cornwall for his work in connection with the Royal Cornwall Show. He was also a near relative of John Passmore Edwards, the well-known English journalist, newspaper proprietor, and philanthropist.

Mr. Edwards was one of seven children, he being the fifth. His father died at the age of forty-five when Mr. Edwards was ten years old. He received his elementary education privately, later attending the Truro Grammar School and the Redruth School of Mines. This was followed by a post-graduate course in Coal Mining in Wales where he won several prizes and a free scholarship for three years at the schools.

Before the completion of the mining course, the Boer War broke out, and he became a Trooper in Paget's Horse attached to the Imperial Yeomanry. He was seventeen at this time, and he received a four-bar medal, inscribed, "Cape Colony, Orange Free State, South Africa 1901—South Africa 1902".

On his return from the Boer War he found that a calamity had overtaken his family. His mother had befriended a poor woman who was dying from tuberculosis of the throat. Through the consequent infection, an only brother and three sisters died within a short period.

He resumed his studies at the mining school in Wales, and, in 1905, he accepted a position in India as Metallurgist with the Mysore Gold Mining Company. In 1908 he returned to England and worked as a Surveyor in a tin mine for the East Pool Mining Company, at Cornwall. A year later he went to the Rand, South Africa, to act as Surveyor for an underground development of the City Deep Gold Mining Company.

Mr. Edwards was engaged by the Messina Development Company, Limited, from 1910 to 1913 as Mine Surveyor, Chemist, and General Engineer in the development of a large high-grade copper mine at Messina, North Transvaal.

In 1913, he went to the West Indies as Superintendent for the Curacao Phosphate Company. He had charge of the installation of self-acting inclines and aerial ropeways, the construction of bins and wharves for shipping phosphates, the erection of buildings, machine shops, employers' houses, and native quarters, as well as the dredging of a channel from the sea to a lagoon which formed a natural harbor.

During the period of the World War, from 1915 to 1919, he accepted a commission as Lieutenant and, later, as Captain of a Tunneling Company in the Royal Engineers on the Somme. At different times on special work, he had charge of from 800 to 1 000 sappers. In the capture of Mont St. Quentin he was favorably mentioned in military dispatches by his superiors.

* Memoir prepared by L. A. Jenny, M. Am. Soc. C. E., and J. I. Leonard, Assoc. M. Am. Soc. C. E.

After the war, during 1919 and 1920, Mr. Edwards was associated with Professor Bernard W. Holman, of the Royal School of Mines, on research work in connection with the Cornish tin tailings. During this period, he did some prospecting in Spain on his own account.

The roving spirit still claiming him, he returned to Africa. For about a year he was Construction Engineer on some manganese property for the Dagwin Concession in West Africa, and for another year he was Irrigation Engineer for the Compagnie Générale des Colonies at Haut Senegal, West Africa. This Company was employed by the French Government to study the possibilities of the irrigation of the Niger Valley for the cultivation of cotton.

In 1924, Mr. Edwards went to South America, where he was employed as a Mining Engineer with the Poderosa Mining Company, in Chile, a concern engaged in the mining of copper. During the absence of the Manager for six months, Mr. Edwards was in complete charge of the mine. Remaining in South America, he later accepted an engagement with the Chile Exploration Mining Company supervising the construction of buildings and complete facilities for mining operations. Subsequently, during 1927, he worked on a hydro-electric development in Peru.

Early in 1928, Mr. Edwards went to New York, N. Y., and soon thereafter became associated with the valuation of the Interborough Rapid Transit Company. He was engaged on this work at the time of his death, on October 24, 1928, following an operation for appendicitis. He was buried with military honors in St. Michael's Cemetery, at Astoria, N. Y.

In 1919, he was married to Raymonde Helen Marie Louise Marguerite Vogues, daughter of M. Bertin Vogues, of Paris, France. M. Vogues was at one time Chargé d'Affaires in Chile and Minister of Instruction in Paris, as well as an editor of prominence and a proprietor of scientific journals in France.

Mr. Edwards was a capable engineer and held in high esteem by the members of his profession. Those with whom he came in contact were invariably impressed with his kindly and courteous bearing and his character as a gentleman. To know him was to respect him and increasingly admire his many virtues. He was a good friend, a faithful brother, and a dutiful son. He is survived by two sisters living at Carbis Bay, Cornwall, England.

Mr. Edwards was elected an Associate Member of the American Society of Civil Engineers on January 16, 1928.

FRANK ALEXANDER GIESTING, Assoc. M. Am. Soc. C. E.*

DIED APRIL 25, 1928.

Frank Alexander Giesting was born in San Francisco, Calif., on April 4, 1881. He was the son of Joseph G. Giesting and Clara Enneking Giesting. His youth was spent in the city of his birth, where he attended public and private schools until the end of his seventeenth year.

At that time, at the outbreak of the Spanish-American War, he enlisted as a private in the First California Heavy Artillery. Although perhaps the youngest member of his Company, he, even at that early age, exhibited such qualities of leadership that he arose almost immediately to the non-commissioned rank of Sergeant. He was chosen as a member of a small detachment from his Company to accompany the first Army Expedition to the Philippine Islands where he served with distinction until mustered out of the Volunteer Service in August, 1899.

In 1900 Mr. Giesting received a civil appointment in the Postal Department, at which time he returned to the Philippine Islands where he remained about two years. Resigning from the Postal Service in 1902, he returned to San Francisco and matriculated in the College of Civil Engineering of the University of California, Berkeley, Calif., at the beginning of the succeeding semester. He was graduated in May, 1906, with the degree of Bachelor of Science, and almost immediately began his professional career with the Progreso Mining Company at Triunfo, Baja California, Mexico, where he remained until July, 1907. At this time he was engaged for a short period as Transitman and, later, as Resident Engineer on construction for the Southern Pacific Railroad Company, then being built in Mexico.

In November, 1907, Mr. Giesting entered the service of the Mexican Light and Power Company, in which he acted first as Draftsman, then as Engineer and Superintendent on construction. It was during this engagement that he had complete charge of the construction of the famous Tanengo Tunnel (1 300 m. long) and the auxiliary works of this incline tunnel from Salto Chico to the power house. Coincidently, he was in charge of the 6 700-m. tunnel on the Laxaxalpan Diversion.

In July, 1912, he became General Superintendent for the engineering firm of Jacobs and Davies, Incorporated, which had taken over all the engineering work of the Mexican Light and Power Company, and served in that capacity until October, 1913. During the next two years he was engaged in private practice as Consulting Engineer in San Francisco.

From February, 1915, until April, 1917, he served as General Superintendent for the Aluminum Company of America in dam construction work at Alcoa, Tenn.

At the entrance of America into the World War, Mr. Giesting immediately resigned his position with the Aluminum Company and entered the Plattsburg Military Training Camp. His former military experiences, together with his obvious ability to lead men, resulted in his almost immediate transfer to the

* Memoir prepared by Alva F. Hughes, Min. Engr., New York, N. Y.

Training Camp for Engineers at Camp Humphrey, Va., from which he was graduated in the first class with the rank of Major of Engineers. His first assignment was at Camp Upton, Long Island, in the formation and building of which he gave prominent assistance. When the 302d Engineers of the 77th Division was formed, Major Giesting was assigned to that regiment. This regiment went overseas in March, 1918, and soon after its arrival in France, due to the promotion of his Senior Officers, he was made Lieutenant Colonel and given command of his Regiment. Under his leadership the 302d Engineers made an enviable record in the Argonne and were in the front line on Armistice Day. He had been given the rank of Colonel of Engineers and in that capacity returned to the United States with his Regiment in April, 1919, being mustered out of the service shortly thereafter.

After several months of rest, Colonel Giesting returned to the practice of his profession as General Superintendent of the Vanadium Corporation of America from 1920 to 1921, and, subsequently, with the Engineering Department of the National Carbon Company from 1922 to 1924. His next engagement was with the Delaware and Hudson Railroad Company with which he was connected from 1924 until 1926. From April, 1926, to the time of his death, he was in the service of the Port of New York Authority as Assistant to the Chief Executive Officer.

Colonel Giesting's outstanding qualities of leadership and organizing ability marked him as an exceptional member of the Engineering Fraternity. In going over his record it is interesting to recall that in his capacity as Resident Engineer for the Mexican Light and Power Company he had complete charge of the construction of what at that time was regarded as the longest incline tunnel in the world; and, further, as to his military record, that as far as is known he was the only Reserve Officer in command of a Combat Regiment of Engineers during the World War. In his character, he was quiet and unobtrusive, and always generous to a host of friends who mourn his passing. He was a great Engineer and a great Soldier.

Colonel Giesting was elected an Associate Member of the American Society of Civil Engineers on October 1, 1913.

CLARENCE MELROSE LARSON, Assoc. M. Am. Soc. C. E.*

DIED JUNE 9, 1928.

Clarence Melrose Larson was born on April 10, 1874, on a farm at Wauzeka, Wis., the son of L. C. and Mercy Celia (Dunning) Larson. When a small boy he moved with his family to Dakota and for several years, or until he was about ready for High School, attended a country school. He was graduated from the Preparatory College in Bridgewater, S. Dak., and then from the University of Washington at Seattle, Wash., in 1899, receiving the degree of Bachelor of Arts. While attending school in Seattle, Mr. Larson financed his expenses by working for the Third Street and Suburban Railway Company during the summers of 1898, 1899, and 1900. His work consisted of operating cars and assisting in the repair and maintenance of the cars and line.

In the summer of 1901 he assisted on the construction of a high-voltage transmission line for the Snoqualmie Falls Power Company and, subsequently, for ten months he was a Computer in the office of the City Engineer at Seattle, finally taking charge of office calculations for city street grading, paving, and the construction of the sewer and water system extensions.

In the summer of 1902 Mr. Larson was a Transitman on the preliminary survey for the construction of the Alaska Central Railway. In 1903, he moved to Madison, Wis., and entered the employ of the State of Wisconsin with the State Board of Assessments, as Assistant Inspector during a valuation of the property of the steam railroads of the State and a special investigation of land values and county records. At this time Mr. Larson took up engineering courses in the University of Wisconsin and, as before in Washington, financed his education by summer employment, and was graduated in June, 1905, securing the degree of Bachelor of Science in Civil Engineering. During this period he made surveys and estimates for park improvements for the Madison Park and Pleasure Drive Association.

As Assistant Resident Engineer for the National Railroad Company of Mexico, Mr. Larson was from March to August, 1905, in charge of maintaining about 500 miles of line, and constructing spurs. In March, 1906, he completed the construction work on eight miles of road, including a 446-ft. steel bridge with a 240-ft. steel arch, for the Cordoba and Huatasco Railway Company, Vera Cruz, Mexico.

Shortly thereafter Mr. Larson returned to Wisconsin and again entered the employ of the State as Assistant Engineer for the Board of Assessments and the Railroad Commission. He continued with these Departments which had charge of the valuation of railroads, street and interurban railroads, water, gas, electric, and telephone utilities, until 1909. In this year he received the degree of Civil Engineer from the University of Wisconsin.

In 1909 he again left the State employ to accept a position with the Chicago and Alton Railroad and the Toledo, St. Louis and Western Railroad Companies as Real Estate Engineer, which position he held until 1911. He then entered the employ of the New York Central Railroad Company as

* Memoir prepared by C. B. Hayden, Esq., Madison, Wis.

Engineer in field charge of the valuation of property and remained with this Company for eight months. Mr. Larson then returned to Wisconsin and again entered the employ of the State as Assistant Chief Engineer of the Railroad Commission and Tax Commission. He held this position until he was appointed Chief Engineer of the Railroad Commission in 1913 in which capacity he continued until his death.

On December 25, 1905, he was married to Mabel Claire Davenport, of Madison, Wis. He is survived by his widow, two sons, Philip and John, and a daughter, Elizabeth.

In the discharge of his regular duties with the Railroad Commission, Mr. Larson had complete charge of the valuations of the utilities and railroads of the State where rate matters were involved and also when security issues were sought. He also had under his general supervision the formulation and enforcement of the service and safety orders of the Commission.

From time to time he was a member of important organizations and committees having in charge matters of great public concern; he was, at the time of his death, a Member of the Transportation Survey Committee of Milwaukee, Wis., and of the Board of Directors of the Provident Building and Loan Association. He had also retired from a local Traffic Committee shortly before his last illness. He took an active part in all matters relating to the Engineering Profession and was a Past-President of the Technical Club of Madison.

Mr. Larson had a modest, unobtrusive nature. Loved by all who knew him, he was ever cognizant of merit in others, but always reluctant to assume or accept honor or preferment. His capacity for work was enormous, and he was always fully equal to any task which he might accept. Keen of intellect and unusually observant of detail, he seldom failed to cover completely and sift thoroughly the most involved and trying problems, and when it was necessary to recall the details of a question which might not have been considered for a long time, perhaps not in years, he could depend on his memory to produce the facts. His ability was recognized at the University of Washington when he was elected to Phi Beta Kappa.

Mr. Larson delighted in music, and was for years a member of the Mozart Men's Chorus; he was quite a linguist, having a general knowledge of Spanish, French, Norwegian, and German. He was a Thirty-second Degree Mason and a member of the Shrine. He was also a member of the Phi Gamma Delta Fraternity.

Mr. Larson was elected an Associate Member of the American Society of Civil Engineers on October 7, 1908.

WALTER HARLAN LECKLITER, Assoc. M. Am. Soc. C. E.*

DIED JANUARY 29, 1928.

Walter Harlan Leckliter, the son of John H. and Cornelia (Hanks) Leckliter, was born at Carbon, near Corning, Iowa, on November 19, 1883. He was graduated from the Corning High School in 1904, and from Iowa State College, at Ames, Iowa, in 1909, with the degree of Bachelor of Civil Engineering. In the interval between his Freshman and Sophomore years in college he was engaged with a surveying party on construction work for the Missouri Pacific Railroad Company, in Southern Missouri. He stood well in his studies at college and in his Senior year was elected to the Tau Beta Pi Fraternity.

After his graduation, in July, 1909, Mr. Leckliter entered the employ of the Chicago, Burlington, and Quincy Railroad Company, on maintenance work in Wyoming. He began this engagement as Rodman and was subsequently advanced to the position of Head of Party.

Previous to this time, he had taken and passed a civil service examination, and in May, 1910, he received a Government appointment to the Philippine Islands, where for three years he built roads at Baguio, the Summer Capital.

His work in the Philippines also included a several months' engagement on preliminary surveys for irrigation, highways, and bridge construction. In connection with the latter, he designed bridges and culverts of reinforced concrete and harbor improvements which consisted of docks, sea walls, and other similar structures, for the City of Samboanga. He was also in charge of the office of the Bureau of Public Works in Baguio, which office regulated and controlled all buildings, grounds, roads, water-works, telephone, and sewerage systems, etc., for the city. He also had charge of an extension of the water-works system, of which the estimated value was $20 000.

In 1913 Mr. Leckliter returned to the United States, and was employed as the first County Engineer of Adams County, Iowa. In this capacity he was engaged in road and bridge construction. In 1914, he entered private practice and began contracting for paving, with headquarters in Des Moines, Iowa. Later, he was employed as Superintendent of Construction with Akin and Flutter, General Contractors, until 1920, when he again engaged in private practice as a contractor, principally in grading and paving in Southern Iowa and Missouri. He continued in this work until ill health necessitated his retirement in 1927. He died on January 29, 1928, at his home in Des Moines.

In his school days he was quite an athlete; he was Captain of his High School football team, although he never "made" the 'Varsity eleven. One of his college papers called him "a leader on the Campus". Besides Tau Beta Pi his only social memberships included a college Fraternity, "Adelante", and the local militia company at Corning.

Mr. Leckliter's character is perhaps best indicated by what other people thought of him. As a supporter of a widowed mother, and of a younger sister, whom he sent through college, he was conscientious to the largest degree.

* Memoir compiled from information on file at the Headquarters of the Society.

Even during his last illness, he was not immune from the demands of his wide friendship. One of his former laboring men wrote that he was out of work and tramping through Louisiana, and closed with "I know that if you only knew how much I needed money, you would send me some". At that time, he was besieged with financial demands because of the many expenses incidental to a long illness; yet he told his wife to mail the man a check.

One of his business partners has said of him, "There was a square man. I have traveled over all this country with him and there was nothing crooked in him." To his many friends, to his family, to whom he meant so much, his loss is great. Such a man must indeed be counted a success in life.

He was married on March 2, 1918, to Helen Widner, of Corning, Iowa. Besides his widow, he is survived by the following members of his family: His mother, Mrs. C. J. Leckliter, two brothers, Mr. Ralph E. Leckliter, of Corning, and Mr. Oliver L. Leckliter, of Des Moines; and four sisters, Mrs. Alma Bilderback, of Council Bluffs, Iowa, Mrs. Katherine Farrar, of Richmond, Calif., Mrs. Charles McGhee, of Steins, N. Mex., and Mrs. Arthur W. Miller, of LaGrange, Ill.

Mr. Leckliter was elected a Junior of the American Society of Civil Engineers on October 1, 1912, and an Associate Member on August 31, 1915.

ALFRED LEVY, Assoc. M. Am. Soc. C. E.*

DIED MARCH 23, 1928.

Alfred Levy was born at Darlington, England, on April 26, 1878. He received his education in England, after which he served an apprenticeship from September, 1892, to April, 1899, with Mr. F. W. Lyall, Civil Engineer, of Darlington, in the surveying and construction of railways, water-works, roads, etc. His services were retained by that firm until April, 1900, when he was engaged as Assistant Engineer under Sir James Bell on the Lancashire, Derbyshire, and East Coast Railway, on maintenance and new works until April, 1903. In May of the same year he was engaged by the Consulting Engineers for the Cape Government Railways (Messrs. Gregory, Eyles and Warring) and sent to South Africa under contract as Assistant Engineer on the survey and construction of the Indwe-Maclear Line (105 miles in length); he was in charge of 30 miles of this road from earthwork to plate-laying. In May, 1906, he went to England on furlough after which he again returned to South Africa.

From February to August, 1907, Mr. Levy was Assistant Engineer on the Cape Government Railways under Mr. M. D. Robinson, and was employed on the Coastal Section of the Mossel Bay-George Line (33½ miles in length). He had charge of all outside work necessary to complete construction, including setting out, testing of foundations, and the erection of a steel-pile bridge, 650 ft. long. He subsequently returned to England where he was again employed by Mr. E. W. Lyall, of Darlington. Among other engagements he carried out a survey for reclamation work in the Tees Estuary for the Cargo Fleet Ironworks.

In July, 1908, Mr. Levy was appointed Chief Engineer of the Ferrocarril Central Dominicano, Puerto Plata, Dominican Republic (under Mr. H. Gibson). He acted for six months as General Manager, returning to England in 1912.

In January, 1913, he was appointed to the Staff of A. M. Tippett, Engineer-in-Chief of the South African Railways. He was employed for four months on grade and curve improvements on the South-Eastern Line and was then transferred to the Benoni-Welgedacht Line.

When the World War broke out in 1914, Mr. Levy was employed on the survey and construction of the strategical line from Prieska to Upington, in connection with the German Southwest Campaign. During 1915 he was engaged for eight months on reparation work, after serious washouts, on the Bandolier Kop-Messina Line.

In 1916 he was transferred to Ladysmith, Natal, to take charge of the remodeling of the Passenger, Freight, and Locomotive Yard. Heavy earthwork was involved as well as a double-track steel bridge over the Klip River. In 1918 he went to Johannesburg as Assistant Superintendent of Maintenance. The following year he was transferred to Bloemfontein and East London and

* Memoir prepared by Jervis Gibbon, Dist. Engr., South African Rys. and Harbors, Johannesburg, South Africa.

again to Johannesburg in 1922 in the same capacity. At the time of his death, Mr. Levy had been appointed System Engineer, with headquarters at East London, but had not actually taken up the work.

He always insisted on a high standard of track maintenance and was responsible for numerous improvements for the purpose of eliminating sharp curves and recentering, to allow for transition curves on the sections on which the fast trains ran. His reports on engineering work were concise and his recommendations particularly sound.

He had made a special study of the problem of soil erosion and was most successful in the methods he used for its prevention. His estimates for new works and programs for re-laying, etc., of permanent way were most carefully prepared as to quantities and prices, and local conditions were always allowed for in the price of labor. He had the faculty of preparing plans in such a way as to convey the information required without elaborate or superfluous detail.

In making Staff changes, Mr. Levy was most considerate as to educational facilities for the children of the men concerned. Fortunately for the Engineering Profession, he has handed on these splendid traditions to the younger engineers who have had the privilege of working with him.

On December 31, 1912, Mr. Levy was married to Florence Thomas, of Northallerton, Yorkshire, England, who survives him, together with two children, a daughter aged 14 and a son aged 11. He was essentially a family man, and was devoted to his wife and children.

"So many worlds, so much to do,
So little done, such things to be,
How know I what had need of thee,
For thou were strong as thou wert true!"

Mr. Levy was elected an Associate Member of the American Society of Civil Engineers on December 5, 1911. He was also a Member of the South African Society of Civil Engineers.

VIRGIL SAMMS ONSTOTT, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 11, 1927.

Virgil Samms Onstott, the son of Dr. Elmer Onstott and Emma J. Onstott, was born on September 22, 1897, at Saltsburg, Pa. He was graduated from Saltsburg High School in June, 1915, and in the fall of that year he entered Kiskiminetas Springs School from which he was graduated with high honors in 1917, winning a medal for proficiency in mathematics as well as a scholarship conferred by the Cornell Alumni Association of Western Pennsylvania.

In September, 1917, Mr. Onstott entered Cornell University at Ithaca, N. Y. He enlisted in the Students' Army Training Corps, on October 8, 1918, and was assigned to Company H of the Reserve Officers Training Corps, from which he received his discharge the following year. In 1921, he was graduated from Cornell University with honors and a degree in Civil Engineering.

Subsequent to his graduation he was employed by the Pennsylvania Department of Highways first as Inspector and, later, as Senior Inspector in charge of various kinds of pavement construction work. In 1924 he was engaged as Assistant Resident Engineer in charge of State Highway construction in Beaver County, Pennsylvania, with headquarters at Pittsburgh and at Rochester, Pa., which position he held until his death.

Mr. Onstott was a member of the Presbyterian Church of Saltsburg with which he was affiliated from his early youth. On December 26, 1923, he was commissioned as Second Lieutenant in the United States Engineer Officers Reserve Corps.

He is survived by his widow, Margaret Anne Onstott, and an infant son, also his parents and one brother, Howard K. Onstott, of Cleveland, Ohio, and one sister, Mrs. G. G. Waite, of Toronto, Ont., Canada.

Mr. Onstott not only had all the qualifications of a good engineer, but a character which presaged his success. His loyalty and his steady purpose of co-operating in any undertaking which was assigned to him, commanded the respect and admiration of his associates. His calm judgment and unpretentious manner were noticeable in everything he undertook so willingly. It was, therefore, only natural for him to analyze his problems thoroughly—a characteristic so essential in a good engineer. His passing is a distinct loss to the profession.

Mr. Onstott was elected an Associate Member of the American Society of Civil Engineers on March 14, 1927.

* Memoir prepared by J. L. Herber, M. Am. Soc. C. E.

JAMES MADISON PORTER, 3d, Assoc. M. Am. Soc. C. E.*

DIED JUNE 3, 1928.

James Madison Porter, 3d, the son of James Madison Porter, Jr., and Ruth Pierson (Cook) Porter, was born in Easton, Pa., on May 10, 1864.

He was descended from a long line of distinguished ancestors and his family has been prominent in the making of Pennsylvania history. His father, James Madison Porter, Jr., an eminent lawyer and distinguished diplomat at the Courts of Vienna and Berlin, was a Thirty-third Degree Free Mason and Grand Master of the Pennsylvania Grand Masonic Lodge. His grandfather, James Madison Porter, was for many years one of the leaders of the Pennsylvania Bar and was President Judge of the 23d Judicial Circuit which comprised at that time the Counties of Wayne, Pike, Monroe, and Carbon. Judge Porter was appointed Secretary of War by President John Tyler, but the appointment was not concurred in by the United States Senate. He was one of the founders and the first President of the Board of Trustees of Lafayette College, at Easton, a position which he held for twenty-five years, serving as Lecturer on Jurisprudence and Political Economy without compensation during the entire period.

Judge Porter's father, the great-grandfather of James Madison Porter, 3d, was Maj.-Gen. Andrew Porter, Commissary General of the American Forces during the Revolutionary War. He was offered the post of Secretary of War in the Cabinet of President James Monroe, but owing to the infirmities of age, declined to serve. General Porter had six sons, all of whom became prominent in National life: David Rittenhouse was Governor of Pennsylvania; George Bryan was Governor of Michigan; William Augustus Porter, LL.D., the son of David Rittenhouse, was District Attorney for the City of Philadelphia, Pa., and afterward Judge of the Court of the Alabama Claims; and another son of David Rittenhouse was Maj.-Gen. Horace Porter of Civil War fame. Rear-Admiral David Porter, U. S. N., Gen. Fitz-John Porter, and Gen. Andrew Porter were all collateral relatives of James Madison Porter, 3d.

Mr. Porter attended the public schools of Easton until 1879, when, following the death of his father, he, with his mother and sister, moved to Hackettstown, N. J. He prepared for college at the Centenary Collegiate Institute of Hackettstown and Blair Academy at Blairstown, N. J., and entered Lafayette College, in the autumn of 1882. When he went to Easton, he lived with his grandfather in the house that continued to be his residence until the time of his death.

In June, 1886, he was graduated from Lafayette College with the degree of Civil Engineer. Following short engagements with Davis and Grier and the Lehigh Valley Railroad Company, he entered the service of Tippett and Wood, Phillipsburg, N. J., as Chief Engineer. His duties in this position covered the design and construction of tanks and stand-pipes. He retained

* Memoir prepared by Lynn Perry, M. Am. Soc. C. E.

this connection for the remainder of his active career, even after he took up his college duties. During this time he was engaged on the design and construction of many steel structures. One of the most important of these was the cantilever bridge connecting Easton and Phillipsburg, referred to in many articles and books on bridge engineering. This bridge which will remain as a monument to his genius for many years, was built in 1895, and has no top chord bracing. Mr. Porter was well-known as a consulting structural engineer and, during his active career, he designed many highway and trolley bridges as well as many stand-pipes and elevated tanks. He was a pioneer in the development of pressure filters.

In 1890, on the death of Professor Joseph G. Fox, Head of the Civil Engineering Department at Lafayette College, Mr. Porter was appointed Instructor in that Department and became Adjunct Professor of Civil Engineering on June 25, of the same year. On October 22, 1891, he was made Professor of Civil and Topographical Engineering, in charge of the Department, and in 1908, was appointed Professor of, and Director of the Division of, Civil Engineering. He occupied this chair until 1916 when he resigned after completing twenty-six years of service to his Alma Mater. Many generations of Lafayette men remember his outstanding qualities of leadership, teaching ability, sterling character, and genial disposition.

Professor Porter was active in church as well as technical, business, and civic affairs, and was a leader in every undertaking with which he was connected. He was a trustworthy friend of his colleagues and respected and beloved by all who were privileged to know him and who came into contact with him.

He served as Vice-President and President of the General Crushed Stone Company; Secretary of the American Society for Testing Materials; Director of the Easton Trust Company; President and Director of the Easton Tau Chapter of Zeta Psi; Vice-President and Director of the Northampton Country Club and the Pomfret Club. He was a member of the University Clubs of New York, N. Y., and Philadelphia, Pa., and the Automobile Club of America.

He was married on November 15, 1888, to Mary Virginia Drake, the daughter of Samuel Arndt Drake, of Easton, who, with an only son, James Madison Porter, IV, survives him.

Professor Porter was elected an Associate Member of the American Society of Civil Engineers on May 4, 1892.

JOHN GANSOVERTTE ROSE, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 27, 1927.

John Gansovertte Rose was born on April 11, 1878, in Hutchinson, Kans. He was graduated from the Hutchinson High School, and, later, from Nickerson College, where he completed a post-graduate course in 1903, and subsequently taught for three years. After holding various engineering positions until 1907, he entered the University of Colorado at Denver, Colo., from which he received the degree of Bachelor of Science in Civil Engineering in 1911.

During his vacation periods in 1909 and 1910, Mr. Rose assisted in both field and office for the firm of Field, Fellows, and Hinderlider, of Denver, Engineers for the Orchard Construction Company. This project includes 12 000 acres of land near Grand Junction, Colo. The irrigation system embraces a movable diversion dam 380 ft. long, extending across the Grand River; 9 miles of power canal, about 6 miles of which were bench and trestle flume; a hydraulic power plant consisting of four units of Leffel turbines, directly connected with centrifugal pumps, two of which operated a lift of 75 ft. and the other two, a lift of 125 ft.; 40 miles of distributing canals; 1 800 ft. of concrete-lined tunnel; and various other structures, such as inverted siphons, concrete culverts, highway bridges, waste-gates, etc. The estimated cost of this varied construction work was $1 250 000.

In June and July, 1911, Mr. Rose served as Engineer for the Badita Reservoir Company for which he made stream measurements and hydraulic investigations. He also submitted reports on a reservoir site in Southern Colorado.

From September, 1911, to May, 1912, he was employed by the Goldsborough Company, Engineers for the Laramie Water Company of Laramie, Wyo., on a 150 000-acre project. During this period he acted as Instrumentman on the preliminary and final location of canals having capacities of 1 000 sec-ft. and less. In June, 1912, he became Assistant Engineer in charge of the construction of canals for the Goldsborough Company. One of these, a 350 sec-ft. canal, 9 miles long, was located in a rough mountainous country covered with a dense growth of pine timber, the final estimated cost of construction of which was $168 000.

In November, when work on the canal had to be abandoned on account of the weather, Mr. Rose entered the employ of the Kansas City Structural Steel Company, of Kansas City, Mo. During the remainder of this year, and until May, 1913, he acted as Structural Detailer on smelter and railroad buildings, including stairways and hip-and-valley work.

From June, 1913, to October, 1915, he served as Engineer and Draftsman with the Consolidation Coal Company of Jenkins, Ky., making title maps of 100 000 acres of coal lands in the Cumberland Mountains. He also supervised the compilation of a complete index system of all notebooks (approximately 2 000), maps, and records of these lands, which had been collected throughout a period of forty years.

* Memoir prepared by W. L. Prouty, Assoc. M. Am. Soc. C. E., and A. E. Palen, M. Am. Soc. C. E.

From November, 1915, to March, 1916, Mr. Rose served as Draftsman for the Kennicott Company of Chicago, Ill. This Company was engaged in the manufacture of water softeners, rapid filters, boilers, gas retorts, etc., which involved considerable pipe-fitting work, straight and spiral stairways, and varied similar construction, on all of which he had assignments.

In March, 1916, he became Draftsman for the American Bridge Company at Gary, Ind. During his engagement with this firm, his work included the preparation of shop drawings for highway bridges and for a large blast furnace and rolling mill.

In September, 1916, he was appointed Assistant Engineer with the Atchison, Topeka, and Santa Fé Railway Company, continuing until June, 1918, on the location survey of a double-track line, 65 miles long, between Carrollton and Moberly, Mo., to join the surveys of the Burlington Road for a new joint railway between Kansas City and St. Louis, Mo. This location was controlled by a definite list of limitations, such as (1) distance evaluated at $200 000 per mile; (2) curvature evaluated at $480 per degree; (3) rise and fall evaluated at $700 per ft.; (4) maximum grade, eastbound track, 0.3%; and (5) maximum grade, westbound track, 0.4 per cent.

As may be inferred, this project involved some heavy construction work (single cuts amounting to 500 000 cu. yd.), such as an under-crossing of the Wabash Railroad Terminal Yards at Moberly, and also included a large reservoir for water supply. Messrs. V. C. Coffey, Location Engineer, and Woodbury Howe, Chief Location Engineer, were in charge of this unusually complicated undertaking.

During June and July, 1917, Mr. Rose located a line, about 70 miles long, on the plains of Western Kansas, between Satanta and the Colorado State Line. From August to November, he made a close preliminary survey of a line between Kingfisher, Okla., and Shattuck on the Texas border (a distance of about 135 miles). From November until the early spring of 1918, he located a line (14 miles long) between Cassoday and Bazarr, in Eastern Kansas, and a belt line, with two alternate locations, around the Town of El Dorado, Kans., in order to relieve the traffic from the adjoining oil fields. Messrs. J. C. Beye acted as Location Engineer and H. C. Steward, as Chief Location Engineer, on the Kansas and Oklahoma surveys.

This continued engagement with the Santa Fé Railway Company gave Mr. Rose a broad and valued range of experience in railroad location. His duties during the two years of service covered all phases of the work required in making surveys, maps, profiles, estimates, and reports.

From February to June, 1918, he was associated with the United States Reclamation Service on the Rio Grande Project, at El Paso, Tex., in responsible charge of canals, farm laterals, and topographic surveys. He also made estimates of the cost of reconstruction and co-ordination of 40 miles of some old Spanish canals in the El Paso Valley.

During the summer he served as Assistant Engineer with the Idaho Irrigation Company of Shoshone, Idaho, in charge of a system of distribution canals and the replacement and installation of concrete head-gates, checks, drops, etc.

During September and November, he was engaged with Lyman E. Bishop, M. Am. Soc. C. E., of Denver, Colo., as Resident Engineer in charge of construction of canal structures for the Meadow Farms Company, at Hardin, Colo.

In March, 1919, Mr. Rose was engaged as Chief of a Road Survey Party with the United States Bureau of Public Roads, District No. 3, with headquarters at Denver, in charge of the Deadwood-Hotsprings Project in the Black Hills in Lawrence, Pennington, and Custer Counties, South Dakota. This project was about 70 miles in length. Location surveys were made over about 60 miles, and construction was then in progress on approximately 16 miles of the road. His duties embraced the location and design of the road and all its structures, as well as supervision of construction, part of which was done under contract and part by force account.

In addition to this work, Mr. Rose was called on to consult and advise with local and county officials, as well as State and Forest Service officials, in various road matters relative to the Federal Aid Road Act. In this connection he had an opportunity to inspect numerous types of road construction and materials, to advise in matters of administrative organization and methods of management, and to inspect and check plans for other projects. As a matter of special interest it was his privilege to conceive and develop a new method of mass diagram which also serves as a haul sheet and furnishes an excellent means of balancing cut and fill quantities. This graph has been used extensively throughout District No. 3, and has received much favorable comment.

In 1921, Mr. Rose was appointed Assistant Highway Engineer and was sent to Washington, D. C., to receive special training as Materials Engineer on Federal Aid construction in the States of Wyoming, Colorado, and New Mexico. He held this position until his death.

Mr. Rose was married on September 15, 1912, in Denver, to Marie K. Venemann who, with four children, Jennie May, Helen Marie, Charles R., and Richard W., survives him. He is also survived by two sisters and two brothers.

Mr. Rose was a member of Union Lodge No. 7, A. F. and A. M., of Denver. He was also a member of the Colorado Section of the Society, and his death was felt as a personal loss to every member of the Section and to all who were in any way brought into contact with him.

A man who was loved by all who knew him, he was identified by his kindly ways as a genuine friend to his many acquaintances and business associates. In his home, he was a true husband and a real father; in the business world, he was a capable and efficient engineer.

Mr. Rose was elected an Associate Member of the American Society of Civil Engineers on April 14, 1919.

MICHAEL HEALEY RYAN, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 29, 1927.

Michael Healey Ryan was born on March 30, 1876, at Beverly, Mass., the son of Michael C. Ryan and Annie (Healey) Ryan. He pepared for college at the Lynn, Mass., Classical High School. In 1895, he entered the Lawrence Scientific School of Harvard University where he completed the four-year course and received the degree of Bachelor of Science in Civil Engineering with the Class of 1899.

During the summer of 1899 and from January to August, 1900, Mr. Ryan was Assistant Instructor in Surveying in the Lawrence Scientific School. He commenced and finished his active professional career on the New York Subway work. This service began on the construction of the first subway in New York City, on September 20, 1900, as Assistant Engineer on the Rapid Transit Engineering Staff which was organized by William Barclay Parsons, Hon. M. Am. Soc. C. E., Chief Engineer of the Board of Rapid Transit Railroad Commissioners, and was continuous from this time for nearly 19 years, until his resignation on March 31, 1919.

During the first seven months he worked in the General Offices of the Engineering Department. He started his field work in May, 1901, on the Lenox Avenue Subway (Section 9, Contract 1) in charge of a line and grade party. About two years later (March, 1903), he was given charge, under the Section Engineer, of the field parties, the inspection of construction, and office work on the Lenox Avenue Subway between 135th and 145th Streets, and the Manhattan side of the Harlem River Crossing (Section 9-A, Contract 1). This subway work was varied in character. It included steel beam, reinforced concrete, arch, tube, and concrete retaining wall construction, and also the Manhattan Approach to the Harlem River Tunnel crossing. On the completion of this work Mr. Ryan was put in charge of surveys for some routes of proposed new subways, on which duties he was engaged until the Board of Rapid Transit Railroad Commissioners was succeeded by the Public Service Commission on July 1, 1907.

Under the new Commission Mr. Ryan made a number of investigations and reports with respect to the service conditions on the surface-car lines in New York City. Later, he was employed in arbitration matters in connection with the settlement of the claims on Contract 1 for the completion of the first subway.

When construction on the Dual Subway System was begun, he was assigned to the Seventh Division as Assistant Division Engineer. He was in direct charge, under the Division Engineer and Chief Engineer, of the work of the first Sub-Division of the Seventh Division from its beginning to its completion; and, later, he was also in charge of finishing the work of the second Sub-Division. These two sub-divisions included nearly 6 miles of new subways, the construction of which cost approximately $20 000 000.

* Memoir prepared by D. L. Turner, M. Am. Soc. C. E.

The first Sub-Division work covered the lower portion of the Interborough Seventh Avenue Subway in Manhattan from the Battery through Greenwich Street, Varick Street, West Broadway, and Seventh Avenue to 17th Street (Sections 1-A, 1, 2, 3 and 4 of Routes 4 and 38). It included the construction, under difficult conditions, of a connection with the existing subway in Battery Park. In Battery Park, along Greenwich Street and West Broadway, the subway ran under the Manhattan Elevated structure. It was a two-track subway to Chambers Street and a four-track line from there on.

The second Sub-Division work was started and almost finished under another Assistant Division Engineer, but Mr. Ryan completed it. It included the building of the two-track Interborough Subway in Manhattan from a connection with the Seventh Avenue Line at West Broadway, thence under Park Place, under the Post Office Building, across Park Row, under the original subway and under Beekman and William Streets (Sections 1 and 2 of Route 48). This was one of the most difficult sections to construct on the entire Dual System. In Brooklyn, the second Sub-Division included the new subway from a connection with the Fourth Avenue Subway, at Fulton Street, thence along St. Felix Street and Flatbush Avenue to Malbone Street (Sections 1, 1-A, 1-B, 2-A of Route 12). This subway was constructed for operation by both the Interborough Company and the New York Rapid Transit Corporation. Where it is jointly operated, it is a six-track subway. The remainder of the line consists of two tracks. The two-track line is known as the Brighton Beach Connection and is operated by the New York Rapid Transit Corporation. The four-track line is a part of the Eastern Parkway Line operated by the Interborough Rapid Transit Company. One section of the line is constructed under the Atlantic Avenue Terminal of the Long Island Railroad.

During his entire contact with this great work Mr. Ryan was strong and active both in body and mind. He had a high sense of responsibility and devotion to duty. His work was always eminently satisfactory, and he was held in uniformly high regard by all his associates.

On the completion of the subway work under his charge, Mr. Ryan resigned from the service of the Commission to complete his study of law. From 1909 to 1912 he was registered in the New York University Law School. During 1919 and 1920 he was a student at the Harvard Law School and, in 1922, he was graduated with honors from the Boston University Law School. He was admitted to the Massachusetts Bar, but never practiced.

In the later years of his life Mr. Ryan devoted a great deal of time to travel. He died suddenly in Boston, Mass., from a heart attack, on September 29, 1927, a few days before he was to sail for Europe on another extended trip abroad. He never married.

Mr. Ryan was elected a Junior of the American Society of Civil Engineers on December 3, 1901, and an Associate Member on April 1, 1908.

GEORGE CHRISTIAN SCHOENBERGER, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 24, 1928.

George Christian Schoenberger was born in Buras, Plaquemines Parish, La., on January 17, 1875, the son of George M. and Mary (Walker) Schoenberger. He received his early education at Buras, and subsequently entered the Louisiana State University at Baton Rouge, La., from which he was graduated in 1898, receiving a Bachelor of Science degree in Civil and Mechanical Engineering. During his college career, he was a member of the famous football team of 1896, took an active interest in the military life of the college, serving as Major during his Senior year, and was a member of the Sigma Alpha Epsilon Fraternity.

Shortly after his graduation, Mr. Schoenberger entered the employ of the State Board of Engineers of Louisiana, which, in later years, was to have him as its Chief Engineer during a most trying period.

He began his professional career as Rodman, and later, was promoted to be Levee Inspector on the Red River. After a year with the State Board, he resigned to accept a position with the Houston Irrigation Company as Assistant Engineer in charge of irrigation work in Southwestern Louisiana. This engagement was followed by short services as Rodman and Inspector with the United States Engineer Office, and as Field Superintendent with the Mississippi Construction Company, engaged in levee work.

In November, 1901, Mr. Schoenberger returned to the State Board of Engineers as Surveyor in charge of party on location and construction of levees. Just a year later, in November, 1902, he was appointed Junior Engineer with the U. S. Engineer Office, New Orleans, La., in charge of levee construction in the Lafourche and Pontchartrain Levee Districts. The following six years were spent in this capacity. During a part of this time, Mr. Schoenberger and his family made their home in Natchez, Miss., where they enjoyed the society of a host of friends.

Although Mr. Schoenberger rather frequently changed positions during this early period, his work always was related to river control, in some of its varied phases. He must have realized early that this was to be his life work, and that a broad training embodying all its branches was highly desirable. Consequently, in October, 1908, he again changed positions, this time going to the Mississippi River Commission, 4th District, District Engineer's Office, at New Orleans, with which he stayed until 1917, when he was appointed a Member of the Board of State Engineers.

During the high-water periods of 1912, 1913, 1915, and 1922, much of the responsibility for keeping intact the levee lines in the 5th Louisiana and Tensas Basin Levee Districts was Mr. Schoenberger's, and due largely to his management in rescue work after the break at Fagette, La., no lives were lost. It was during this flood that Mr. Schoenberger first began to attract attention by his consummate skill and untiring efforts.

* Memoir prepared by Gervais Lombard, Esq., New Orleans, La., and A. F. Jacobi, Assoc. M. Am. Soc. C. E.

From the time in 1917 that he was appointed a Member of the State Board of Engineers by Governor Ruffin G. Pleasant, until his death, Mr. Schoenberger was constantly with the State Board, having been re-appointed in 1920 by Governor John M. Parker, and in January, 1925, being named Chief Engineer by Governor Henry L. Fuqua to fill the vacancy caused by the death of the late Frank M. Kerr, M. Am. Soc. C. E.

The record flood of the Mississippi River and its tributaries in 1927 brought forth the sterling qualities of Mr. Schoenberger, upon whose shoulders fell a large share of the responsibility for the protection of the levees and property of thousands of people in the Lower Valley. He took a leading part in the cutting of the Caernarvon Levee below New Orleans, creating the artificial crevasse which was to relieve the danger of a break at the city above. Supervising the holding of the levees in the upper section of the State occupied every available hour of his time, and he fought to the last ditch for every foot of levee. It was only after everything that was humanly possible had been done that the several disastrous crevasses occurred. It was a losing fight at the time, but with defeat came victory, for the great disaster opened the eyes of the entire country to the need of adequate flood control.

With complete victory in sight, his quarter-century battle against the flood menace of the Mississippi River came to an end on Monday, September 24, 1928, when he died suddenly from a heart attack at his home. Although complaining of pains in the region of the heart, he had arisen as usual, dressed, and prepared to go to his office. While in the garden of his home, he was stricken and died before the arrival of a physician. Mr. Schoenberger was described as a martyr to flood-control work by his physician who pronounced the weak condition of his heart as due to this strenuous work during the fight to save the levees in 1927, and his labors in Washington, D. C., in behalf of Federal flood control.

Public tribute was paid to Mr. Schoenberger after his death by his numerous friends and admirers, many of whom held high office. The following editorial published in New Orleans, just after his death, expresses the esteem in which he was publicly held:

"Personally modest and unassuming, George C. Schoenberger was one of those talented Louisianians whose work had escaped general public notice until last year when the greatest flood in the history of the Mississippi River centered attention on the men who bore the brunt of the battle against almost hopeless odds. In this crisis he emerged as an effective and skillful leader of the State's flood forces, whose command he had assumed two years before upon his appointment as Chief of State Engineers.

"Although disaster after disaster overwhelmed the flood-plain of the State, his courage never slackened, nor was there ever any flagging in his resolution to fight to the last to save every possible acre from destruction and ruin. His personal presence was felt wherever the water threatened in the far-flung battle line from the south bank of the Arkansas River to the Gulf of Mexico. In the long history of Mississippi River floods probably no more critical situation could be cited than that existing on the memorable night of Good Friday, 1927, when a rain and windstorm whipped the waters of the swollen Mississippi between New Orleans and Baton Rouge, shattering levees at a dozen different points, and threatening imminent disaster, which was averted only after sev-

eral days of furious work. The holding of the levee lines on the Mississippi below Red River Landing until the Bayou des Glaises crevasses had relieved the pressure in the main stream, was a notable achievement in itself.

"For the task which confronted him in the 1927 flood Mr. Schoenberger had been in training since his graduation from the State University in 1898, practically his entire time since then having been devoted to river work. He had espoused the spillway cause along with other notable engineers prior to the 1927 flood, and in the fight at Washington last fall and winter for adequate flood control legislation his views had marked effect. His unexpected death, following a year and a half of intense activity, first in the gruelling battle to hold the levees and afterwards at Washington, is a distinct loss to the State, to the service of which he had devoted the most useful years of his life."

He was married on January 8, 1902, to Podine Conrad Pope, of Baton Rouge, La. He is survived by his widow, three sons, George C., Jr., Ripley Pope, and Sidney Conrad, and one daughter, Podine.

Mr. Schoenberger was elected an Associate Member of the American Society of Civil Engineers on November 27, 1917.

WALTER TUTTLE SPENCER, Assoc. M. Am. Soc. C. E.*

DIED AUGUST 19, 1928.

Walter Tuttle Spencer was born in Guilford, Conn., on July 5, 1869, the youngest of three sons of Christopher Spencer and his wife, Jane E. Collins Spencer. He prepared for college at Guilford Institute, and entered the Sheffield Scientific School of Yale University from which he was graduated in 1890.

Immediately after his graduation, Mr. Spencer entered the service of the New York, New Haven and Hartford Railroad Company, with which Company he was connected for thirty-eight years. From 1893 to 1914, he was in the Engineering Department, having been appointed Division Engineer of the Northampton-Air Line Division in 1893. From this time he served, successively, as Division Engineer on the Highland, Hartford, Western, and Providence Divisions. In 1914 he was transferred to the Operating Department, as Superintendent of the Old Colony Division at Taunton, Mass.; and, in 1919, he was appointed Superintendent of the Boston Division with headquarters at Boston, Mass., which position he held at the time of his death.

Mr. Spencer's abilities as a Railroad Engineer were of the highest quality. He handled many problems of railroad construction, as well as maintenance work successfully and satisfactorily. Some of the more important of these were: The double-tracking of the Air Line Division; and of the Western Division; the Morgan Street Yard Improvements, at Hartford, Conn.; elimination of grade-crossings, at East Hartford; the Walnut Street improvements, at Hartford; elimination of grade-crossings at Westfield and Northampton, Mass.; the Farmington River Bridges, at Farmington and Collinsville, Conn.; the first concrete arch bridge ever built by the "New Haven", located at West Haven, Conn.; the Park River Bridge, at Hartford; and numerous grade-crossing elimination projects which the "New Haven" Railroad was developing during Mr. Spencer's service as Division Engineer.

His later position as Superintendent of a Division gave him a varied experience in the three Southern New England States. The requirements of his calling made it necessary for him, during periods of severe weather, or heavy traffic, to remain at his desk for days at a time. In his handling of men he believed firmly in the principle of even-handed justice. Where the matter of discipline was involved he would listen with patience to the plea of one for the shortcomings of another and he always tempered justice with mercy. It was as if the person in difficulty were some one close to him.

Mr. Spencer was married to Dorothy E. Dain, of Waterbury, Conn., who survives him, as does one brother, Frederick C. Spencer, of Guilford, Conn.

He was a member of the Connecticut Society of Civil Engineers, the Traffic Club of New England, the New England Railroad Club, and the New Haven Railroad Club.

* Memoir prepared by Paul Sterling, M. Am. Soc. C. E.

Walter Tuttle Spencer was a modest man. He was never in the forefront, always retiring and reticent, always even-tempered and soft-spoken. To know him was to love him. The high place which he held among his associates had been won by his own ability and single-hearted devotion. For him, life ended on a high plane.

Mr. Spencer was elected a Junior of the American Society of Civil Engineers on May 2, 1893, and an Associate Member on October 4, 1899.

FRANK ANDREW TILLMAN, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 2, 1927.

Frank Andrew Tillman, the son of Peter M. and Ida Tillman, was born on September 27, 1888, at Waverly, N. Y. His early education was obtained in the Waverly Public Schools, after which he attended the University of Colorado at Denver, Colo., for two terms from October, 1908, to June, 1909, and from September, 1909, to June, 1910, taking special night and part-day studies in mathematics, plain surveying, municipal and irrigation engineering, construction, and design.

During the summers of 1908 and 1909, Mr. Tillman was engaged as Chainman, Rodman, and Topographer on preliminary and location surveys for the Denver, Laramie, and Northwestern Railroad, and as Rodman on Construction.

In June, 1910, he accepted a position as Transitman in charge of party on a land survey of 65 000 acres, comprising section line, irrigation ditch, fence line, building location, and general development, near Laramie, Wyo. He also spent some months on coal mine surveys at Medicine Bow, Wyo., and on the general layout of the Town of Milliken, Colo. In the fall of 1911 he acted as Levelman, for the Goldsborough Engineering Company, of Chicago, Ill., on a topographical survey of 30 000 acres in Wyoming, later, becoming Draftsman and Computer for this Company in Denver, Colo., on irrigation structures, lateral and canal projects, etc.

From January to April, 1913, Mr. Tillman was employed as Office Engineer for the Denver Realty Company on sub-divisions and utilities. He then returned to the Goldsborough Engineering Company as Chief of Construction on irrigation structures, canals, and laterals, until September, 1913, when he was engaged as Engineer for the Enalpac Oil and Gas Company on the design, location, and construction of pump-houses, refineries, derricks, and pipe lines, at Casper and Cody, Wyo.

In July, 1915, he came East to Binghamton, N. Y., where he was employed until May, 1917, by the City as Instrumentman on preliminary surveys and location for an intercepting sewer and other municipal work. He subsequently became Assistant City Engineer for the City of Binghamton in charge of sewer construction and design.

In September, 1918, Mr. Tillman entered the United States Government Service at Perth Amboy, N. J., on housing projects, topography, utilities, and street planning. The following year, however, he returned to Binghamton, where he acted as Secretary to the Commissioner of Public Works and Superintendent of Parks.

In 1920, he accepted a position as Assistant Engineer with Hoadley and Giles, a civil engineering firm of Binghamton, in charge of field parties and on general engineering work. He assisted in the design of the water supply and sewer systems of Johnson City, N. Y., and designed the proposed water system for Endicott and West Endicott, N. Y. He also assisted in the sur-

* Memoir prepared by John A. Giles, M. Am. Soc. C. E.

veying and planning of the various subdivisions, and served as Office Engineer on computations and design.

In April, 1921, Mr. Tillman was appointed Commissioner of Public Works and Engineer of Johnson City, in charge of the design, construction, and maintenance of all public utilities. He held this position until his sudden death on September 2, 1927, from intestinal pneumonia.

In 1921, he was married to Lois A. Kilmer, of Binghamton, who, with a daughter, survives him.

Mr. Tillman was a member of the Baptist Church and prominent in the Masonic Fraternity as a member of Waverly Lodge, A. F. and A. M., the Scottish Rite Bodies, of Cheyenne, Wyo., and Kalurah Temple, Nobles of the Mystic Shrine, of Binghamton, N. Y. He was also a member of the Kiwanis Club of Binghamton, N. Y.

He was most popular among his many friends and associates in the Engineering Profession, all of whom liked him for his genial disposition and respected him for his ability and thoroughness as an engineer. As a public official, he incurred the good-will of his associates and commanded the respect of the public.

Mr. Tillman was elected an Associate Member of the American Society of Civil Engineers on May 28, 1923.

EDWARD JOHN TULLY, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 27, 1928.

Edward John Tully was born at Omaha, Nebr., on June 23, 1893, the son of John Charles Tully and Gertrude (Stein) Tully. Most of his life was spent in Omaha, where he attended the public schools, finishing High School in 1909.

He was employed by the Concrete Engineering Company, in Omaha, for several years, leaving to enter the Government service during the World War. During this period he was engaged in the Ship Building Department, first in Washington, D. C., and then in Philadelphia, Pa., later going to Camp Funston, Kansas. He was not sent overseas, however.

After returning to Omaha, Mr. Tully was employed by the Metropolitan Utilities District. He was Chief Draftsman for the design of the Omaha Filter Plant built in 1923 at a cost of $600 000 for improving the water supply of the City. As Draftsman, he also assisted in the design of a 48-in. water main, 7 miles long, costing in excess of $800 000. He designed the foundation and connections for two pumps with capacities of 30 000 000 gal. per day. After serving with the Metropolitan Utilities District for three and one-half years, under the supervision of C. D. Robinson, M. Am. Soc. C. E., Mr. Tully was forced to resign on account of illness.

In an unsuccessful attempt to regain his health, he spent the following two years, until his death, in California. When Mr. Tully left Omaha for Sierra Madre, Calif., he was engaged to be married to Genevieve Kennedy a sweetheart of several years. On account of his illness they thought it advisable to delay the marriage. On the advice of relatives, however, Miss Kennedy accompanied by Mr. Tully's aunt, went to California, arriving on a Tuesday. The wedding ceremony was performed Wednesday afternoon and Mr. Tully passed away Saturday morning. Mr. Tully's remains were brought back to Omaha from California, and he was laid to rest in St. Mary's Cemetery, beside his mother and father.

Mr. Tully was very fond of outdoor sports. He was an expert swimmer and skater, and played baseball on several junior teams. He was very ambitious, possessing a keen, creative mind. During his school days he worked in his uncle's grocery store from five o'clock in the morning until it was time for him to go to school, and then again after school hours and on Saturdays. He also attended night school to further his engineering knowledge, and because he loved his work, was always studying during his sickness. He associated with older men rather than men of his own age, having such interest in his work that he felt they could help and advise him from experience. A man of likeable personality, he was quiet and reserved, but loved by all who knew him. Had he lived longer, he doubtless would have been very successful. Among the associations that he cherished most, were his connections with the Society.

Mr. Tully was elected an Associate Member of the American Society of Civil Engineers on August 30, 1926.

* Memoir prepared by Mrs. Genevieve Kennedy Tully, Omaha, Nebr.

ALBERT ALEXANDER VAN PETTEN, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 27, 1927.

Albert Alexander Van Petten was born at Farmington, Ill., on June 9, 1883. He was graduated from the University of Illinois in 1907 with the degree of Bachelor of Science. While he was still attending college, he did apprentice work in civil engineering with the Illinois Central Railroad Company, the Yazoo and Mississippi Valley Railroad Company, and the South Porto Rico Sugar Company.

After graduation, Mr. Van Petten re-entered the employ of this latter Company and, in 1907-1909, had charge of surveying and mapping cane lands, as well as the planning of a fire protection system, including a 3 000 000-gal. reservoir, for the Company's sugar factory. He also made surveys and plans for an irrigation pumping plant furnishing water to 1 000 acres and planned and installed a gravity irrigation system covering 1 500 acres of land. Later, for the same Company, he took part in the planning and construction of three irrigation pumping plants and the re-construction of a 2 500-ton sugar factory on the Fortuna property of the Company near Ponce, Porto Rico.

From Fortuna, he was transferred to the Pagan property of the Company, where he designed and constructed railroad yards for the transference of cane, and completed surveys for the installation of three irrigation pumping plants, each of a daily capacity of 4 000 000 gal. In addition, he surveyed and completed plans for a diversion dam to supply water for a gravity irrigation system.

From 1912 to 1914, inclusive, Mr. Van Petten was Superintendent of Construction of the Dam and Power House at Comerio, Porto Rico, for the San Juan Light and Power Company. He completed this work and from it is derived the power for the electric lighting and street railway system of San Juan, Porto Rico.

During the early part of 1915 he entered the service, as Chief Civil Engineer, of the Punta Alegre Sugar Company, which was then engaged in the development of a large sugar property at Punta San Juan, Cuba. This project included the planting of about 16 000 acres in cane, the construction of 50 miles of standard gauge railroad, the erection of a sugar factory with a grinding capacity of 3 000 tons of cane per day, and the construction of living houses for several hundred employees.

During the progress of this development work, a serious drainage problem arose, threatening, through the inundation of about one-half the cane area, to jeopardize the whole investment valued at several million dollars. Lands of higher elevation, beyond the boundaries of the Company's holdings, delivered their drainage water on these cane lands and kept them submerged long enough to effect serious damage to the crop. Mr. Van Petten met this situation by constructing a diversion drainage ditch at the highest elevation of the Company's land, which completely prevented further inundations and safeguarded the entire investment. Before the completion of this project by the

* Memoir prepared by H. Edson, Esq., New York, N. Y.

Punta Alegre Sugar Company, Mr. Van Petten was made its General Manager and, as such, brought the property into operating condition.

In 1919, he took service as Civil Engineer with the Barahona Sugar Company, which was engaged at that time in developing a sugar property near Barahona, Santo Domingo. This project embraced the clearing of 20 000 acres of land, and planting them in cane; the planning and construction of a complete irrigation system covering the entire area and including the construction of a diversion dam in the Yaque del Sur River, a stream subject to torrential freshets, the laying out and construction of 60 km. of meter gauge railroad; the erection of a sugar factory with a daily capacity of 4 000 tons of cane; the construction of docks for loading cargo boats; the building of villages to house about 5 000 people; the construction of an aqueduct, 13 km. long to supply these people with fresh water as well as the people of the adjoining Town of Barahona, with about the same population; and, finally, the planning and construction of a drainage system to carry off the surplus irrigation water from the canefields.

On this Barahona work, as was the case in the Punta Alegre development, Mr. Van Petten's ability, both as a civil engineer and as an executive, became so apparent that he was made General Manager of the whole project and, as such, successfully completed it and turned it over to the operating company in 1922.

At the completion of his Barahona work, Mr. Van Petten was connected with the Macareño and General Sugars Companies in the development of their sugar properties in Cuba and finally accepted the position of General Manager of the Mercedes property belonging to the Cuba Cane Sugar Corporation, where he remained until his death on November 27, 1927.

On November 6, 1907, Mr. Van Petten was married to Jessye Gurney, who survives him, with four children, one son, Douglas, and three daughters, Willa, Alberta, and Jeanne.

Mr. Van Petten was a Mason and a member of the Island Chapter, Havana, Cuba.

His sterling qualities endeared him to all with whom he came in contact and his ability marked him as one of the outstanding construction and operating men of the sugar industry, with which he had been connected during the greater part of his active life. He was one of those singularly attractive and dependable men whose death is an irreparable loss to his family. He leaves a void which his friends find it impossible to fill.

Mr. Van Petten was elected an Associate Member of the American Society of Civil Engineers on December 5, 1911.

HOWARD ELLIOTT, Affiliate, Am. Soc. C. E.*

DIED JULY 8, 1928.

Howard Elliott was born in New York, N. Y. on December 6, 1860, the son of Charles Wyllys Elliott and Mary (Whyte) Elliott. Charles Elliott Perkins, who as President so efficiently guided the destinies of the Chicago, Burlington and Quincy Railroad Company during its period of greatest expansion, was his cousin.

Mr. Elliott's early inclinations are shown in the fact that after passing through the High School of Cambridge, Mass., he entered what was then known as the Lawrence Scientific School of Harvard University, from which he was graduated with the degree of Civil Engineer in 1881. He plunged at once into railroad work, and, in October of that year, he entered the employ of the Burlington Railroad Company, with which he was to be intimately connected, either directly or indirectly, for many years. As a matter of fact he had been a Rodman on that road the year before he received his degree.

While he served in various capacities on various lines during his lifetime, Mr. Elliott's specific service as related to engineering may be said to have begun in 1896, when for five years he was General Manager of the Missouri Lines of the Burlington Railroad. In 1901, he became Second Vice-President of that Company, from which position, in 1906, he was promoted to the Presidency of the Northern Pacific Railway Company. He made his home at this time in St. Paul, Minn. From 1903 to 1913 there was a very marked development in the Northwest. During his administration as President he directed the greatest construction program ever attempted by the Northern Pacific Railway. The capacity of the road was greatly increased, and the agricultural districts were better served by the construction of branch lines, and, in addition, the West Coast District was improved between Portland, Ore., and the Canadian boundary.

The late James J. Hill, F. Am. Soc. C. E., was then the dominant figure in the Northwest, especially in the group of railroads comprising the Great Northern, Northern Pacific, and Burlington Companies. The late E. H. Harriman was the leader in the Union Pacific and Southern Pacific group. It was Mr. Elliott's good fortune to be associated with these remarkable men and to take part in the memorable "Hill-Harriman" contests in railroad building in Washington, Idaho, and Oregon. This was a most important period in the history of the Northern transcontinental lines. While some remnants of the old feeling of bitterness remained, the community of ownership which had come about as a result in the formation of the Northern Securities Company was established more strongly day by day. Thus, the Great Northern and Northern Pacific Systems, growing more closely together, presented a united front to the rather insistent demands of the Harriman System. As part of the complete fortification, in a railroad sense, of the Pacific North-

* Memoir prepared by Ralph Budd and W. L. Darling, Members, Am. Soc. C. E.

west, the Spokane, Portland and Seattle Railway was constructed from Spokane, Wash., to Portland, a distance of 380 miles. Mr. Elliott had his part in this joint project, the conception and responsibility for which, of course, belonged directly to Mr. Hill.

The Northern Securities Company was declared illegal, under the Sherman Anti-Trust Law, upon suit by the United States Government; but the vital feature of this decision was that it did not affect the joint ownership established by the two Northern Lines of the Burlington property, its stock having been purchased outright and bonds issued to finance the purchase. At this time there was a deep hostility throughout the United States to railroad policies, and this enmity had to be turned first into neutrality and then into friendship. To succeed in this plan it was necessary systematically to carry on public education in the fundamentals of the situation. As a result Mr. Elliott was an important factor in such work through all his active life. He traveled across the Continent many times and made scores of addresses (some of which were printed), in which facts about the railroads were dispassionately presented before commercial clubs, business men's associations, and other bodies. The more formal talks which were distributed widely in the Northwest no doubt had a wholesome effect in the territory served by the Northern Pacific System, and were very helpful in directing the attention of the people to the need of remedial legislation.

By the summer of 1913 there had developed in New England a railroad situation as unpromising and as difficult to handle as that which had existed in the territory of the two Northern transcontinentals. The New York, New Haven and Hartford Railroad Company was the great railroad corporation of New England. It had been expanded to take in most of the railroad properties of that section, and its finances had become seriously affected. Much hostility had been aroused against the management of the road, particularly over the policy which included a consolidation of all New England transportation activities—steam railroads, trolleys, and steamship companies—to be dominated by the New Haven Company. A number of prominent New Englanders interested in an adequate and permanent transportation service for New England, chief among them Mr. Elliott's friends, the late Henry Lee Higginson and Theodore N. Vail, invited and urged Mr. Elliott to come East and take up the task. As his children were either at school or college in the East, and practically all his relatives and old friends were there, he found the idea attractive. Then, too, since the Board of Directors of the Northern Pacific Company met in New York, it had been necessary for him to make from eight to ten trips a year between St. Paul, Minn., and the Atlantic Coast, which, with the necessary inspection trips in the West as far as the Pacific Coast, represented traveling from 30 000 to 40 000 miles per year.

Mr. Elliott, realizing to some extent the seriousness of the situation, decided to take up the work, after discussing the matter fully with friends in Boston, Mass., New York, and Philadelphia, Pa. Making his residence in Boston, he became associated with the New York, New Haven and Hartford Railroad Company as its President on September 1, 1913, and soon became Chair-

man of the Board of Directors, being succeeded by Mr. James H. Hustis as President. At that time the New Haven System consisted not only of its rail lines, but also included in its ownership or control the Central New England Railway Company, the Boston and Maine Railroad Company, the New York, Ontario, and Western Railway Company, the New England Steamship Company, the Hartford and New York Transportation Company, substantially all the street railway lines in Rhode Island and Connecticut, and the important street railways of Massachusetts, in Berkshire County, and in the Cities of Springfield and Worcester. It was expected that the Chairman of the System would exercise general oversight of the holdings of the New Haven Company, each of which was to be in charge of a President, and that the Board of Directors of the New Haven Lines, being responsible for the parent company and its holdings, should act as a supreme advisory body to the Chairman. These plans were soon upset by the action of the Federal Government, however, in bringing suit to compel the New Haven Company to give up the Boston and Maine Railroad, and the Massachusetts, Rhode Island, and Connecticut trolleys.

Mr. Elliott labored long and earnestly to avert the Consent Decree, which was forced on the New Haven Company by the Administration at a time when this Company, because of its financial embarrassment, could not afford to resist the Government. Mr. Elliott accepted the situation, however, and with what remained of the New Haven System began earnestly to present to Southern New England the serious problems which confronted the transportation agency and the communities which were dependent upon it. In his speeches and writings he urged the necessity for confidence, patience, and co-operation, and, greatly to his credit, secured them all. His attitude and action inspired a revival of the belief that the New Haven System might be restored to its former high state. Incessant work in this field impaired his health, and on May 1, 1917, he resigned as Chairman and President, and took a position on the Railroads' War Board, at Washington, D. C., where, together with the other members of the Board, he represented all the railroads until the beginning of Federal Control in the same year.

In 1920, Mr. Elliott became Chairman of the Board of Directors of the Northern Pacific Railway Company, and took an active part in the management of that property until his death. He was also a Director of the Chicago, Burlington and Quincy Railroad Company from 1918 until his death, as well as a Director of many companies connected with railroads and other allied interests, as well as a member of many clubs and scientific, business, and social organizations.

Mr. Elliott was also a very ardent and enthusiastic Harvard man, and Harvard University, in turn, thought most highly of him. As early as 1909 he was elected one of its Board of Overseers, and the Alumni Association made him its President for the year 1917. He was extremely interested in the work of the University, especially that of the School of Transportation, founded in honor of Mr. James J. Hill.

The honorary degree of Doctor of Laws was conferred on Mr. Elliott by several colleges, namely, Middlebury College, Vermont, in 1916; Trinity Col-

lege, Connecticut, in 1914; and Carleton College, Minnesota, in 1927. He also received the honorary degree of Doctor of Science from the University of Pennsylvania in 1927.

Mr. Elliott was married on October 12, 1892, to Janet Churchill. They had two daughters and one son. He was an extremely attractive man personally because he seemed actually to radiate kindness and good will. These qualities contributed greatly to his practical success.

Mr. Elliott died on July 8, 1928, while still actively engaged in the handling of railroad affairs to which so much of his life had been devoted. Few men have left behind them a larger circle of appreciative associates and admiring friends.

Mr. Elliott was elected an Affiliate of the American Society of Civil Engineers on June 5, 1900.

WILLIAM PENDLETON PALMER, Affiliate, Am. Soc. C. E.*

DIED DECEMBER 17, 1927.

William Pendleton Palmer, the son of James Stewart and Eleanor Pendleton (Mason) Palmer, was born in Pittsburgh, Pa., on June 17, 1861. His father was a Captain in the 155th Regiment of Pennsylvania and died during the Civil War. His mother was a descendant of an old Colonial family.

After completing a four years' course which included Mechanical Drafting, he was graduated from the Pittsburgh Central High School in 1878. Subsequently, he entered the employ of the Lewis, Oliver and Phillips Company, with which he remained until May, 1881, occupying various minor positions, as well as that of Traveling Salesman.

On May 27, 1881, Mr. Palmer began his service with Wilson, Walker, and Company, which, on January 1, 1886, was absorbed by Carnegie, Phipps, and Company, Limited. In July, 1892, the latter Company was united with the Carnegie Steel Company, Limited, and, with these various Carnegie interests, Mr. Palmer occupied, successively, the positions of Draftsman, Traveling Salesman, Secretary, General Sales Agent, and Assistant to the President.

In 1896, he resigned from the latter position to accept an appointment as Second Vice-President of the Illinois Steel Company, in Chicago, Ill. When the American Steel and Wire Company of New Jersey was organized, on January 13, 1899, he became a Director and General Manager of that Company. On May 9, 1900, Mr. Palmer was elected President of the American Steel and Wire Company and held this position until his death.

Mr. Palmer was also President of the American Mining Company. He was made a Director of the United States Steel Corporation in 1922, and was re-elected in 1924 and 1927. He likewise acted as a Director of the H. C. Frick Coke Company and of the Cleveland Trust Company, and was a Trustee of the Lakeside Hospital, Case Library, and Oberlin College. He was a member of the Protestant Episcopal Church.

Mr. Palmer had a predilection for historical literature. He gathered from various sources all that is known of the wire industry. This information, in the form of written data, together with exhibits of machinery used in the industry, forms a notable collection known as the Industrial Museum of the American Steel and Wire Company, located at Worcester, Mass.

It was also Mr. Palmer's pleasure to collect historical data and Americana, particularly books, maps, manuscripts, photographs, etc., both Union and Confederate, relating to the Civil War, Abraham Lincoln, and slavery. This collection, believed to be the largest in the country outside the Library of Congress, he presented to the Western Reserve Historical Society of Cleveland.

Mr. Palmer was married on July 24, 1898, to Mary Boleyn Adams, of Chicago, who, with a daughter, Mrs. William Chisholm, II, and a son, William Pendleton, Jr., survives him.

He had served as President of the Western Reserve Historical Society since 1913 and was a member of the following societies and clubs: The Engineers

* Memoir prepared by George H. Tinker, M. Am. Soc. C. E.

Society of Western Pennsylvania; the Cleveland Chamber of Commerce; The Chamber of Commerce of the United States; the Society of Colonial Wars; the American Antiquarian Society; the Military Order of the Loyal Legion; the Union Club; the Rowfant Club; the Cleveland Country Club; the Tavern Club; the Mayfield Club; the Kirtland Club; and the Chagrin Valley Hunt Club of Cleveland; the Duquesne Club and the Pittsburgh Club, of Pittsburgh, Pa.; the Chicago Club, of Chicago, Ill.; and the Engineers' Club and India House, of New York, N. Y.; also the Worcester Club and the Rufus Putnam Society, of Worcester, Mass.; and the Megantic Fish and Game Corporation of Belmont, Mass.

Mr. Palmer was elected an Affiliate of the American Society of Civil Engineers on March 3, 1896.

CHARLES FREDERICK QUINCY, Affiliate, Am. Soc. C. E.*

DIED OCTOBER 1, 1927.

Charles Frederick Quincy, the son of George Henry and Mary Caroline (Sweetser) Quincy, was born in Newton, Mass., on July 16, 1856. On his father's side he was a direct descendant of Edmund Quincy who came from England in 1628 and settled in Massachusetts.

Mr. Quincy's elementary training was received at the Newton High School which, together with some time spent under the guidance of a private tutor, completed his education. It was during this period that he spent two years at sea, due to ill health, and was shipwrecked off the coast of Denmark.

In 1886, he entered the railroad supply business, a founder of the firm which first operated as the Dunham Manufacturing Company and, later, as the Q and C Company, of which he became President in 1887, and with which he was connected during the remainder of his active business life. Subsequent to 1922, Mr. Quincy gradually lessened his active participation in the work of the Company, and, in 1926, he was appointed Chairman of the Board of Directors, which office he held until his death. Mr. Quincy passed away on October 1, 1927, at his summer home, Centre Harbor, N. H.

He was also Chairman of the Board of the Dorr-Miller Differential Company, and the Miller Transmission Company and Vice-President and Director of the Kelvinator and Westchester Company.

Mr. Quincy was a member of the American Society of Mechanical Engineers, American Institute of Mining and Metallurgical Engineers, American Association for the Advancement of Science, and the American Society for Testing Materials.

He also held membership in the Railroad Club, the Greenwich Country Club, and the Lotos Club of New York, the Chicago Club, the New York Botanical Society, the New York Zoological Society, the National Geographical Society, and the Metropolitan Museum of Natural History.

Mr. Quincy's entry into the various mechanical societies was due to his success in presenting new railroad devices to the railroad trade. He was a great friend of the under-privileged boy, having been the first President of the Allendale Association at Lake Villa, Ill., and a member of the Board of the Boys Club Federation of New York and Hope Farm, at Verbank, N. Y.

On October 22, 1879, Mr. Quincy was married to Etta Molineaux Ives. He is survived by his widow and four children, Mrs. A. Q. Karcher, and Polly, Edmund, and Roger Bradshaw Quincy.

Mr. Quincy was elected an Affiliate of the American Society of Civil Engineers on February 4, 1896.

* Memoir compiled from information on file at the Headquarters of the Society.

LUCERN S. STEWART, Affiliate, Am. Soc. C. E.*

DIED NOVEMBER 29, 1927.

Lucern S. Stewart was born at Marshall, Ill., on May 5, 1856. He received his education in the public schools of Illinois.

Mr. Stewart's first bridge work was with the Wabash, Chester, and Western Railroad Company, in Illinois, and he was rapidly promoted to be Superintendent of Bridges.

In 1885, he was employed by the late George S. Morison, Past-President, Am. Soc. C. E., Chief Engineer, to build the caissons for the Illinois Central Railroad Bridge over the Ohio River, at Cairo, Ill. After finishing this work, Mr. Morison sent him to the Merchants Bridge, in St. Louis, Mo., then under construction. He was soon transferred in 1887, to Memphis, Tenn., and made General Foreman of Substructure on the Kansas City, Fort Scott and Memphis Railroad Bridge over the Mississippi River. The construction of this bridge extended over a period of about five years, and the experience obtained under Mr. Morison as Chief Engineer, and the late Alfred Noble, Past-President, Am. Soc. C. E., Resident Engineer, was invaluable to Mr. Stewart. When the Memphis Bridge was finished in 1892, he took charge of the substructure work on the Burlington Bridge over the Mississippi River, near St. Louis.

In 1893, Mr. Stewart entered the service of the late A. J. Tullock, M. Am. Soc. C. E., Proprietor of the Missouri Valley Bridge and Iron Works, as Superintendent on the substructure of the Missouri River Bridge, at Leavenworth, Kans., and in 1895 and 1896, he was Superintendent of the Missouri River Bridge, at Jefferson City, Mo.

In 1896, when contract work was almost at a standstill because of a financial crisis, Mr. Stewart was employed by the Kansas City, Fort Scott and Memphis Railroad Company, for which he carried on an extensive reconstruction program on bridges until August, 1898, when he again entered the service of Mr. Tullock. During the next six years he had charge of the following large substructure contracts: Reconstruction of some of the old piers on the St. Louis, Iron Mountain, and Southern Railway Bridge over the Arkansas River, at Little Rock, Ark.; the Kansas City, Pittsburgh and Gulf Railway Bridge over the Red River, at Index, Tex.; the Tampico Wharf for the Mexican Government at Tampico, Mexico; the Texas and Pacific Railway Bridge over Old River at Steamboat Island, in Louisiana; the El Paso and Southwestern Railway Bridge over the Rio Grande, near El Paso, Tex.; the Fort Smith and Western Railway Bridge over the South Canadian River, at Garner, Indian Territory, and two bridges for the Memphis, Helena and Louisiana Railway Company (Missouri Pacific Lines) over the Arkansas and White Rivers, in Arkansas.

* Memoir prepared by William Harris Bosler, M. Am. Soc. C. E.

After the death of Mr. Tullock in 1904, the Missouri Valley Bridge and Iron Company was organized, and Mr. Stewart was made Superintendent of Construction, which position he held until December, 1906, when he resigned to organize the Union Bridge and Construction Company, of which he was made President. He continued as President of this Company until October, 1921, when he was made Chairman of the Board of Directors, which position he retained until his death.

After the organization of his own company, Mr. Stewart successfully executed a number of large substructure contracts, some of which were: The Mississippi River Bridge, at Keithburg, Ill.; two bridges at Portland, Ore., over the Willamette River; the Harahan Bridge over the Mississippi River, at Memphis, Tenn.; the Paducah and Illinois (Burlington) Bridge over the Ohio River, at Metropolis, Ill.; the New Orleans and Pacific Railway Bridge over the Atchafalaya River, in Louisiana; and two bridges for the Northern Pacific Railway Company, over the Yellowstone and Missouri Rivers, in Montana.

In 1917, when the United States Government called for contractors to build ships, Mr. Stewart accepted contracts to build six 3 500-ton hulls of the Ferris type, three cargo hulls of the 2 000-ton type, and six 5 000-ton hulls of the Daugherty type. The first nine of these hulls were successfully completed and went into service, but those of the Daugherty type were never completed, the contract having been cancelled after the signing of the Armistice.

Practically all the substructure work which Mr. Stewart executed, was done by the pneumatic process. He probably acquired more practical experience and a greater knowledge of pneumatic foundation work than any other man of his time. The base on which this experience and knowledge was founded, was ability, integrity, energy, and resourcefulness, combined with a keen foresight, and the faculty to judge men.

As evidence of the esteem in which he was held by engineers, the following is cited: In 1902, a contractor of New York City inquired of Mr. Alfred Noble the name of the best foundation man in the United States to take charge of an important piece of work. Mr. Noble replied "the name of that man is L. S. Stewart, and you will be fortunate if you can secure his services".

From Ralph Modjeski, M. Am. Soc. C. E., comes the following tribute:

"I have known Mr. Stewart for many years; my first acquaintance with him was about 36 years ago, when, as general foreman, he was in charge of building the difficult foundations of the old Memphis Bridge. Later, as head of the Union Bridge and Construction Company, he built the foundations and piers of the second Memphis or Harahan Bridge. On these important pieces of work, as well as on many others, he commanded the admiration, respect, and friendship of every one who came in contact with him. Every one recognized in him great energy, resourcefulness, thoroughness, and absolute integrity. It was often said that 'no one could knock the caisson together quicker and better than L. S. Stewart'. One felt that within his cheerful, amiable and even disposition, dwelt an indomitable energy and honesty of purpose. Through his death the Engineering Profession and his many friends have suffered an inestimable loss."

In 1923, Mr. Stewart practically retired from active service, and moved with his family to Tampa, Fla., where he remained until his death. He is survived by his widow and one son, Mr. O. H. Stewart, of Tampa.

He was a York Rite Mason and a member of Abdallah Temple, A. A. O. N. M. S., of Leavenworth, Kans.

Mr. Stewart was elected an Affiliate of the American Society of Civil Engineers on February 6, 1912.

MARIO JOHN MIDOLO, Jun. Am. Soc. C. E.*

DIED MARCH 11, 1926.

Mario John Midolo, the son of John and Kathryn Midolo, was born in Syracuse, Italy, on May 21, 1900, and received his primary education in his native country. When the boy was seven years old, the family came to America and settled in New York, N. Y., where he continued his elementary education in the public schools. This at first proved quite difficult as he was not well versed in the English language; but it was not long before he was one of the most promising students in the school he attended.

After remaining in New York about five years, the family removed to Philadelphia, Pa., where Mr. Midolo entered the Drexel (Public) School, and finished his elementary course in 1915. At this time, the question of higher education and his future profession was uppermost in his mind. He then entered the South Philadelphia Manual Training High School and finished the course there which brought him nearer his goal, namely, the profession of Civil Engineering. He was graduated well up in his class in February, 1919, and, owing to the record that he had made while a student, he was chosen to enter Pennsylvania State College, in September, 1919.

This proved to be another stepping stone toward his ambition, and his untiring efforts and application were soon rewarded. He was graduated from Pennsylvania State College in June, 1923, with the degree of Bachelor of Science in Civil Engineering.

Engaging in his profession, Mr. Midolo first served as Assistant to the Superintendent on Sanitary Sewer Construction for the Perna Construction Company. Later, he followed Land Surveying and was associated with Mr. Thornton Hollingshead, of Morristown, N. J. Shortly afterward he accepted a position as Field Engineer with the Barber Asphalt Paving Company, of Philadelphia.

As he had now had considerable professional experience, he felt he would like to make a permanent connection. Accordingly, Mr. Midolo took the civil service examination in connection with the Bureau of Surveys, City of Philadelphia, and was successful in securing an appointment in one of the District Offices (7th Survey District), where he remained until September 15, 1925. He then accepted a position as Engineer and Estimator for Mr. Frank Brennan, a well known private contractor in South Philadelphia.

It was while in Mr. Brennan's employ that Mr. Midolo contracted his fatal illness. Shortly before Christmas, 1925, he caught a heavy cold and was compelled to remain at home for a time, but his energy and love for his work took him back to the office. Although ambitious to continue his work, his health gradually began to decline, and he was compelled to resign his position.

* Memoir prepared by Francis A. Cotney, Esq., Philadelphia, Pa.

He died on March 11, 1926, and is survived by his father and several brothers and sisters, all residents of Philadelphia. Modest and unassuming, and devoted to his family, he was cut off at the beginning of a promising career.

Mr. Midolo was elected a Junior of the American Society of Civil Engineers on December 15, 1924. He was also a member of the Penn State Club of Philadelphia.

WILLIAM BACON WELLS, Jun. Am. Soc. C. E.*

DIED FEBRUARY 17, 1928.

William Bacon Wells, the son of George William Wells and Amy Bacon Wells, was born at Lewis, Kans., on August 26, 1899. He received his Grammar and High School education at Lewis, and studied Civil Engineering at Kansas University, from which he was graduated in 1922 with the degree of Bachelor of Science in Civil Engineering.

After his graduation, Mr. Wells was engaged as Assistant City Engineer in Ellsworth, Kans. In this capacity, he acted as Resident Engineer on the construction of the water-works system in that city.

In 1923 he entered the employ of F. E. Devlin, Civil Engineer, of Wichita, Kans., and for the next two years he was Resident Engineer for the Company in charge of various municipal improvements in Caldwell, Kans., Waurika, Okla., and Englewood, Colo.

In 1925, when the Devlin Engineering Company was organized, with a branch office in Amarillo, Tex., Mr. Wells went with the writer to act as Engineer for the firm on projects in Western Texas and Eastern New Mexico. In this capacity he designed and supervised the construction of storm sewers and drainage works in Clarendon, Tex.; a sanitary sewer system in Brownfield, Tex.; water-works and sewer extensions and street paving in Portales, N. Mex.; street improvements at O'Donnel, Tex.; and street paving at Tulia, Tex. In 1927, Mr. Wells returned to Kansas to take charge of the installation of a sanitary sewer system in Cedarvale; he had completed this project a few months before his death at Clay Center, Kans.

While the foregoing account covers the work done by Mr. Wells during the short span of life allotted to him, mention should be made of some other things—the things of the spirit that remain and are even more permanent than the structures reared by this young engineer.

On completing his engineering training he chose to enter the ranks of those engineers who are fighting the battle of "Main Street"—fighting for the betterment of living conditions in the "small towns" of the Southwest. The writer recalls how, after many weary miles of driving over the plains of Texas, he would discuss with Mr. Wells the problems of these small towns that were being built. It was not the actual construction work in itself which was found so difficult, but the earlier task of the incorporation of these new towns with all the consequent handicaps that surround such an undertaking. The struggle with the apathy and ignorance of some of the inhabitants, the opposition in promoting mass meetings, and the discussions as to whether the bonds for the sewer and water systems—those elementary necessities of civilized living—should be voted for, were only some of the obstacles encountered.

In all these things, Mr. Wells showed not only great energy and ability, but also a rare understanding of these pioneer people from whom he sprang.

* Memoir prepared by Joseph Rady, Assoc. M. Am. Soc. C. E.

He loved the Southwest and its people, worked for them, and gave his life for them. He died of ptomaine poisoning, in the language of his native land, "with his boots on". He summed up his life's work aptly in closing his report to the City Commission of Clarendon, with these words: "It is our hope that this report may lead to a healthier and more beautiful Clarendon."

Mr. Wells was a member of the Delta Upsilon Fraternity and the Kansas Alumni Association.

His marriage, in June, 1925, to Norma McFadden, of Nevada, Mo., was the culmination of a romance of college days. He is survived by his widow and his parents.

Mr. Wells was elected a Junior of the American Society of Civil Engineers on March 12, 1923.

AUTHOR INDEX

ABBOT, FREDERIC VAUGHAN.
Memoir of. 1745.

ACKHART, ANDREW LEWIS.
Memoir of. 1923.

ADAMS, FREDERICK BAIRD.
Memoir of. 1925.

ADAMS, HENRY SEWALL.
Memoir of. 1747.

ANDERSON, ROBERT PAUL.
Memoir of. 1750.

ANGIER, WALTER EUGENE.
Memoir of. 1752.

AYRES, Q. C.
Mississippi River flood control. 878.

BAILEY, FRANK S.
Continuous beams over three spans. 1384.
Hydrostatic uplift in pervious soils. 1353.
The science of foundations. 330.

BALCH, LELAND RELLA.
Memoir of. 1754.

BALDWIN, HIRAM ELLSWORTH.
Memoir of. 1926.

BALL, JOHN WESLEY.
Memoir of. 1756.

BALLESTER, R. E.
Precise weir measurements. 1136.

BANTEL, E. C. H.
Silting of lake at Austin, Texas. 1717.

BARLOW, DeWITT D.
Progress in waterways engineering. 214.

BARR, JOHN TONER.
Memoir of. 1758.

BAUMAN, PAUL.
Experiments on models of Pit River dams. 518.
Load distribution in high arch dams. 1670.

BAYLY, HOWARD PAUL.
Memoir of. 1928.

BAXTER, GEORGE STRONG.
Memoir of. 1760.

BEAHAN, WILLARD.
Memoir of. 1762.

BEANFIELD, R. McC.
"Unusual Engineering Features of an Immense Theatre Building." 152.

BELZNER, THEODORE.
Engineering features of a theatre building. 182.

BENNETT, C. S.
Results of Miami flood control system. 1602.

BISSELL, HEZEKIAH.
Memoir of. 1764.

BIXBY, WILLIAM HERBERT.
Memoir of. 1768.

BLACK, W. M.
"Advances in Waterways Engineering During a Half Century." 191.

BLAISDELL, A. H.
New theory for the centrifugal pump. 63.

BLUNT, WILLIAM TITCOMB.
Memoir of. 1772.

BOGGS, F. C.
"The Delaware River from Philadelphia to the Sea." 218.

BOYNTON, GEORGE HERBERT.
Memoir of. 1774.

BREMNER, GEORGE HAMPTON.
Memoir of. 1777.

BROOKS, CHARLES F.
Mississippi River flood control. 894.

BROWN, EARL I.
Delaware River improvement. 249.

BRYAN, KIRK.
Silting of lake at Austin, Texas. 1703.

BUDD, RALPH.
The Virginian Railway electrification. 634.

BURKE, WILLIAM CHARLES.
Memoir of. 1779.

BURNELL, EUGENE DICKINSON.
Memoir of. 1781.

BURT, HENRY JACKSON.
Memoir of. 1784.

CAIN, WILLIAM.
Arch dam analysis by trial load method. 1265.
Load distribution in high arch dams. 1666.

CARLL, DAVID SYLVANUS.
Memoir of. 1786.

CARMAN, J. ERNEST.
The O'Shaughnessy Dam and Reservoir. 1493.

CAUGHEY, R. A.
Continuous beams over three spans. 1410.

CHANDLER, E. L.
Hydrostatic uplift in pervious soils. 1356.
Upward pressures under dams. 1551.

CHATLEY, HERBERT.
The science of foundations. 313.

CHURCHILL, JOHN CHARLES.
Memoir of. 1788.

CLARK, A. W.
Conowingo hydro-electric development. 990.

CLIFFORD, WALTER WOODBRIDGE.
Memoir of. 1790.

COLEMAN, J. F.
"Levees as a Means of Flood Control for the Mississippi River." 755.

CONDRON, T. L.
The science of foundations. 331.

CONSTANT, F. H.
Arch dam analysis by trial load method. 1241.
Load distribution in high arch dams. 1677.

CORNELL, C. B.
"The O'Shaughnessy Dam and Reservoir." 1428.

COUGHLIN, WILLIAM GODLEY.
Memoir of. 1792.

COX, A. B.
New theory for the centrifugal pump. 76.

CRANE, CLARENCE AUSTIN.
Memoir of. 1794.

CRAWFORD, MERLIN CROSS.
Memoir of. 1929.

CUMMINGS, ELMORE DAVID.
Memoir of. 1796.

CURRY, CHARLES KENNETH.
Memoir of. 1930.

DAVENPORT, R. W.
Mississippi River flood control. 947.

DAVIES, J. VIPOND.
Hydrostatic uplift in pervious soils. 1341.

DAVIS, ROBERT WAITE.
Memoir of. 1931.

DAWLEY, WILLIAM SANBORN.
Memoir of. 1798.

De BLOIS, K. L.
Results of Miami flood control system. 1610.

DENNIS, H. W.
Experiments on models of Pit River dams. 511.

DITTOE, W. H.
The O'Shaughnessy Dam and Reservoir. 1495.

DIXON, G. GALE.
The O'Shaughnessy Dam and Reservoir. 1495.

DONNELL, LLOYD H.
New theory for the centrifugal pump. 71.

DONNELLY, JOSEPH FRANCIS SINNOTT.
Memoir of. 1933.

DOUSMAN, JAMES HOPKINS.
Memoir of. 1801.

EDWARDS, GUY BANKER.
Memoir of. 1935.

EDWARDS, JOHN MARTYNN GRENFELL.
Memoir of. 1937.

EGLIN, WILLIAM C. L.
Conowingo hydro-electric development. 979.

EIFFERT, C. H.
"Hydraulic Studies and Operating Results on the Miami Flood Control System." 1583.
Mississippi River flood control. 900.

Precise weir measurements. 1127.

PARSONS, H. de B.
"Hydrostatic Uplift in Pervious Soils." 1317.
Upward pressures under dams. 1574.

PAUL, CHARLES H.
Mississippi River flood control. 853.
Results of Miami flood control system. 1616.

PEARSON, EDWARD JONES.
Memoir of. 1882.

PORTER, JAMES MADISON, 3d,
Memoir of. 1948.

POTTER, W. B.
The Virginian Railway electrification. 628.

POWELL, WILLIAM JENNER.
Silting of lake at Austin, Texas. 1728.

PRICE, WILLIAM GUNN.
Memoir of. 1885.
Mississippi River flood control. 887.

PROAL, ARTHUR BREESE, Jr.
Memoir of. 1887.

QUINCY, CHARLES FREDERICK.
Memoir of. 1971.

RAMSER, C. E.
Mississippi River flood control. 933.

RAY, GEORGE J.
The Virginian Railway electrification. 641.

REED, OREN.
Experiments on models of Pit River dams. 497.
"Maximum Flood Discharge in San Joaquin Valley, California." 406.
Mississippi River flood control. 890.
Silting of lake at Austin, Texas. 1691.

REED, P. L.
New theory for the centrifugal pump. 35.

REEVES, HARLEY EDSON.
Memoir of. 1889.

REHBOCK, TH.
Precise weir measurements. 1143.

RICH, GEORGE R.
Arch dam analysis by trial load method. 1229.

RIGGS, MORRIS JOHN.
Memoir of. 1890.

ROBINSON, A. W.
The great Yangtze Bar. 120.

ROBINSON, H. F.
Silting of lake at Austin, Texas. 1695.

ROSE, JOHN GANSOVERTTE.
Memoir of. 1950.

ROSE, RUDOLF VIEDT.
Memoir of. 1892.

RYAN, MICHAEL HEALEY.
Memoir of. 1953.

SANDS, EDWARD EMMET.
Memoir of. 1893.

SAVAGE, J. L.
Arch dam analysis by trial load method. 1289.

SCHEIDENHELM, F. W.
Experiments on models of Pit River dams. 506.
"Power as Affecting Flood Control." 815.

SCHLICK, W. J.
Mississippi River flood control. 905.
